I will conclude my talk by further demonstrate the impact of surface treatment and interfacial design routes to the achievement of record power conversion efficiencies in Hp-based quantum dot solar cells [3]. Therein, our approach is driven by a targeted ligand exchange chemistry that results in subsequent anion and cation exchange reactions at the quantum dot surface [4].

9:00 AM ★ES15.11.03 Electronic Properties at Surfaces of n= 1 and 2 Ruddlesden-Popper Phase Perovskites Scott Silver1, Hong Li2, Jean-Luc Bredas2 and Antoine Kahn1; 1Department of Electrical Engineering, Princeton University, Princeton, New Jersey, United States; 2School of Chemistry and Biochemistry and Center for Organic Photonics and Electronics, Georgia Institute of Technology, Atlanta, Georgia, United States.

Increasing attention has been placed over the past few years on 2D Ruddlesden-Popper phase (RPP) metal halides, perceived as interesting photovoltaic materials in their own right, and also as potentially efficient capping materials to improve the long-term stability of 3D metal halide perovskite solar cells. Energy level alignment at 2D/3D
heterojunctions and stability of the 2D materials are therefore of considerable interest. We focus here on the electronic surface, surface potential and response to light irradiation of films of the 2D RPP metal halides, Ba$_2$PbI$_4$ (n=1) and Ba$_2$Ca$_2$Pb$_3$I$_7$ (n=2). Direct and inverse photoemission spectroscopy coupled with theoretical computation of the DOS are used to determine the materials electron affinity (EA)/ionization energy (IE), equal to 3.1.5.8 eV for Ba$_2$PbI$_4$ [1] and 3.3.5.7 eV for Ba$_2$Ca$_2$Pb$_3$I$_7$. A full identification of the various contribution to the valence and conduction band DOS is made. We investigate the surface potential of these films via Kelvin probe force microscopy and show reproducible surface photovoltage under supra-band gap light irradiation, corresponding to a reduction of the downward band bending. Long term degradation of the work function is not observed, in contrast to previous observations on 3D perovskite surfaces. Finally, a composition analysis of the n=2 Ba$_2$Ca$_2$Pb$_3$I$_7$ using XPS, shows that the surface is not stoichiometric and resembles the composition of RPPs with larger n. We propose that the n=2 phases at the surface create a type I interface with the n=2 phase. This information together with the IE and EA as determined by UPS and IPES, respectively, outline the energy landscape of this material.

9:30 AM ES15.11.04

Spiro-MeOTAD Hole Transport Material in Perovskite-Based Solar Cells

In halide perovskite-based solar cells, optimization of hole transport materials (HTMs) is important for enhancing solar power conversion efficiency and stability [1, 2]. At OIST, a team of researchers in the Energy Materials and Surface Sciences Unit has been making concerted efforts to study 2.2',7',7''-tetrakis[N,N-di(4-methoxyphenyl)amino]-9,9'-spirobi fluorenone (spiro-MeOTAD), which is the most widely used HTM in perovskite solar cells [2,9]. In this talk, we will present our latest understanding of fundamental interactions between Li-bis(trifluoromethanesulfonyl)-imide (LiTFSI), tert-butylpyridine (t-BP), spiro-MeOTAD and perovskites. Also, we will show how gas exposure (e.g., exposure to O$_2$, H$_2$O, N$_2$) influences electronic energy level alignments and conductivity of such HTM films that is closely associated with performances and stability in perovskite-based solar cells.

Effect of Ligand Groups on Photoexcited Charge Carrier Dynamics at Perovskite/TiO$_2$ Interface

Landon Johnson, Dmitri Kilin, Aaron Forde, Yulun Han, Fatima B, Physics and Mathematics, North Dakota State University, Fargo, North Dakota, United States; Chemistry and Biochemistry, North Dakota State University, Fargo, North Dakota, United States; North Dakota State University, Fargo, North Dakota, United States.

Perovskite-based solar cells have been a popular research topic for the better part of the last decade due to their rapidly increasing power conversion efficiencies and ease of their fabrication. TiO$_2$ is frequently used as an electron transport material (ETM) in perovskite-based solar cells because of its low cost, low toxicity, versatility in sizes and structures, and chemical stability. Despite the successes of perovskites in solar cells, there are still aspects about their operation that are not fully understood. One example is the role of ligand groups acting as a bridge between the perovskite and ETM. This computational research aims to explore the effects that these ligand groups, which are adsorbed to a polycrystalline (TiO$_2$) for brevity) nanochaper, have on the photoexcited charge carrier dynamics within a perovskite-based solar cell. Density functional theory is used to find the ground state energies of the perovskite/TiO$_2$ solar cell as well as compute the molecular dynamics trajectory, where non-adiabatic electron-phonon couplings are calculated “on-the-fly.” These couplings are then used to calculate the Redfield tensor which is ultimately used to compute the photoexcited charge carrier dynamics. It is found that the ligand groups can alter the band gap, band alignment, charge transfer characteristics, accessible excitation pathways, and excited charge carrier lifetimes.

Cirumventing Defects in Halide Perovskite Solar Cells Through the Application of Ferrocene Oxide Extraction Layers

Monica Lira-Cantu, Nanostructured Materials for Photovoltaic Energy Group, Catalan Institute of Nanoscience and Nanotechnology (ICN2), Bellaterra, Spain.

Highly stable halide perovskite solar cells employ semiconductor oxides as electron transport materials. Defects in these oxides, such as oxygen vacancies (O$_{vac}$), act as recombination centres and, under air and UV light, reduce the stability of the solar cell. Under the same conditions, the PbZrTiO$_3$ ferrocene oxide employs O$_{vac}$ for the creation of defect-dipoles responsible for photo-carrier separation and current transport, evading device degradation. We report the application of PbZrO$_3$ as the electron extraction material in triple cation halide perovskite solar cells. The application of a bias voltage (poling) up to 2 V, under UV light, is a critical step to induce charge transport in the ferrocene oxide. Champion cells result in power conversion efficiencies of ~11% after poling. Stability analysis, carried out at 1-sun AM 1.5 G, including UV light in air for unencapsulated devices, shows negligible degradation for hours in comparison with reference solar cells applying SnO$_2$ which degrades in only a few minutes. Our experiments indicate the effect of ferrocenyl from the PZT, however alternative conducting mechanisms affected by the accumulation of charges or the migration of ions (or the combination of them) can also be present. Our results demonstrate, for the first time, the application of ferrocene oxide as an electron extraction material in efficient and stable solar cells.
PSCs. These findings are also a step forward for the development of perovskite-based solar cells.

**Understanding the Energy Transfer Mechanism at the Perovskite—Organic Hybrid Interface**

Sarah Wieghold1, Juan-Pablo Correa-Baena2 and Lea Nienhaus1; 1Florida State University, Tallahassee, Florida, United States; 2Georgia Institute of Technology, Atlanta, Georgia, United States.

Understanding the energy transfer mechanism across hybrid interfaces which combine both inorganic and organic semiconductors is crucial in the advancement of optoelectronic devices. The exact energy transfer mechanism between inorganic and organic materials remains obscure, particularly where there is a large amount of structural inhomogeneity within the material.

Recent advances have shown that both lead sulfide (PbS) quantum dots, as well as CsPbX quantum dots are capable of efficient triplet energy transfer at such organic-inorganic hybrid interfaces.[1,2,3] Combining scanning probe microscopes with ensemble time-resolved optical spectroscopy, we investigate the underlying mechanism of energy transfer at hybrid interfaces comprised of lead halide perovskites and organic semiconductors. By understanding the interplay between the morphology and the band alignment arising from the perovskite composition, as well as the mechanism of the energy transfer at the hybrid interface, we can tailor our active materials to increase device performance by optimizing this energy transfer process.

11:15 AM ES15.11.08

**Ultra High Vacuum Scanning Probe Microscopy Investigations on Hybrid Organic Inorganic Perovskites**

Thibaut Gallet, Evandro Lanzoni, Christian Kameni Bounenou and Alex Redinger; University of Luxembourg, Esch/Alzette, Luxembourg.

Surface and interface passivation are of central importance for high efficiency perovskite solar devices. Despite the enormous efforts that have been undertaken in the last years to improve the power conversion efficiency of the devices, the surface properties are still not very well understood. Moreover, the polycrystallinity of the material leads to lateral fluctuations of the surface properties on the nanometer scale, which makes the analysis difficult and challenging. Scanning probe microscopy (SPM) techniques are ideal to gain a much deeper understanding of the surfaces and interfaces due to their high spatial resolution.

In this contribution, we present our results obtained on hybrid perovskites studied with scanning tunneling microscopy (STM) and spectroscopy (STS) combined with Kelvin Probe Force Microscopy (KPFM). All our studies have been carried out under ultra-high vacuum (UHV) conditions on clean absorbers that have not been exposed to air. In a first part, we show why ultra-high vacuum is indispensable for an accurate analysis of the nanometer scale properties. We compare KPFM measurements before and after air exposure in our UHV KPFM setup and compare the results to measurements under ambient conditions. In particular, we discuss the changes of the facet-dependent contrast of the grains, which is smeared out and reduced after air exposure, and we discuss the observed changes of the work function at the grain boundaries. Furthermore, we compare our results to the available literature.

In the second part, we discuss in detail the nanometer scale variations of coevaporated methylammonium lead iodide absorbers with minority carrier lifetimes exceeding one microsecond. In particular, we investigate the lateral variations of the workfunction on these absorbers layers and discuss the implications for the resulting solar cell devices. We will link our results from SPM to the specific growth conditions we used during synthesis.

Finally, we compare the results to another thin film technology, namely Cu(In,Ga)Se2. This comparison is essential to understand why hybrid organic inorganic perovskites outperform Cu(In,Ga)Se2 in terms of minority carrier lifetime and exceptionally high open-circuit voltages. In this part we use STS measurements to compare the local density of states of the perovskite and of the Cu(In,Ga)Se2 surfaces. It becomes evident from our measurements that the defect density at the surface is much lower for the perovskites, which underlines why these semiconductors perform so exceptionally well as well absorber layers in solar cells.

11:30 AM ES15.11.09

**Why Are Hot Holes Easier to Extract Than Hot Electrons From Halide Perovskite Solar Cells?**

Ibrahim Dursun, Partha Maiti, Jun Yin, Bekir Turedi, Ayan A. Zhumekenov, Kwang Joo Lee, Omar F. Mohammed and Osman Bakr; King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

The power conversion efficiency of light harvesting devices is limited by the rapid thermalization of charge carriers that are photoexcited with energies above the bandgap of the absorbing material. As these so-called ‘hot’ carriers are difficult to collect, their cooling places an upper bound on the available photon energy that a given solar cell may utilize. Recently, studies on hot carriers in methylammonium lead iodide (MAPbI3) perovskite have noted that they cooldown at an appreciably slower rate than carriers in other photovoltaic materials. However, the relaxation rate is still rapid in absolute terms, and hence, their capture and collection (before relaxing to the band edge) have not been shown so far. Here we demonstrate and explain the efficiency of hot carrier extraction from MAPbI3 using TiO2 and Spiro-OMeTAD as an electron transporting layer (ETL) and hole transporting layer (HTL), respectively, via real-time observation of the carrier dynamics with femtosecond transient absorption spectroscopy and supported by density functional theory (DFT) calculation. Time-resolved experiments have shown that a quasi-equilibrium distribution of hot carriers while not appreciably affected by the presence of TiO2 can be stabilized in a negative pressure environment with the application of hydrostatic tensile strain. Using density functional theory, we explore negative pressure induced phase transitions, and their consequent optoelectronic properties.

11:45 AM ES15.11.10

**Understanding the Nanocrystal Size Dependence of Phase Stability in CsPbI3**

Ruoxi Yang1, Aaron Fafarman2 and Liang Z. Tan1; 1Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Chemical and Biological Engineering, Drexel University, Philadelphia, Pennsylvania, United States.

CsPbI3, a promising candidate for photovoltaic and light-emitting diode applications, is structurally unstable and transforms into an orthorhombic phase at room temperature. CsPbI3, in nanocrystal form, on the other hand, has displayed better thermal stability than in the bulk, and the stability depends on the size of the nanocrystal. Yet, not many studies have shed light on the underlying mechanisms. Using first-principles calculations, we demonstrate phase stability changes as a function of varying crystal size, which result from the competition between short-range bond formation and long-range electrostatic energies. Comparing these simulations with experiment, we show that this mechanism is analogous to the application of negative pressure, explaining the correlation between high-symmetry phase stability and nanostructuring. These results suggest that bulk phase CsPbI3 can be stabilized in a negative pressure environment with the application of hydrostatic tensile strain. Using density functional theory, we explore negative pressure induced phase transitions, and their consequent optoelectronic properties.
Halide Perovskites have a remarkably low defect density, especially if we consider the quick and “chimie douce” way of preparation of films as well as of most single crystals. The densities are all deduced from the common (all direct) measurements for charge or neutral defects. In this talk I will show how this behaviour reflects a quite fundamental property of these materials, with a rather simple basis. The talk will combine experimental results from several sources, including our own, for thermodynamic, optical, and electrical data. It is plausible that our conclusions can be generalized to help look for other ultra-low defect density materials.

Thanks to David Egger (Regensburg), Omer Yaffe and Leocor Kronik (Weizmann Inst.)

Following Free Carrier Formation and the Generation of Coherent Optical Phonons in Lead Iodide Perovskite Sanford Ruhman

Under solar irradiation, most photons absorbed in methyl ammonium lead iodide perovskite (MAPbI$_3$) possess ~0.4 eV of excess energy above the 1.65 eV band gap (BG), and characterizing the important stages of free carrier generation and relaxation dynamics requires ultrafast spectroscopic investigation. Carrier cooling and recombination in hybrid perovskites occurs in ps and ns timescales respectively. Probing exciton dissociation however requires extreme (sub-10 fs) time resolution. The significance of optical phonon coupling to free carriers in these materials (polarons) has recently been the subject of lively debate. To date only a few time domain measurements have reported impulsive phonon activity, and those reports have not converged in terms of the active phonon frequencies or coupling strengths. Here, we present high S/N sub-10 fs pump-probe spectroscopy of MAPbI$_3$ films to record ultrafast exciton dissociation, which has not been reported previously. High above band gap excitation in MAPbI$_3$ provides an opportunity to observe free carrier generation followed by cooling dynamics. Transient transmission (TT) spectra of MAPbI$_3$ films after photoexcitation reveal a number of features which are common to previous pump-probe studies of this system. First, a photoinduced bleach at the optical BG which appears constantly and grows to its full magnitude during carrier cooling, is attributed to hot carrier induced screening of the exciton transition and state filling. Another is an absorption feature rising below the band edge assigned to band gap renormalization and shifting of exciton transition. This feature also appears immediately after excitation, but decays over the carrier cooling stage. The third is a slow rising broad induced absorption feature in the inter-band region. Using the extreme time resolution here, a sharp red shift of exciton transition is observed at early times. Surprisingly, the photoinduced band bleach derived by extracting a band integral over the whole probing range, appears abruptly with a delay of 20 fs after the pump excitation. This delay in rising of band integral bleach is assigned to exciton dissociation or the breakup of localized e-h pair. To the best of our knowledge this is the first recording of this phase of free carrier formation following above BG photoexcitation in this material, or in bulk semiconductors. Observing this phase hinges on the ultrashort pump pulses ability to generate such localized carrier pairs even high above the BG due to coherent excitation of a broad band of “k” states. Finally, the delayed ~0.4 ps rise of the band integral is compatible with carrier cooling.

The pump-probe spectra also reveal weak periodic modulations. The residual modulations at different probe wavelengths were extracted by subtracting the transient signal. The Fourier analysis of the residual modulation detects predominantly two of active phonon modes: low frequency mode ~110 cm$^{-1}$ and a high frequency mode ~240 cm$^{-1}$ assigned to the torsions of methylammonium cation (Fig. 2d). The amplitudes of these spectral modulations were used to estimate the electron-phonon coupling strength, assuming a displaced harmonic oscillator model. The estimated coupling strengths (Huang-Rhys parameter, S: 0.02-0.04) for the MAPbI$_3$ films are well within the weak coupling regime, which is compatible with free carriers existing as large polarons in these materials. These observed phonon modes may not be responsible for perovskite’s moderate carrier mobility, which requires intermediate electron-phonon coupling.

In conclusion, sub 10fs above band gap pump-probe data resuggest that, instantly generated localized hot excitons dissociate to free carriers within ~20 fs. Faint spectral modulations in the transient signals are assigned to coherent phonons. These modulations are assigned to longitudinal optical (LO) phonons weakly coupled to the electronic transition.

3:00 PM *ES15.12.03
Phonon Coherences Reveal the Polaronic Character of Excitons in Two-Dimensional Lead Halide Perovskites Felix Thouin, David A. Valverde Chavez, Ilaria Bargigia, Daniele Cortecchia, Annamaria Petrozza, David Beljonne, Ajay R. Srimath Kandada and Carlo Silva; Georgia Institute of Technology, Atlanta, Georgia, United States; 2Center for Nano Science and Technology@PoliMi, Istituto Italiano di Tecnologia, Milan, Italy; 3Laboratory for Chemistry of Novel Materials, Université de Mons, Mons, Belgium.

Hybrid organic-inorganic semiconductors feature complex lattice dynamics due to the “softness” arising from non-covalent bonds between molecular moieties and the inorganic network, and to the ionic character of the crystal. Such complex lattice motion has profound consequences on the fundamental character of primary photoexcitations with respect to purely covalent semiconductor crystals. In this work, we establish that this dynamic structural complexity gives rise to the coexistence of diverse excitonic resonances in a prototypical two-dimensional lead iodide perovskite, each with a distinct degree of polaronic character. By means of high-resolution resonant impulsive stimulated Raman spectroscopy, we address the coupling of both charge carriers and excitons to low-frequency optical phonons (those with frequency ≤ 50 cm$^{-1}$). Resonant photoexcitation results in vibrational wavepacket dynamics that evolve along different configurational coordinates for distinct excitons and photocarriers. Employing density functional theory calculations, we assign the observed coherent vibrational modes to various phonons involving motion in the lead-iodide layers. We thus conclude that different excitons induce specific lattice reorganizations that are distinct from those involving charge carriers, which are signatures of polaronic binding. Our conclusions provide a novel perspective of the energetic/configurational landscape involving globally neutral primary photoexcitations in a broad class of emerging hybrid semiconductor materials.

Evidence of Electronically Decoupled Organic and Inorganic Sublattices in Methylammonium Lead Iodide from Infrared Vibrational Excitation Peijun Guo, Arun Kumar Mannodi Kanakkithodi, Jue Gong, Yi Xia, Tao Xu, Maria K. Chan, Mercouri G. Kanatzidis and Richard D. Schaller; 1Argonne National Laboratory, Lemont, Illinois, United States; 2Northwestern University, Evanston, Illinois, United States; 3Northwestern University, Evanston, Illinois, United States.

Organic-inorganic hybrid perovskites such as methylammonium lead iodide (CH$_3$NH$_3$PbI$_3$) are solution-processable semiconductors for high-efficiency solar cells and light-emitting devices owing to their long carrier lifetime and diffusion length. Determining whether the solar organic cations with strong dynamic disorder benefit the optoelectronic properties of CH$_3$NH$_3$PbI$_3$ has been challenging. Herein, via transient absorption measurements employing an infrared pump tuned to a methylammonium N-H stretching vibration, we observe vibrational energy transfer from the selectively excited organic mode to the entire crystal lattice in nanosecond timescale. The observed transient electronic signatures, during the period of thermal-nonequilibrium when the induced thermal motions are mostly concentrated on the organic sublattice, reveal that the induced motions of the organic cations do not apparently alter absorption or photoluminescence response of CH$_3$NH$_3$PbI$_3$, beyond thermal effects. Our results suggest that the attractive optoelectronic properties of CH$_3$NH$_3$PbI$_3$ mainly derive from the inorganic lead-halide framework.

3:45 PM *ES15.12.05
Light Emitting Diodes Based on Inorganic Composite Halide Perovskites Xiujuan Lian, Xi Wang and Hanwei Gao; Physics, Florida State University, Tallahassee, Florida, United States.
CsPbBr₃ is a promising type of light-emitting halide perovskite with inorganic composition and desirable thermal stability. The luminescence efficiency of pristine CsPbBr₃ thin films, however, appears to be limited. In this work, light emitting diodes based on CsPbBr₃:CsPbBr₆ composites are demonstrated. Both quantum efficiency and emission brightness are improved significantly compared with similar devices constructed using pure CsPbBr₃. The high brightness can be attributed to the enhanced radiative recombination from CsPbBr₆ crystallites confined in the CsPbBr₃ host matrix. The unfavorable charge transport property of CsPbBr₆ can be circumvented by optimizing the ratio between the host and the guest components and the total thickness of the composite thin films. The inorganic composition of the emitting layer also leads to improved device stability under the condition of continuous operation.

Coherent Spin and Quasi-Particle Dynamics in Two-Dimensional Lead Halide Perovskites David Giovannii², Herlina A. Dewi², ³, Subodhi Mhaisalkar², ³, Neeraj Mathews¹ and Tze Chien Sun¹; ¹School of Material Science and Engineering, Nanyang Technological University, Singapore, Singapore; ²School of Physical and Mathematical Sciences, Department of Physics and Applied Physics, Nanyang Technological University, Singapore, Singapore; ³Energy Research Institute @ NTU (ERI@N), Nanyang Technological University, Singapore, Singapore.

Layered 2D halide perovskites, with their alternating organic and inorganic atomic layers that form self-assembled multi-quantum wells (MQW), have been shown to possess robust light-matter coupling, owing to quantum and dielectric confinement effect. Within their periodic structures lie a hotbed of robust photophysical phenomena, rising from the coherent quantum-mechanical interplays between exciton, spin, phonon, and photon. Herein, we explicate these intricate dynamics via transient absorption spectroscopy. Few to be highlighted here are: (i) the robust spin-selective optical Stark effect, which are few times stronger than in conventional inorganic semiconductors; (ii) ultrafast carrier thermalization and spin relaxation via exchange interaction; and (iii) strong coherent exciton-photon coupling. Origin of transient spectral features and exciton relaxation pathways are also revealed from detailed phenomenological modelling of the transient dynamics. Importantly, our work unravels the understanding of complex optical spin and quasi-particle interactions in these layered 2D halide perovskites, which are the key to exploit their full potential.

4:15 PM ES15.12.07
Structural Dynamics in Hybrid Halide Perovskites—Bulk Rashba Splitting and Carrier Localization Chao Zheng¹, Shidong Yu¹, ² and Oleg Rubel¹; ¹Department of Materials Science and Engineering, McMaster University, Hamilton, Ontario, Canada; ²College of Materials Science and Engineering, Jilin University, Changchun City, China.

The extended carrier lifetime in hybrid halide perovskites was attributed to a quasi-indirect band gap that arises due to Rashba splitting in both conduction and valence band edges. We will present results for an effective relativistic band structure of (CH₃NH₃)₂PbI₆ with focus on the dispersion of electronic states near the band edges of (CH₃NH₃)₂PbI₆ affected by thermal structural fluctuations [1]. We establish a relation between the magnitude of Rashba splitting and the deviation of Pb-atom from its center-symmetric site in the PbOoctahedron. In order for the splitting energy to reach the thermal energy of 26 meV (room temperature), the displacement should be of the order 0.3 Ang, which is far above the static displacements of 0.1 Ang for Pb-atoms in the tetragonal phase of (CH₃NH₃)₂PbI₆.

The significant dynamic enhancement of the Rashba splitting observed at earlier simulation times (less than 2 ps) later weakens and becomes less than the thermal energy despite the average displacement of Pb-atoms remaining large (0.37 Ang). It is randomization of Pb-displacement vectors and associated cancelation of the net effective magnetic field acting on electrons at the conduction band edge is responsible for reduction of the Rashba splitting.

The lattice dynamics also leads to deterioration of Bloch character [2] for states in the valence band, which leads to charge localization in (CH₃NH₃)₂PbI₆, is therefore affected. These results call into question the quasi-indirect band gap as a reason for the long carrier lifetime observed in (CH₃NH₃)₂PbI₆ at room temperature. An alternative mechanism involves dynamic localization of holes and their reduced overlap with electrons in reciprocal space.

Nonlinear Optical Responses of MAPbCl₃ Perovskite Single Crystals Studied by Z-Scan Method Keiichi Ohara, Hirokazu Tahara, Takumi Yamada, Tomoko Aharen, Hideki Hiori and Yoshishiko Kanemitsu; Kyoto University, Uji, Japan.

In recent years, there have been extensive studies made on optical and electronic properties of lead halide perovskite semiconductors, MAPbX₃ (MA = CH₃NH₃, X = I, Br, and Cl) from the fundamental physics viewpoint and from the interest in the application to functional photonic devices [1]. These direct-gap semiconductors exhibit sharp absorption spectra with very small Urbach energies, strong light emission with no essential Stokes shift, and long carrier diffusion lengths, leading to high energy conversion efficiencies of solar cells. Besides solar cell applications, MAPbX₃ perovskites are considered as materials for light-emitting diodes, lasers, optical modulators, and nonlinear optical crystals [2-4]. Especially, it is very important to elucidate their nonlinear optical response for future device applications. Among them, a wide-gap semiconductor MAPbI₃ has attracted attention as a photonic device material in the blue spectral region [2].

In this work, we clarify the nonlinear refractive index and nonlinear absorption coefficient of MAPbCl₃ single crystals and their wavelength dependence. The thin film sample of MAPbCl₃ has a grain structure and strong light scattering occurs in the blue spectral region, being an obstacle for measuring their essential optical characteristics. In order to eliminate the influence of light scattering, a large bulk single crystal was used. Third-order nonlinear optical coefficients were determined by the Z-scan method. We determined the nonlinear refractive index from the close aperture measurement and the nonlinear absorption coefficient from the open aperture measurement at various excitation wavelengths. Nonlinear optical responses can be explained by a simple two band model. Our measurements clearly shows that MAPbCl₃ perovskites are simple direct-gap semiconductors and the nonlinear optical coefficients are comparable to GaAs single crystals [5].

Part of this work was supported by JST-CREST (JPMJCR16N3).

4:45 PM ES15.12.09
Efficient Anti-Stokes Photoluminescence from CH₃NH₃PbI₃ Perovskite Semiconductors Takumi Yamada, Tomoko Aharen and Yoshishiko Kanemitsu; Kyoto University, Kyoto, Japan.

Organic-inorganic hybrid perovskite semiconductors are collecting much attention as a new class of optical device materials. In particular, CH₃NH₃PbI₃ (MAPbI₃) shows highly efficient photoluminescence (PL) with no Stokes shift even at room temperature due to the band-to-band transition. Many unique optical phenomena based on efficient PL with no Stokes shift, such as photon recycling and radiative cooling, have been discussed [1,2]. Photon recycling is caused by the repeated light emission and reabsorption processes. The laser cooling of semiconductors is induced by anti-Stokes PL (AS-PL) via photon absorption. One important factor to anti-Stokes phenomena in semiconductors is a high external quantum efficiency (EQE). However, laser cooling has not been achieved even for GaAs/GaInP quantum well with EQE of 99.5% [3]. Therefore, it is important to clarify the material properties and experimental conditions required for laser cooling. Specifically, it is necessary to clarify the physics of AS-PL and its reabsorption in the perovskites by employing both optically thin and thick samples.

In this study, we prepared optically thin film and thick single crystal of MAPbI₃, and investigated their AS-PL characteristics [4]. Using PL excitation (PLE) spectroscopy, we determined the excitation-energy dependence of the AS-PL and the Stokes PL (S-PL) by dividing the PL spectrum into anti-Stokes and Stokes parts. We obtained the up-conversion gain spectrum defined as the intensity difference between the AS-PLE and S-PLE spectra. The gain spectra showed a broad spectral shape and its maximum point was located below the balanced point where the anti-Stokes PLE and Stokes PLE intensities become equal. The broad shape of the up-conversion gain spectrum suggests that unique phonon dynamics, such as large anharmonicity and polaron formation, play an important role of efficient up-conversion process in the perovskites.

Part of this work was supported by JST-CREST (JPMJCR16N3) and JSPS Research Fellowships for Young Scientists (17J08790).

In Situ 8:15 AM
doing this, i.e. by exciting a single photon up-conversion
phenomenon has recently been demonstrated in CsPbBr nanocrystals with an external quantum efficiency greater than 70%. This high efficiency seems to odd with previous studies, as perovskite nanocrystals are known to generally lack mid-gap states.

This presentation will discuss our recent progress in examining one photon up-conversion in all-inorganic perovskite nanocrystals, especially regarding the potential role of an intermediate state in the excitation process, as well as the optimization of the up-conversion via plasmonic enhancement in systems coupled to metal nanoparticles. Specifically, we have shown that a facile surface treatment increases the efficiency of one photon up-conversion in CsPbBr nanocrystals, even if it increases the traditional down-converted photoluminescence quantum yield to essentially unity indicating a lack of mid-gap trap states. This increase in up-conversion efficiency, despite the lack of mid-gap states, suggests that such states act as loss pathways rather than acting as intermediate states necessary to the excitation mechanism. Additionally, we show that through the presence of a localized surface plasmon, e.g. by depositing gold nanoparticles, the observed up-conversion blue shifts, indicating more efficient use of thermal energy to drive optical emission. These results suggest another mechanism may be the key to understanding and optimizing one photon up-conversion, one that does not involve discrete mid-gap states. The efficiency of this up-conversion mechanism in CsPbBr makes this material a good candidate for optically driven cooling. As such, we will also discuss initial thermometry studies of cooling power in perovskite nanocrystal films.

8:15 AM ES15.13.02
In Situ Transient Absorption Spectroscopy of Perovskite Nanocrystal Formation and Growth

Methyllammonium lead halide perovskites have attracted significant interest for their desirable electronic properties. Nanocrystals formed from these materials have shown great promise for use in LEDs and lasers due to their high fluorescence quantum yield and the tunability of their emission throughout the visible spectrum. The rapid kinetics of common nanocrystal syntheses such as hot-injection – combined with the inherent instability of the partially capped nucleation centers that are nascent nanocrystals – precludes the use of time-resolved spectroscopy to measure the evolution of excited state dynamics during the formation of fully passivated nanocrystals. The ability to measure electronic structure and dynamics during this process would deepen our understanding of the relationship between synthetic parameters and the resulting functional electronic properties. Here we use an ambient, room temperature ligand-mediated nanocrystal synthesis with reaction timescales more favorable for study via transient absorption (TA) spectroscopy. By coupling this synthesis with transient absorption spectroscopy, we are able to provide the first ever characterization of excited state dynamics in unstable, immature perovskite nanocrystals as they grow and their surfaces are capped with passivating ligands. We observe a previously unreported signature in the TA spectrum of immature nanocrystals that is not present in fully formed nanocrystals. This work helps elucidate the role the surface of these materials plays in excited state dynamics, as well as providing new insight into the evolution of exciton dynamics during perovskite nanocrystal growth and formation. Future measurements utilizing a single-shot transient absorption (ssTA) spectrometer that is capable of measuring entire transients in a few seconds will enable the spectroscopic observation of nanocrystal syntheses in real-time.

8:30 AM ES15.13.03
Bright Triplet Excitons in Cesium Lead Halide Perovskites

The observation of a ground optically forbidden “dark” exciton state in semiconductor nanocrystals was first reported in the seminal paper of Nirmal et al. in 1995. Later research in nanowires, nanorods, and nanodot systems has shown that the ground exciton state in all these semiconductor structures is a dark exciton, leading us to believe that the ground exciton must be dark. Because dark excitons release photons slowly, hindering emission, semiconductor nanostructures that disobey this rule have been sought. However, despite considerable experimental and theoretical efforts, no nanocrystals have been identified in which the lowest exciton is bright. Three years ago however cesium lead halide perovskite (CsPbX3, with X = Cl, Br or I) nanocrystals were grown, which without too much effort, demonstrated very bright photoluminescence (PL) with quantum yield 50-90% at room temperature. This bright emission was traced to a very short radiative decay time. The nanocrystals emit light about 20 and 1,000 times faster than any other semiconductor nanocrystal at room and cryogenic temperatures, respectively. The increase of the decay time with temperature is inconsistent with a dark ground state exciton, suggesting that in these nanocrystals the ground exciton state is bright. We use an effective-mass model and group theory to demonstrate the possibility of such a ground bright exciton must be dark. Because dark excitons release photons slowly, hindering emission, semiconductor nanostructures that disobey this rule have been sought. However, despite considerable experimental and theoretical efforts, no nanocrystals have been identified in which the lowest exciton is bright. Three years ago however cesium lead halide perovskite (CsPbX3, with X = Cl, Br or I) nanocrystals were grown, which without too much effort, demonstrated very bright photoluminescence (PL) with quantum yield 50-90% at room temperature. This bright emission was traced to a very short radiative decay time. The nanocrystals emit light about 20 and 1,000 times faster than any other semiconductor nanocrystal at room and cryogenic temperatures, respectively. The increase of the decay time with temperature is inconsistent with a dark ground state exciton, suggesting that in these nanocrystals the ground exciton state is bright. We use an effective-mass model and group theory to demonstrate the possibility of such a ground bright exciton.
such more device-oriented structures give further insight into the complete charge separation process as it occurs in corresponding photodetectors.

Strong Exciton–Photon Coupling in Perovskite Microcavities Xin Feng Liu; NCNST, Beijing, China.

Hybrid organic-inorganic perovskites (HOIPs) are low-cost and highly efficient optoelectronic and photovoltaic materials for applications in solar cells, emitting diodes (LEDs)[1-3], and so on, which is correlated with their intrinsic structures. Now the hybrid perovskite families include three-dimensional (3D) (CH$_3$NH$_3$PbX$_3$), two-dimensional (2D) ((C$_6$H$_5$NH$_3$)$_2$PbI$_3$) and nanostructured (CH$_3$NH$_3$PbBr$_3$ nanoparticles) materials. However, physical exploration to such materials is still at early stage and full assessment of their structures and properties is still missing.

High pressure[4] and various temperature[5] allow easy access to various structures and interactions among the constituent atoms and molecules, which will in return significantly change the corresponding physical and chemical properties. Therefore, exploring correlations between pressure-induced structural and electronic changes of hybrid perovskites is essential to well understand the intrinsic structural stability and establish structure-property relationship for optimizing their functionality in practical long-term applications.

Importantly, up to now, realizing the controlled growth of two dimensional perovskite at sub-10 nm scale remains a great challenge, which has largely limited the development and applications of two dimensional perovskites. We employed the atomic crystal modulated photoluminescence imaging and obtained the carrier mobility of about 28 cm$^2$/Vs. Meanwhile, we achieved high quality laser arrays based on the in-plane directional CsPbX$_2$ materials, which also show composition-dependent strong exciton-photon coupling[6]. Unfortunately, the devices based on perovskite nanostructures still need improvement due to their environmental instability and device fabrication process incompatibility. To address these problems, we report a novel laser devices fabricated by directly growing CsPbBr$_3$ nanoparticles on prepatterned indium tin oxide (ITO) electrodes via a vapor-phase deposition[7]. Besides, we demonstrate the visualizing carrier transport of these all-inorganic CsPbBr$_3$ perovskite nanoparticles by electric field modulated photoluminescence imaging and obtained the carrier mobility of about 28 cm$^2$/Vs[8]. Importantly, up to now, realizing the controlled growth of two dimensional perovskite at sub-10 nm scale remains a great challenge, which has largely limited the development and applications of two dimensional perovskites. We employed the atomic crystal semiconductor such as TMDs (eg. WS$_2$, MoS$_2$) as substrate materials, and obtained uniform TMDs/Perovskite hybrid heterostructures, with the thickness can be well controlled at sub-10 nm scale. These results suggest that the novel low dimensional perovskite nanostructures may open up new opportunities for various applications in integrated electronics, optoelectronics, and quantum electronics.

Controlled Synthesis and Photonics Applications of Low Dimensional Metal Halide Perovskites Anlian Pan; College of Materials Science and Engineering, Hunan University, Changsha, China.

Low dimensional halide perovskites have attracted enormous attention due to their superior optical and electronic properties. Very recently, intense research has been directed toward the fabrication of the low dimension perovskite materials for laser applications, the performance of such lasers is highly dependent on the quality of the material and cavity, which makes it challenging. Herein, we demonstrate that cesium lead halide perovskite nanorods fabricated via vapor methods, which can also serve as gain media and effective cavities for tunable lasers[9]. Meanwhile, we have also achieved single-mode laser based on cesium lead halide perovskite submicron sphere at room temperature[10]. Furthermore, we achieved epitaxial growth of single-crystal cesium lead bromide perovskite film on Metal Oxide Perovskite (SrTiO$_3$) and developed a novel vapor-solution method for preparation of high-quality perovskite films on flexible substrates[11], both perovskite based structures show high-performance in photodetection among visible light. Moreover, the photodetector can be extended to near-infrared range through designing novel perovskite–erbium silicate nanosheet hybrid structures, which exhibit remarkable spectral response at ~1.54 μm[12]. Considering the perovskite based application, we demonstrated the controlled growth of in-plane directional perovskite CsPbBr$_3$ nanowires on annealed M-plane sapphire substrates, and the guided nanowire exhibit excellent photoresponse properties a very fast response speed[13]. In addition, we achieved high quality laser arrays based on the in-plane directional CsPbX$_2$ perovskite nanowires, which also show composition-dependent strong exciton-photon coupling[14]. Unfortunately, the devices based on perovskite nanostructures still need improvement due to their environmental instability and device fabrication process incompatibility. To address these problems, we report a novel laser devices fabricated by directly growing CsPbBr$_3$ nanoparticles on prepatterned indium tin oxide (ITO) electrodes via a vapor-phase deposition[15]. Besides, we demonstrate the visualizing carrier transport of these all-inorganic CsPbBr$_3$ perovskite nanoparticles by electric field modulated photoluminescence imaging and obtained the carrier mobility of about 28 cm$^2$/Vs[16]. Importantly, up to now, realizing the controlled growth of two dimensional perovskite at sub-10 nm scale remains a great challenge, which has largely limited the development and applications of two dimensional perovskites. We employed the atomic crystal semiconductor such as TMDs (eg. WS$_2$, MoS$_2$) as substrate materials, and obtained uniform TMDs/Perovskite hybrid heterostructures, with the thickness can be well controlled at sub-10 nm scale. Dynamics and Interfacial Effects of Intrinsic Surface Defects at the Atomic-Scale in CH$_3$NH$_3$PbBr$_3$ Collin Stecker$^1$, Kesi Liu$^2$, Jeremy Hieule$^1$, Zhenyu Liu$^2$, Robin Ohmann$^1$, Luis K. Ono$^1$, Guofeng Wang$^1$; ‘Okinawa Institute of Science and Technology, Okinawa, Japan; ‘Swanson School of Engineering, University of
Understanding the nature of defects in organic-inorganic hybrid perovskites (OHPs) is one of the key challenges to improving perovskite-based devices. Surface defects are of special interest because they exist at interfaces in the final device. The concept of ion migration has been used to explain the anomalous current-voltage hysteresis phenomenon observed in hybrid organic-inorganic perovskites (OHPs), and has also been implicated as potential cause for long-term material degradation. Theoretical studies have predicted vacancy assisted migration may be a possible mechanism, but the dynamics that occur at the atomic scale are still not well clarified experimentally. Scanning tunneling microscopy (STM) offers the ability to probe the surface of OHPs with atomic resolution, including resolving individual vacancy defects. Scanning the same area multiple times allows for observation of dynamic events. Here, ion migration to and from the surface was imaged at the atomic scale, and DFT calculations indicate that a step-wise mechanism for migration of MABr vacancies is energetically favorable, shedding light on the mechanism by which vacancy-assisted ion migration occurs. It is also shown that the presence of surface vacancies affects the local work function, which has implications for charge transfer between layers in a device.

References
Various modulation spectroscopic methods have been developed and employed in the PV research; impedance, capacitance, admittance, light-intensity modulation, to name a few. Each of them is built on its own physical picture, whose basic notion has long been tested and the validity confirmed, at least in the inorganic semiconductor research. However, once these techniques are applied to the perovskite PVS, we have encountered difficulties in interpreting the data in a consistent manner. It is now clear that the culprit is the ion motion, which is as influential as electron motion in some cases. We will try to reinterpret the conflicting results from the point of view of the ion motion.

In the modulation spectroscopy, one usually modulates the applied potential or the carrier density. The response would be the extracted current or the voltage across the device. As the word “spectroscopy” implies, one measures the response as a function of the modulation frequency in the linear regime, i.e., with the small enough modulation depth so that nonlinearity does not enter. The out-of-phase response normally carries the important information because it reflects the carrier dynamics in the device. In the traditional inorganic PVS, only electrons are the charge carriers. Despite this simplicity, it is hard to distinguish various mechanisms, notable examples being (1) charge trapping-detrapping processes and (2) Maxwell-Wagner polarization. The response becomes multiplicatively more complex in the presence of ions, because the (3) ionic motion not only causes displacement current but also changes the internal electrostatic potential landscape affecting the electron distribution. The three processes enumerated above all fall in similar frequency ranges** so that it is hard to distinguish them.

We have performed various modulation spectroscopy experiments and numerical simulations. Model calculations of the three processes above reveal the signatures one should look for in the data peculiar to each process. Therefore, it is of essential importance to analyze the same set of data in detail and in various ways. We will review our effort in analyzing the data to identify the processes inside the perovskite PVS. The responses as a function of frequency, temperature, illumination intensity and wavelength are combined to arrive at an overall semi-quantitative picture. We will present exemplifying results.

* Although this aspect is not often discussed in the literature, one needs to pay attention to what extent a particular experiment perturbs the system. It is important when data from different types of modulation experiments are compared.

** It is not clear if this is accidental or if there is underlying physics, i.e., correlated ion-electron motion mediated by defects.

Imaging Ion Distribution in Mixed-Halide Lead Perovskites Sarah Wieghold1, Juan-Pablo Correa-Baena2 and Lea Nienhaus1; 3Florida State University, Tallahassee, Florida, United States; 2Georgia Institute of Technology, Atlanta, Georgia, United States.

A key debate involving mixed-cation lead-mixed-halide perovskite thin films relates to the effects of process conditions on film morphology and local performance of perovskite solar cells. The halide distribution in these thin films has been shown to be of great importance for optoelectronic properties and device performances [1]. In particular, in mixed Br/I perovskites with high Br content, the thin films exhibit multiple emission peaks, suggesting segregation of halides [2]. To understand the underlying mechanisms, we map the spatial distribution of the ions in these complex multi-element halide lead perovskite thin films by synchrotron-based nanoprobe X-ray fluorescence (n-XRF). To get more insights into the growth mechanism and the resulting distribution of the halides and alkali ions, we fabricate films with different thicknesses and use scanning probe techniques as well as time-resolved optical spectroscopy. These insights into the interplay between composition, microstructure, and macroscopic properties pave the way to improved performance in this rapidly growing family of multinary lead-halide materials for solar cell applications.

Ion Migration in Hybrid Perovskite and the Consequences for Solar Cells Lucie McGovern, Moritz H. Futscher and Bruno Ehler; FOM Institute AMOLF, Amsterdam, Netherlands.

Solar cells based on organic-inorganic halide perovskites have entered the research field of photovoltaics by storm, already reaching efficiencies close to highly optimized silicon solar cells. In this context ion migration has been drastically influenced perovskites properties at various timescales. To understand the effect of ion migration we compare differently prepared perovskite devices, where we determine activation energies, concentrations and diffusion coefficients of mobile ions using transient ion drift and admittance spectroscopy. We show a correlation between fabrication conditions and ion migration. Our results shed light on the strong influence on the exact fabrication conditions, and will help to develop more robust protocols for the fabrication of highly efficient perovskite devices.

2:30 PM ES15.15.04
Halide Diffusion and Phase Stability in Mixed-Halide Perovskite-Perovskite Lateral Heterostructures Rhiannon (Rhys) M. Kennard1, Clayton J. Dahlman1, Hidenori Nakayama2, Kunal Mukherjee3, Ram Seshadri1 and Michael L. Chabinyc1; 1University of California, Santa Barbara, Santa Barbara, California, United States; 2Mitsubishi Chemical Corporation, Yokohama, Japan.

Mixed-halide perovskites are strong candidates for tandem solar cells and light-emitting devices because they exhibit bandgap tunability over the entire visible spectrum, which is easily accomplished via halide mixing. The most efficient solar cells employ a mixture of halides (typically bromide and iodide) and cations to stabilize the perovskite phase while easily accomplished via halide mixing. The most efficient solar cells employ a mixture of halides (typically bromide and iodide) and cations to stabilize the perovskite phase while effectively controlling the bandgap. The Br/I perovskites with high Br content, the thin films exhibit multiple emission peaks, suggesting segregation of halides [2]. To understand the underlying mechanisms, we map the spatial distribution of the ions in these complex multi-element halide lead perovskite thin films by synchrotron-based nanoprobe X-ray fluorescence (n-XRF). To get more insights into the growth mechanism and the resulting distribution of the halides and alkali ions, we fabricate films with different thicknesses and use scanning probe techniques as well as time-resolved optical spectroscopy. These insights into the interplay between composition, microstructure, and macroscopic properties pave the way to improved performance in this rapidly growing family of multinary lead-halide materials for solar cell applications.

Ion Migration in Mixed-Halide Perovskite Nanostructures Xiaoyong Wang1, Huichao Zhang1, Xu Fu1, Ying Tang2, William Yu3 and Min Xiao1, 2; 1Nanjing University, Nanjing, China; 2Jilin University, Changchun, China; 3University of Arkansas–Fayetteville, Fayetteville, Arkansas, United States.

Semiconductor perovskites of methylammonium (MA) lead halide (MAPbX3, X = Br, Cl, I or mixtures thereof) have been drawing great research attention due to their superior performance in solar cells with a rapidly-rising photo-conversion efficiency towards that of the crystalline silicon counterparts. The main obstacle for commercial advancement of these organolead halide solar cells lies in the instability and degradation of light-harvesting MAPbX3 films. Especially bothersome is the ion migration effect, which is believed to be responsible for the slow conductivity response, anomalous current-voltage hysteresis, giant dielectric constant and switchable photocurrent in the MAPbI3 perovskites. Meanwhile, ion migration is manifested in mixed-halide MAPbBrI1x (0 < x < 3) perovskites as a light-induced segregation of iodide- and bromide-rich domains that can revert
back to the original phase in the dark. The iodide-rich domains in the MAPbBr$_{3-x}$ perovskites would cause a red shift in the photoluminescence (PL) that has been similarly observed in the CsPbBr$_{3-x}$ perovskites, confirming a universal role played by the migration of halide ions in the light-induced phase separation process. In addition to the bulk mixed-halide perovskites mentioned above, the phase separation effect has also been observed in the CsPbBr$_{3-x}$ nanocrystals (NCs) albeit from the photoluminescence measurements. Given the nanoscale size of the iodide-rich domain that are preferentially located along the grain boundaries of the bulk mixed-halide perovskites, the CsPbBr$_{3-x}$ NCs with a normally defective surface could provide a succinct understanding of the phase separation process from a bottom-up point of view.

Here we focus on mixed-halide CsPbBr$_{3-x}$ NCs to investigate the phase separation effect at both the ensemble-film and the single-particle levels. With laser excitation, the ensemble film of CsPbBr$_{3-x}$ NCs demonstrates a blue shift from ~630 to ~520 nm in the PL that can revert back in the dark, which can be attributed to the migration of iodide ions out of and back to the excitation volume. For an isolated single CsPbBr$_{3-x}$ NC, the PL is also blue shifted upon laser excitation but never returns back in the dark, signifying the necessary existence of nearby NCs to channel the migration of iodide ions. Interestingly, the blue-shifted PL can also be induced when the CsPbBr$_{3-x}$ NCs are electrically biased in the dark without the injection of excited-state charge carriers. This strongly suggests that it is the local electric field to break the iodide bonds that triggers the ion migration process in photo-excited CsPbBr$_{3-x}$ NCs. While the enlarged energy bandgap is mainly caused by bromide enrichment in the mixed-halide CsPbBr$_{3-x}$ NCs, we additionally show that lattice distortion by the migration of iodide ions could also make a minor contribution, as verified by the observation of a blue shift in the PL as large as 20 nm from the single-halide CsPbI$_x$ NCs upon laser excitation.

Except the blue-shifted PL, we believe that the ion migration mechanism proposed above could also be employed to describe the phase segregation processes observed in all the other mixed-halide perovskite materials. A spatial size of tens of nanometers are normally required for the formation of a iodide-rich domain in bulk films of the mixed-halide perovskites, which is obviously difficult to be accommodated in any single CsPbBr$_{3-x}$ NC to trap the photo-excitcated excitons, so that they would recombine with a photon energy dictated by the bandgap of the bromide-rich domains.

Small and Large Polarons in 2D and 3D Hybrid Perovskites

Due to the highly deformable and polar nature of the metal halide framework, hybrid perovskites are very prone to lattice relaxation, which causes self-trapping of the elementary excitations into phonon-dressed localized states. In low-dimensional perovskites (e.g. 2D structures), where Coulomb interactions are enhanced by reduced dielectric screening and quantum confinement effects, the formation of self-trapped excitons (small polarons) manifests itself in apparent radiative recombination effects. Ab-initio calculations have indicated that the excess charge is spatially confined to one crystal unit cell or less, inducing local distortions of the inorganic layers. Photoexcitation in 2D perovskites gives rise to photoinduced lattice deformations associated to polaronic exciton states, with a characteristic fine structure in the absorption line-shapes. On the other hand, for charge carriers in 3D perovskites, the lattice distortion leads to the formation of charged polaron states that, due to the long-range electron phonon interaction typical of ionic crystals, may extend over several lattice sites (large polarons). Large polarons can display band-like coherent transport with substantial mobility (>1 cm$^2$/Vs), that falls with increasing temperature. In this presentation, we will provide an overview of our recent theoretical and experimental studies on small and large polaron generation and relaxation dynamics in 2D and 3D perovskites.

4:00 PM ES15.16.02
Impact of Cation Composition on Polaron Formation and Charge Carrier Mobility in Perovskites

Andrei Petsiuk1, Hannes Hempel1, Martin Stolterfoth2, Pascal Becker1, Dieter Neher2, Rainer Eichberger1 and Thomas Unold1; "Helmholtz Zentrum Berlin, Berlin, Germany; "University of Potsdam, Berlin, Germany.

Perovskites exhibit excellent opto-electronic properties – apart from their rather moderate charge carrier mobilities. These low mobilities have been attributed to the formation of large polarons and dynamic disorder due to low energetic phonons. However, the prevalent Hellwarth-Feynman theory of polarons still overestimates the mobility by an order of magnitude and the limiting mechanism is still unclear. Here, we investigate the mismatch between polaron theory and observe mobilities by varying cation composition of perovskites. To this end, the charge carrier mobility and the optical phonon spectrum of XPO$_4$ perovskite thin films with different Cs, MA and FA composition are measured by time-resolved terahertz spectroscopy. The main phonon modes are observed for all samples at ca. 0.9 THz (30 cm$^{-1}$) and ca. 1.9 THz (63 cm$^{-1}$) and exhibit only minor shifts with cation composition. This observation supports the assignment of these main optical phonon modes to 1-ph vibrations on the anion lattice. The cation composition only slightly distorts the unit cell with minor impact on the I-Pb bond.

The measured charge carrier mobilities are in the range of 40-90 cm$^2$/Vs which further supports similar polaron formation for different cation compositions. The difference can be attributed to variations in the ionic screening with cation composition and to the microstructure of the samples.

Finally, we identify several reasons for the difference between measured mobilities and estimation by the Hellwarth-Feynman theory.

First, we find higher mobilities for lower photo-exciated charge carrier concentrations. The measured mobility on MAPbI$_3$ at low injection is 81 cm$^2$/Vs which is 2-3 times larger than typical literature values. This value is relatively close to the mobility of 230 cm$^2$/Vs which we estimated by the Hellwarth-Feynman theory.

Second, the observed phonon modes are mostly of transversal character, which are not considered in the mobility estimation by the Hellwarth-Feynman theory. The potential impact of such phonon modes on the mobility of halide perovskites will be discussed.

4:15 PM ES15.16.03
Interplay Between Structure and Physical Properties in Organic-Inorganic 2D Perovskites

Jean-Christophe Blancou1, Jacky Even2, Andreas Stier3, Claudine Katan1, Jared Crochet1 and Aditya Mohite2; "Los Alamos National Laboratory, Los Alamos, New Mexico, United States; "Rice University, Houston, Texas, United States; "Institut National des Sciences Appliquées, Rennes, France; "Technische Universität München, Garching, Germany; "Université de Rennes, Rennes, France.

Solution processed, organic-inorganic (hybrid) 2D perovskites have recently emerged as efficient semiconductors for light emission and photovoltaics, with technologically relevant stability [1]. Hybrid 2D perovskites feature unique structural characteristics related to the hybrid nature of their crystal lattice, which includes soft and dynamic lattice structure and organic-inorganic atom-thick interfaces. However, there is still little knowledge of the interplay between, on the one hand, the photo-excited states and electronic properties of hybrid perovskites and, on the other hand, the unique structural characteristics of this class of materials. Here, using optical spectroscopy and 60-Tesla magneto-absorption supported by modelling, we report the dependence of the formation, dynamics, and recombination of exciton states on the structural and compositional details of hybrid 2D perovskites. First, our work reveals that the exciton properties (reduced mass, binding energy, etc.) are tailored by both the thickness of the 2D perovskites and the size of the organic molecules in the lattice [2]. Second, our observations demonstrate the existence of unique electronic states located at the edges of the 2D perovskite layers [3], which are understood to result from local distortions of the lattice at the edges, and which promote exciton dissociation and localization [4]. Finally, we will discuss some of our recent results that provides insight into the hetero-coupling between hybrid 2D perovskites and graphene-like layers such as graphene and transition metal dichalcogenides.

Additionally, we have demonstrated the effect of Cl additives on ideality factors of our devices as well as lower recombination using impedance spectroscopy. Importantly, molecular engineering by applying chloride (Cl) additives greatly enhances the stability of the PSCs, which show only 5% degradation after aging for 90 days.

The presence of surface and grain boundary defects in organic–inorganic halide perovskite films is detrimental to both the performance and operational stability of perovskite solar cells (PSCs). Compositional engineering and surface treatment of perovskites are effective approaches to passivate these defects. Here, we study the effect of chloride additives on the bulk and surface defects of mixed-cation and halide PSCs. We found that using an anti-solvent technique, the perovskite film is divided into two separated layers, i.e., a bottom layer with large grains and a thin capping layer with small grains. The addition of formamidinium chloride (FACl) into the precursor solution removes the small-grained perovskite capping layer and suppresses the formation of bulk and surface defects, providing a perovskite film with remarkably enhanced crystallinity and large grain size up to over 1 μm. Time-resolved photoluminescence measurements show longer lifetimes for perovskite films modified by FACl and subsequently passivated by 1-Adamantylamine hydrochloride (ADAHCl) as compared to the reference sample. These treatments improve the film quality and enable a high PCE of 21.2% and $V_{oc}$ of 1152 mV with negligible hysteresis.

Importantly, molecular engineering by applying chloride (Cl) additives greatly enhances the stability of the PSCs, which show only 5% degradation after aging for 90 days. Additionally, we have demonstrated the effect of Cl additives on ideality factors of our devices as well as lower recombination using impedance spectroscopy.

Understanding and Designing Interfaces and Defects in Perovskite Solar Cells

Juan-Pablo Correa-Baena; School of Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Perovskite solar cells promise to yield efficiencies beyond 30% by further improving the quality of the materials and devices. Electronic defect passivation, and suppression of detrimental charge-carrier recombination at the different device interfaces has been used as a strategy to achieve high performance perovskite solar cells. In this presentation, I will discuss the role of electronic defects and how these can be passivated to improve charge-carrier lifetimes and to achieve high open-circuit voltages. I will discuss the characterization of 2D and 3D defects, such as grain boundaries, crystal surface defects, and precipitate formation within the films, by synchrotron-based techniques. The importance of interfaces and their contribution to detrimental recombination will also be discussed. As a result of these contributions to better understanding 2D and 3D defects, the perovskite solar cell field has been able to improve device performance. Albeit the rapid improvements in performance, there is still a need to improve these defects to push these solar cells beyond the current state-of-the-art.

9:00 AM *ES16.01.02*

Interface Modification and Molecular Engineering in the Perovskite Architecture Enable Highly Efficient, Stable and Electroluminescent Perovskite Solar Cells

Mohammad Mahdi Tavakoli; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Non-radiative recombination loss specially at the interfaces is a big challenge in the perovskite solar cells (PSCs) and affect the performance, stability, reproducibility of devices. Engineering the interfacial regions of the PSCs using an interface layer or additives is an effective strategy to address this issue. Our new findings report on a major breakthrough in the PSCs research. We discovered amazingly effective ways to mitigate the radiationless recombination of charge carriers at the interfaces of the perovskite with either electron transporting layer (ETL) or the hole transporting layer (HTL). In terms of ETL modification, we treat the surface of ETLs in the PSCs using SnO2 and graphene, results in drastically improved the charge transfer properties, retarded the recombination rate and reduced the unwanted interfacial reactions at the interfaces with perovskite film. Moreover, we found that incorporation of the molecular modulators such as adamantanes either at the interface of perovskite with HTL or into the HTL solution prevents non-radiative recombination drastically, resulting in a highly efficient and stable PSC. Based on these techniques, we achieved PSCs (for both planar and mesoporous structures) with electric to power conversion efficiency (PCE) of ~22%, an open circuit voltage of up to 1245 mV, external electroluminescence yield of 2.5% and a great operational stability, which are the records for triple A-cation PSCs with respect to the band gap (1.61 eV). Our proposed approaches open up a promising route for fabrication of cost-effective solar cell and pave the way for the development and commercialization of the PSCs.

9:30 AM *ES16.01.03*

Surface Defects of CH3NH3PbBr3 and Their Effect on Interfacial Device Properties

Collin Stecker1, Kexi Liu2, Jeremy Hieulle1, Zhenyu Liu2, Robin Ohmann1, Luis K. One1, Guofeng Wang1 and Yabing Qi1; 1Okinawa Institute of Science and Technology, Okinawa, Japan; 2Swanson School of Engineering, University of Pittsburgh, Pittsburgh, Pennsylvania, United States.
Understanding defects in perovskite films is key to improving device performance and stability. It has been hypothesized that vacancy defects enable ion migration, which has been implicated to cause current-voltage hysteresis and long-term material degradation. Additionally, defects at the surface of the perovskite film may affect the interfaces in a device, and interface engineering is seen as an important avenue for improving device performance. Scanning tunneling microscopy (STM) offers the ability to probe the surface of OFPs with atomic resolution, including resolving individual vacancy defects. Scanning the same area multiple times allows for observation of dynamic events. Here, multiple types of defects were resolved and dynamic ion migration to and from the surface was imaged at the atomic scale. DFT calculations indicate vacancy defects are MABr vacancies and that vacancy defects at the surface of the film change the local work function, which has important implications for energy level alignment and charge transfer between layers in a photovoltaic device.

References
The efficiency of perovskite solar cells has skyrocketed from 3.8% to 23.3% in the past few years. For the best MAPbI$_3$ perovskites, the open-circuit voltage deficit, defined as the difference between bandgap and open-circuit voltage ($V_{oc}$), is only 0.37 V, approaching other best technologies such as GaAs [1]. However, similar to III-V materials, higher bandgap perovskites tend to have larger $V_{oc}$ deficits. For example, for 1.64-eV and 1.7-eV perovskites, the best $V_{oc}$-deficits are 0.49 V and 0.51 V, respectively [2]. This voltage loss limits the performance of wide-bandgap perovskites, and their applications on, for instance, tandem solar cells.

The $V_{oc}$ of photovoltaic devices is governed, hierarchically, by recombination in the absorber and the carrier-selective contacts of the devices. Grain engineering has been proven to be an effective way to reduce defect density and, thus, suppress recombination to enhance the $V_{oc}$ [2][3]. In our work, we focus on exploring different carrier-selective contact materials for perovskites.

With inverted architecture, we have replaced PTAA hole contact with boron-doped a-Si:H material. Our first device shows a $V_{oc}$ of 1.02 V on a 1.6-eV CsMAFABr perovskite, and 0.92 V on a 1.67-eV perovskite. These numbers are very close to the PTAA control devices with $V_{oc}$ of -1.1 V. Although the FF is rather poor due to shunts and possible large series resistance due to band misalignment. We are in the process of making new devices without shunts, and characterizing the band alignment between our a-Si:H hole contact and perovskite absorber. By the time we present, we believe we’ll have such information. In addition to the current-voltage measurement, we will use surface photovoltage and XPS/UPS etc technique to obtain the band information, and also use a Sun-Voc tool that we developed to probe the series-resistance-free fill factor of the device with a-Si:H contacts. We’ll also further employ phosphorous-doped a-Si:H as an electron contact to perovskite, and perform a thorough analysis on that as well.

Enhanced Transport and Carrier Selectivity at Perovskite Interfaces Enabled by Ordered Perylene Monolayers

Alexander D. Carl and Ronald L. Grimm; Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

To maximize the scalable deployment of perovskite PV, we investigate low-temperature organic monolayer-based morphologies to chemically and electrically glue perovskites to their contacting phases while maintaining a “soft”, flexible interface and carrier selectivity. We have covalently grafted vertically oriented perylene diimide layers on TiO$_2$ through and inside linkage to a surface-bound silane. Secondary functionalization with a diamine to the terminal anhydride yields A-type cation moieties that serve as a chemical hook for perovskite deposition. UPS-quantified HOMO and LUMO levels of perylene diimide molecules aligned to facilitate electron transport to the TiO$_2$ substrate while blocking holes. Reflection- Absorption Infrared Spectroscopy (RAIRS) and X-ray photoelectron spectroscopy revealed a high coverage of vertically oriented perylene diimide. Perylene interfacial monolayers yield improved energy conversion relative to TiO$_2$ perovskite interfaces that we ascribe to enhanced interfacial carrier selectivity and transport, and reduced recombination. We discuss the present context in the results of other morphologies relevant to tandem photovoltaics.

What Can Impedance Spectroscopy Tell Us (for the Moment) About Perovskite Solar Cells?

Ivan Mora-Sero; Universitat Jaume I, Castello de la Plana, Spain.

Perovskite solar cells are surprising the photovoltaic community as unconventional behaviors have been reported. In most of the cases the origin of these behaviors is not completely understood and also, very important for the final application, how them influence the final performance of the device. On the other hand Impedance spectroscopy is a non-destructive characterization technique that can help in the understanding of these devices. Impedance spectroscopy is a characterization method in the frequency domain that allows to decouple physical processes with different characteristic times at the working conditions i.e. under illumination and applied bias. Despite the huge potentiality of this technique for the characterization of perovskite solar cell a complete model of impedance for this kind of cells applicable in all the conditions and configuration has been elusive for the moment. Undoubtedly, the combined action of electron and holes and ions in perovskite solar cell is at the base of the complex behavior observed in this kind of devices. In this talk we compare the well know dye sensitized solar cells with the perovskite solar cells highlighting similarities and differences. In addition the interest of impedance characterization of different types of perovskite solar cells is discussed.

2:00 PM Ionic-to-Electronic Current Amplification in Hybrid Perovskite Solar Cells—Ionically Gated Transistor-Interface Circuit Model Explains Hysteresis and Impedance of Mixed Conducting Devices

Davide Moia; Ilariu Gemetti; Phil Calado; William Fisher; Michael Stringer; Onkar Ganne; Yinghong He; Pablo Dencoso; David Lidzey; Emilio Palomares; Jenny Nelson and Piers Barnes; 'Physics, Imperial College London, London, United Kingdom; 'ICIQ, Tarragona, Spain; 'Physics, The University of Sheffield, Sheffield, United Kingdom; 'Chemistry, Ludwig-Maximilians-Universität München, Munich, Germany; 'School of Electrical and Electronic Engineering, Newcastle University, Newcastle, United Kingdom.

Mobile ions in hybrid perovskite semiconductors introduce a new degree of freedom to electronic devices suggesting applications beyond photovoltaics. An intuitive device model describing the interplay between ionic and electronic charge transfer is needed to unlock the full potential of the technology. We describe the perovskite-contact interfaces as transistors which couple ionic charge redistribution to energetic barriers controlling electronic injection and recombination. This reveals an amplification factor between the out of phase electronic current and the ionic current. Our findings suggest a strategy to design thin film electronic components with large, tuneable, capacitor-like and inductor-like characteristics. The resulting simple equivalent circuit model, which we verified with time-dependent drift-diffusion simulations of measured impedance spectra, allows a general description and interpretation of perovskite solar cell behaviour.

arXiv:1805.06446

Photo-induced phase separation has been reported for a range of mixed-halide perovskites, which limits the available band-gap energies for photovoltaic applications [1,2]. An enhanced understanding of the phase separation mechanism is essential to rationalize limitations and design stable perovskite semiconductors. Up to now, phase separation and segregation has been detected by means of X-ray diffraction (XRD), photoluminescence (PL) and cathodoluminescence experiments [3,4]. During electron microscope experiments, the electron beam may cause changes in halide perovskites [4, 5] and we here show that phase separation can be induced by electron beam irradiation of the sample. Inorganic CsPb(Br$_{3-x}$I$_x$)$_2$ thin films were deposited by spin-coating and the phase separation investigated in-situ by transmission electron microscopy (TEM). By this approach, it was possible to directly monitor the phase separation of CsPb(Br$_{3-x}$I$_x$)$_2$ thin films on the nanoscale into CsPbI$_3$ and CsPbBr$_3$ domains. We discuss the comparability of the interactions of electrons and photons with the halide-perovskite thin film and correlate the in-situ TEM with XRD and PL measurements of the same samples. Furthermore, we present different approaches of sample preparation for this in-situ TEM investigation.

Atomic Scale Analysis & Electronic Properties Characterization of MAPbI₃ Perovskite Material

Asfhan Jamshaid, Rohin Ohmann, Jeremy Hieulle, Collin Stecker, Luis K. Ono and Yabing Qi; EMSSU, Okinawa Institute of Science & Technology, Onna, Japan.

In recent years, the organic-inorganic hybrid perovskite has gained an increasing research interest in academia for applications in thin film solar cells, due to rapidly increased efficiency (from 3.8% to 23.3% within a decade) [1], high absorbance coefficient [2], low-cost fabrication process, and material availability [3]. Among the hybrid perovskites, MAPbI₃ (CH₃NH₃PbI₃) based solar cells have shown high conversion efficiency with several advantages, such as thermal instability, hysteresis loss at room temperature. Therefore, the commercialization of these solar cells is still a challenge. Understanding and resolving these issues necessitates the investigation of the sample at the atomic scale to determine the underlying fundamental processes. Here, we present the growth and experimental characterization of thin MAPbI₃ films on Au (111) under ultra-high vacuum conditions (UHV = 1x10⁻¹⁰ Torr). The thick films were prepared by vacuum evaporation of the precursor molecules MAI and PbI₂ with a thickness of a few monolayers (approx. 4 nm). We characterize the sample with scanning tunneling microscopy (STM) and X-ray photoelectron spectroscopy (XPS), obtaining information about the atomic structure, and chemical composition. For the electronic properties analysis, we used ultraviolet photoemission spectroscopy (UPS), and inverse photoemission spectroscopy (IPES). Our study will provide the basis for further understanding ion incorporation and stability at the atomic scale.

Understanding and the Modulation of the Interaction Between Electronic and Ionic Charge Transport at Hybrid Perovskite-Liquid Electrolyte Interface

Priya Srivastava and Monojit Bag; Institute of Technology Roorkee, Roorkee, India.

Manifested by high absorbance coefficient, large carrier diffusion length, ambipolar charge transport and moderate mobility of charge carriers, organo-lead halide perovskites recently emerged as a promising candidate for high efficiency and low-cost solution processed solar cells, needs no introduction. Perovskite Solar Cells (PSCs) have already gathered considerable attention, showing a tremendous hike in efficiency from 3.8% by Kojima et al. (2009) to 22.1% by Yang et al. (2017). A lot of research has been done on the efficiency improvement of PSCs by optimization of the film morphology at the interfaces by various characterization techniques including electrochemical impedance spectroscopy (EIS) in a solid-state active device geometry. Recently, the optimization of the film morphology at liquid electrolyte interface by EIS is trending as a more simplified approach. Li et al. have measured the flat band potential, density and type of charge carrier at the perovskite-liquid interface from Mott-Schottky plot for spin coated and spray coated films of methylammonium lead tri-iodide (MAPbI₃) perovskite. Srivastava et al. have optimized the morphology of MAPbI₃ perovskite thin films at liquid interface by controlling nucleation and growth during film fabrication by spin coating the films on the premed substrates. However, there is a need for understanding the charge transfer at these interfaces in more detail. Here, we have studied the kinetics of charge transfer and diffusion at the hybrid organic-inorganic perovskite-liquid electrolyte interface under the effect of applied bias. By applying the different dc bias from 0 to +1V and 0 to -1V, it was found that the ion diffusion at low frequency regime gets modulated due to charge accumulation. The charge transport resistance is initially increased to a maximum at around 0.4 V applied bias along with the decrease in the space charge capacitance. A transition state is observed around 0.4 V to 0.6 V due to the strong electronic-ionic interaction where charge transport resistance decreases and capacitance increases. However, at higher applied bias voltage charge transport resistance increases again and capacitance starts to decrease due to excess ion accumulation. The perovskite films show a similar trend of change in impedance under both positive and negative bias. The Mott-Schottky Plot for forward and reverse voltage scan shows n-type and p-type behavior which indicates the ambipolar nature of perovskite semiconductor. The significant difference in the impedance spectra can be seen in dark and light which is attributed to the high absorbance coefficient of the perovskite material. We have proposed a model to explain the charge kinetics across the perovskite-liquid electrolyte interface.

Tandem Perovskite Architectures—Overcoming the Complexities of Halide Ion Exchange

Prashant V. Kamat, VikashKumar Ravi and Rebecca Scheidt; Radiation Laboratory, Department of Chemistry & Biochemistry, University of Notre Dame, Notre Dame, Indiana, United States.

Mixed halide lead perovskites offer a useful strategy for continuous tuning of semiconductor bandgap. Based on their tunable optical properties these mixed halides are being considered as attractive candidates to develop single junction and multijunction tandem solar cells. The ease of halide ion exchange property poses a problem to create a tandem structure with layers of metal halide perovskites of different compositions. In order to keep the lead halide perovskite nanocrystals intact without undergoing exchange of halide ion and retain the original band structure one needs to suppress the halide ion migration across the nanocrystals. We have now successfully achieved this task by capping CsPbBr₃ and CsPbI₂ nanocrystals with PbSO₄-Oleate. Absorption measurements show that the nanocrystal assemblies maintain their identity as either CsPbBr₃ or CsPbI₂, for several days. Furthermore, we have electrochemically deposited these assemblies as hierarchical structures on electrode surfaces and employ them in light emitting devices. The effectiveness of PbSO₄-Oleate capping of lead halide perovskite nanocrystals offers new opportunities to overcome the challenges of halide ion exchange and aid towards the tandem design of perovskite light harvesting assemblies.

Characterisation of Electron Beam Induced Damage in Multi-Cation and -Anion Perovskite Solar Cells During Electron Microscopy

Ashilan Babagyi, Mohit Raghuvanshi, Bert Conings, Frank Renner, Oana Cociocaru-Mirédin and Hans-Georg Boyen; 1 Institute for Materials Research (IMO-IMOMEC), Diepenbeek, Belgium; 2RWTH Aachen University, Aachen, Germany.

Metal halide perovskites have sparked tremendous enthusiasm in the photovoltaic community with their promising performances. Currently holding a record power conversion efficiency of 23.3%, this exciting material class is approaching the mighty Si-powerhouse, concurrently opening encouraging avenues in (all-) perovskite multi-junction applications while approaching commercial exploitation. At the origin of these highly performing devices lie superior absorber properties that so far have been investigated by a plethora of characterisation techniques. Amongst all, electron microscopy (EM) remains one of the most extensively employed tools for studying the absorber in terms of crystallography, morphology and interfaces, lattice defects, compositions, and charge carrier lifetimes but with severe obstacles such as thermal instability, hysteresis loss at room temperature. However, a crucial challenge upon using EM remains the beam sensitivity of the absorber, especially upon imaging with an increased electron dose. Resulting in structural and chemical changes in the light harvester in function of the total electron dose, it becomes extremely challenging to validate obtained results and those reported in literature. Therefore, a quantitative characterisation of the beam damage is highly necessary to avoid, or at least mitigate, changes to the sample upon imaging in future analysis. Therefore, in this work, we investigate the current degeneration in multi-cation and -anion perovskite solar cells in function of the total electron dose by means of electron beam induced current (EBIC) measurements on rough cross-section of corresponding devices—providing an indirect yet quantitative route to characterise the electron beam induced damage to the absorber. Allowing the extraction of current decay profiles, various compositional perovskites are compared in terms of beam sensitivity, and operational parameters are indicated to avert (or at least mitigate) sample damage during imaging.
Halide perovskite solar cells (HPSCs) present a cutting-edge nanotechnology which has demonstrated remarkable power conversion efficiency increases to a recently reported value of 23% [1]. The high efficiency combined with low-cost production make HPSCs one of the most promising solar cell technologies but significant challenges related to their stability are yet to be solved. Exposure to oxygen, humidity, temperature, atmospheric pressure and UV light stimulates a complex set of degradation mechanisms such as diffusion of molecular oxygen and water, interfaces and the active material degradation, electrode reaction with the organic material to morphological and macroscopic changes [2]. For this reason, devices are encapsulated which prolongs their life and also increases mechanical stability [3]. As the natures and timescales for each of these chemical reactions differ, it is challenging to elucidate the degradation processes. Secondary ion mass spectrometry (SIMS) is one of the few techniques that can offer valuable insights into potential degradation mechanisms by obtaining spatially resolved chemical analysis of organic and inorganic layers and interfaces. In this work, we present the high mass-resolving power depth profiling of HPSCs using the 3D OrbiSIMS [4].

The 3D OrbiSIMS comprises dual beam and dual analyser configuration by integrating a Q Exactive™ HF Hybrid Quadrupole-Orbitrap™ mass spectrometer with a high-resolution imaging ToF-SIMS platform. Advantages of this instrument include a significantly higher duty cycle compared with time-of-flight instruments (using pulsed ion beams), high-mass resolving power (>240,000) and high-mass accuracy (~ 1 ppm), up to 4 orders of magnitude dynamic range for organic materials and the ability to do MS/MS. Here, we apply single beam depth profiling combined with high-mass resolving power to study the interface and interlayer chemistry in HPSCs and the degradation mechanisms that occur when exposed to air. Critical to achieving this is air-free transfer between a sample preparation glovebox and the 3D OrbiSIMS instrument. The air-free transfer protocol will be presented in this work.

5:30 PM ES16.02.09 Probing the Enhanced Stability of 2D Perovskite Solar Cell Materials Bryan Wygant, C. B. Mullins, Andrei Dolocan, David M. Abbott, Quyen Vu and Alexandre Ye; University of Texas at Austin, Austin, Texas, United States.

Organolead halide perovskites are a new class of photovoltaic materials for potential use in thin film solar cells, but suffer from rapid degradation under light and humidity, limiting their viability. Recently developed quasi-2D Ruddlesden-Popper phase perovskites show improved stability but, at present, the mechanism behind the stability is poorly understood. Here, we have used time-of-flight secondary ion mass spectrometry (ToF-SIMS), photoluminescence spectroscopy (PL), electrochemistry, and other techniques to study the chemistry and performance of 2D and 3D phases of methylammonium lead triiodide (MAPI) solar cells as a function of humidity exposure. ToF-SIMS depth profiles of both 2D and 3D MAPI planar solar devices (n-i-p, Cu/Perovskite/PEDOT:PSS) show the formation of a significant hydrolysis-based degradation layer at the surface of only 3D MAPI devices after humidity exposure. Isotopic D₂O studies confirm the layer is caused by ambient humidity, while electrochemistry confirms it is directly related to loss of cell performance. The growth of this hydrolysis layer is found to be inhibited in 2D MAPI devices by the formation of a thin protective layer composed of more thermodynamically-stable 2D phases, clearly observed in PL spectra, which protects the less stable 2D bulk. To confirm that this newly formed 2D layer improves stability, we created solar cells consisting of 3D MAPI films coated with a thin layer of the 2D perovskite, and show that these cells are more stable than un-treated 3D MAPI devices. As a result, we conclude that using 2D perovskite as a protective interface may be a simple way to improve device stability.

10:30 AM *ES16.03.01/ES15.01.01/ES17.03.01 Present Status and Next Important Challenge of Perovskite Photovoltaics Towards Industrialization Tsutomu Miyasaka; Toin University of Yokohama, Yokohama, Japan.

Power conversion efficiency (PCE) of lead halide perovskite solar cell (over 23%) has surpassed those of CIGS and CdTe, approaching the top value of crystalline Si cell. Our group has been able to achieve PCE over 21% by low cost ambient fabrication. However, high PCE of single-cell enabled by lead halide-based perovskite absorbers are now being saturated, taking the Shockley–Queisser (SQ) limit of open-circuit voltage (V_{OC}) (ca.1.32V) into account. Tandem cell making, which can further increases PCE up to 28% or more, leads to higher material and process cost and will raise a question if performance/cost ratio can be accepted in industry. Therefore, a smart way is to create a single cell which has high PCE comparable with that of GaAs (>28%) by reducing bandgap energy to <1.4 eV without accompaniment of increase in V_{OC}. This possibility will bring in a family of metal halide perovskites out of those depending on use of lead. In addition to such efficiency issue, high performance of organo lead halide materials is not compatible with robust high stability required for practical use. Ensuring the intrinsic thermal stability (desirably >200°C) of the perovskites is a key issue before industrialization. In addition, toxicity of lead-based perovskites are going to become the most formidable challenges for real use (commercialization), in particular, for applications to IoT society, which is one of the most promising field of perovskite photovoltaic device in terms of high voltage output even under weak illumination. These thoughts urge us to concentrate our next research of perovskite photovoltaics (PV) more on development of non-lead high efficiency absorbers. Sn perovskite is still a strong candidate because Sn(II) has been found to be stabilized against ambient air by metal doping method (such as Ge). Regarding Bi-based perovskites, we found AgBiI₃ as a promising all-inorganic absorber having high thermal and moisture stability. Stability also highly depends on the property of charge transport materials (CTMs), especially, the kind of hole transporter. Spiro-OMeTAD does not work at high temperature while P3HT, for example, is thermally stable. In our collaboration with JAXA, P3HT-based perovskite devices showed robust stability by exposure to high (100°C) and low (<40°C) temperatures and also to high energy particle radiations (Science, 2018, 2, 148). Selection of CTMs is another important key in combination with non-lead perovskite materials. In conclusion, next direction of perovskite PV should be to enhance PV performance of non-lead all-inorganic semiconductor materials by extended compositional engineering, in parallel with developing thermally stable CTMs. Our on-going studies on non-lead perovskite materials in our group will be introduced in the talk.
Organic-inorganic perovskites enable a combination of useful organic and inorganic properties within a single molecular-scale composite and have attracted substantial interest for use within organic-inorganic electronic devices [1], in part due to the high carrier mobilities, long minority carrier lifetimes, tunable band gaps and relatively benign defects and grain boundaries for systems based on Group 14 metals (e.g., Ge, Sn and Pb) [2]. Indeed, these materials have enabled unprecedented rapid improvement in perovskite photovoltaic performance to levels above 20% power conversion efficiency and with open circuit voltages above 1V for a single junction photovoltaic (PV) device [3]. This talk will provide an historical perspective on foundational work related to the organic-inorganic perovskite semiconductors, including discussion of crystal structure flexibility [4,5], semiconducting properties, film deposition approaches and electronic device applications of the three-dimensional and lower-dimensional perovskite structures. Recent trends in the field, as they relate to application in photovoltaics and related devices, will also be coupled into this discussion.

SESSION ES16.04: Stability and Testing
Session Chairs: Jinsong Huang and Yabing Qi
Tuesday Afternoon, April 23, 2019
PCC North, 100 Level, Room 125 AB

1:30 PM *ES16.04.01
Compositional and Interface Engineering of Perovskite Solar Cells
Anders Hafelielb; Laboratory of Photomolecular Science, Swiss Federal Institute of Technology Lausanne (EPFL), Lausanne, Switzerland.

In our work on perovskite solar cells (PSC) we have achieved efficiencies above 22% with a mixed composition of iodide/bromide and organic and inorganic cations. With the use of SnO2 compact underlayers as electron acceptor contacts we have constructed planar perovskite solar cells with a hysteresis free efficiency above 20%. Through the compositional engineering larger perovskite grains grown in a monolithic manner are observed and reproducibility and device stability have been improved. With regards to lifetime testing, we have shown a promising stability at 85 °C for 500 h under full solar illumination and maximum power point tracking (95% of the initial performance was retained). Recently, we have also commented on the standardization of PSC aging tests.

2:00 PM *ES16.04.02
Degradation Mechanisms of Lead Halide Perovskite Solar Cells and Stability Improvement Strategies
Yabing Qi; Okinawa Institute of Science and Technology, Okinawa, Japan.

Perovskite solar cell research continues to progress rapidly on various fronts. My group at OIST is making efforts to use surface science and advanced material characterization to obtain in-depth understanding about perovskite materials and solar cells [1]. In this talk, I will present our research progress on understanding the degradation mechanism of perovskite materials [2,3] as well as developing strategies to improve stability of perovskite solar cells [4-6].

2:30 PM ES16.04.03
Thermally Stable, Planar Hybrid Perovskite Solar Cells with High Efficiency
Taiho Park; Pohang University of Science and Technology, Pohang, Korea (the Republic of).

Tin oxide (SnO2) is a promising material for the electron transport layer in planar perovskite solar cells (P-PSCs) due to its suitable energy level and high electron mobility. SnO2-based P-PSCs show the highest power conversion efficiency among planar structure devices, but the PCE remains still low compared to the mesoporous TiO2-based PSCs and there is a lack of thermal stability study. In this study, we develop a simple interface engineering to improve optoelectronic properties and the thermal stability of the P-PSCs. The modified SnO2 shows high conductivity, effective charge extraction ability and high recombination resistance. Empirically, efficiencies of 21.43% and 20.5% were reached for the device with doped Spiro-OMeTAD and with dopant-free asy-PBTBDT, respectively, in the present study. The devices with modified SnO2 show excellent stability under mild (humidity of 25%) and harsh conditions (humidity of 85%; temperature of 85°C). Thus, our newly developed method guarantees highly efficient and thermal stable P-PSCs.

2:45 PM ES16.04.04
Highly Efficient and Stable Perovskite Solar Cells via Perovskite Surface Modification
Zhifang Wu and Yabing Qi; Okinawa Institute of Science and Technology, Okinawa, Japan.

Organic-inorganic hybrid perovskite solar cells show the promises as the next-generation photovoltaic technology. The efficiency has quickly increased from 3.8% [1] to 23.2% since 2009. [2] However, instability of perovskite solar cell is a big issue hindering its commercialization and practical applications. By combining thermal-insensitive organic-inorganic perovskite and moisture-resistant electrode, we report successful fabrication of stable organic-inorganic hybrid PSCs which shows enhances stability under tough aging condition. Surface contact is another critical factor affecting solar cell efficiency. After suitable surface modification, solar cell efficiency is significantly improved from 12.2% to 14.9%.

3:00 PM BREAK

3:30 PM ES16.04.05
Engineering Stress in Perovskite Solar Cells to Improve Stability
Nicholas Rolston1, Kevin A. Bush1, Adam Printz1, Aryeh Gold-Parker1, 2, Michael D. McGehee1, Michael F. Toney1, 2 and Reinhold H. Dauskardt1; 1Stanford University, Stanford, California, United States; 2SLAC National Accelerator Laboratory, Menlo Park, California, United States.

Metal halide perovskites hold tremendous promise for next-generation solar cells, more than any other recently developed low-cost active PV material. To fulfill this promise, perovskites must first overcome the chemical and thermomechanical instability that has long been observed in them. While some promising results have recently been achieved in scalability with power conversion efficiencies (PCE) of 12% for 100 cm² perovskite devices, the thermomechanical instability of perovskites remains a significant challenge to producing module-scale perovskite solar cells with operational lifetimes comparable to c-Si and CdTe.

In particular, stresses are generated in perovskite films during processing and magnified in service by environmental effects such as thermal cycling, resulting in the formation of
defects and propagation of fracture and delamination. Additionally, cracks that develop in the film are a source of accelerated degradation for the transport of gases, moisture, and other environmental species. Unfortunately, perovskite layers are exceptionally fragile and susceptible to delamination as measured by their fracture energy—less robust than organic photovoltaics (OPVs) by an order of magnitude and c-Si or copper indium gallium diselenide (CIGS) solar cells by two orders of magnitude. Despite the significance of film stresses for device stability, the origin and magnitude of stresses in perovskite films have been largely overlooked. In addition to causing fracture, stress accelerates the rate of photocatalytic degradation in many materials—such as fuel cells, microelectronics, and photovoltaics—and a recent report shows that perovskite are no exception.

Perovskites can accumulate residual stresses during processing through several pathways. For example, in solar cell devices, perovskites have much higher coefficients of thermal expansion (CTE) than the other device layers and the glass substrate. When perovskites are annealed after deposition and subsequently cooled back to room temperature, a lower-CTE substrate constrains the perovskite from contracting, an effect that generates lattice strain in the film. Given the extreme mechanical fragility of perovskite films, and for further stress development during fabrication and operation (e.g., exposure to environmental stressors such as thermal cycling), these residual stresses could contribute significantly to light, heat, and moisture-based chemical degradation as well as fracture in devices.

In this work, we report on an overlooked factor affecting stability: the residual stresses in perovskite films, which are tensile and can exceed 50 MPa in magnitude, a value high enough to deform copper. These stresses provide a significant driving force for fracture. Films are shown to be more unstable under tensile stress—and conversely more stable under compressive stress—when exposed to heat or humidity. Increasing the formation temperature of perovskite films directly correlates with larger residual stresses, a result of the high thermal expansion coefficient of perovskites. Specifically, this tensile stress forms upon cooling to room temperature, as the substrate constrains the perovskite from shrinking. No evidence of stress relaxation is observed, with the purely elastic film stress attributed to the thermal expansion mismatch between the perovskite and substrate. Additionally, the authors demonstrate that using a bath conversion method to form the perovskite film at room temperature leads to lower stress values that are unaffected by further annealing, indicating complete perovskite formation prior to annealing. It is concluded that reducing the film stress is a novel method for improving perovskite stability, which can be accomplished by lowering formation temperatures, flexible substrates with high thermal expansion coefficients, and externally applied compressive stress after fabrication.

In the current work, CSN testing is used to measure the interface delamination in perovskite and silicon/perovskite tandem solar cells (SPTS), which could lead to lowering of the fill factor (FF) under operating conditions of solar cells. In this test configuration, nanoindentation is performed on the substrate which is typically ~5–20 μm away from the electrode to air interface. The load-displacement curve obtained from the nanoindentation testing will be used to determine the fracture energy with the aid of a semi-quantitative analytical model to compute and compare adhesion and mechanical properties of samples with different interfaces.[2] At the conference, details pertaining to the CSN test and subsequent analytical analysis to get the fracture energy will be presented for various configurations of perovskite solar cells.

Comprehensive Multifactorial Studies on the Degradation of Perovskite Solar Cells in Operation Carlos Biaou, Matt McPhail, Vivek Subramanian and Oscar Dubon; University of California, Berkeley, Berkeley, California, United States.

The issue of long-term stability in perovskite solar cells under atmospheric conditions remains at the forefront of making them viable technologies. To facilitate a firm understanding of the processes at stake and their influence, it is important to employ a systematic investigation of degradation [1]. The interactions between various degradation phenomena (e.g. the effect of load, atmosphere, etc.) can be substantial, warranting the use of multifactorial methodologies to extract dominant effects and their interactions. As such, we use a design of experiments (DOE) methodology, which allows us to identify salient confluent factors and their interactions as they affect the operation of the solar cells. Specifically, we observe the influence of the combination of temperature, humidity, perovskite type, and loading condition on electrical (I-V), crystallographic (XRD), and optical (UV-Vis) characteristics. We also track their impact on the concentration and activation energy of deep level traps in CsxFA1-xPbI3 and MAPbI3 solar cells as a function of degradation via photo-induced conductivity transient spectroscopy. This study thus constitutes a framework upon which we can further our mechanistic understanding of degradation in perovskite solar cells.

Damage-Free Deposition of Transparent Conducting Oxide on Perovskite Solar Cells Shalinee Kadavady1, Jonathan L. Bryan1, Yuji Okamoto2,3 and Zachary Holman1; 1Electrical, Computer, and Energy Engineering, Arizona State University, Tempe, Arizona, United States; 2University of Tsukuba, Tsukuba, Japan.

The wide and tunable bandgap of perovskites makes them attractive for use in tandem solar cells either as a top cell in perovskite/silicon and perovskite/thin film solar cells or as both top and bottom cells in all-perovskite tandem solar cells. For a tandem device, a transparent conducting electrode must be deposited on top of the perovskite solar cell to allow light transmission into the device. The conventional technique to deposit transparent conductive oxide (TCO) materials is sputtering. However, the high kinetic energy of the sputtered atoms and the UV radiation damages underlying layers of the cells (mainly the perovskite and hole contact layers), resulting in an S-shaped or shunted I-V curve with poor cell performance. Previously, a thin protective buffer layer of MoOx or SnO2 has been used before sputtering TCO, which places several processing constraints such as low-temperature deposition of both buffer layers, high transparency of the buffer layer, and appropriate energy level alignment.

In this work, an aerosol-based technique is developed to deposit a uniform TCO thin film on perovskite solar cells without any damage to the other layers of the cell. The technique involves a two-step spraying process. In the first step, a colloidal solution of indium tin oxide (ITO) nanoparticles is sprayed through an ultrasonic atomizer nozzle generating droplets containing nanoparticles. Once the solvent from the droplet evaporates, in the second step, the dry nanoparticles are passed through a fine orifice nozzle along with a carrier gas, creating a spray of nanoparticles which then deposit on the substrate. The pressure downstream the orifice nozzle is almost 10-fold lower than the upstream pressure,
which reduces the drag force on the fine nanoparticles and enables them to deposit on the substrate by impaction rather than flowing away along with the carrier gas. The absence of energetic atoms and radiation makes this technique suitable to deposit any kind of nanoparticle layer on top of perovskites without damage. The presentation will discuss this novel technique and its application in depositing a uniform layer of ITO nanoparticles as a top electrode in perovskite-based tandem solar cells to further boost their efficiency.

Methylammonium-Free, High-Performance and Stable Perovskite Solar Cells on a Planar Architecture Silver-Hamill Turren-Cruz1, Anders Hagfeldt2 and Michael Saliba3; 1Institut fur Silizium Photovoltaik, Helmholtz Zentrum Berlin, Berlin, Germany; 2Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland; 3Adolphe Merkle Institute, Fribourg, Switzerland.

Currently, perovskite solar cells (PSCs) with high performances greater than 20% contain bromine (Br), causing a suboptimal bandgap, and the thermally unstable methylammonium (MA) molecule. Avoiding Br and especially MA can therefore result in more optimal bandgaps and stable perovskites. We show that inorganic cation tuning, using rubidium and cesium, enables highly crystalline formamidinium-based perovskites without Br or MA. On a conventional, planar device architecture, using polymeric interlayers at the electron- and hole-transporting interface, we demonstrate an efficiency of 20.35% (stabilized), one of the highest for MA-free perovskites, with a drastically improved stability reached without the stabilizing influence of mesoporous interlayers. The perovskite is not heated beyond 100°C. Going MA-free is a new direction for perovskites that are inherently stable and compatible with tandem or flexible substrates, which are the main routes commercializing PSCs.

SESSION ES16.05: Poster Session I

A Facile Route to Grain Morphology Controllable Perovskite Thin Films Towards Highly Efficient Perovskite Solar Cells Funguo Zhang1, Jiayan Cong1, Yuanyuan Li1 and Licheng Sun1,2; 1KTH Royal Institute of Technology, Stockholm, Sweden; 2Dalian University of Technology, Dalian, China.

Perovskite photovoltaics have recently attracted extensive attention due to their unprecedented high power conversion efficiencies (PCEs) in combination with primitive manufacturing conditions. However, the inherent polycrystalline nature of perovskite films renders an exceptional density of structural defects, especially at the grain boundaries (GBs) and film surfaces, representing a key challenge that impedes the further performance improvement of perovskite solar cells (PSCs) and large solar module ambitions towards commercialization. Here, a facile strategy is presented utilizing a novel ethylammonium chloride additive to achieve high-quality methylammonium lead iodide (MAPbI3) films. Well-oriented, micron-sized grains were observed, which contribute to an extended carrier lifetime and reduced trap density without compromising for solar cell applications beneficial bandgap of the films. This additive engineering is demonstrated to boost the power conversion efficiency (PCE) to 20.9% and 19.0% for devices with effective areas of 0.126 cm2 and 1.020 cm2, respectively, with negligible current hysteresis and enhanced stability. Besides, perovskite films with a size of 10×10 cm2, and an assembled 16 cm2 (5×5 cm2 module) perovskite solar module with a PCE of over 11% were constructed.

ES16.05.02
Interface Induced Vertical Phase Separation for Economical, Efficient and Stable Perovskite Solar Cell—A Universal Strategy Simplifying the Device Preparation Process Jianxing Xia, Junsheng Luo, Fei Han, Zhongquan Wan, Yu Shi and Chunyang Jia; School of Electronic Science and Engineering, University of Electronic Science and Technology of China, Chengdu, China.

The major obstacles delaying the large scale commercialization of thin film solar cells based on hybrid organic halide perovskite are the complicated multi-step fabrication process, expensive materials, and environment and ion migration induced instability in the devices. In this research, we present a simple film-cover strategy to deposit light absorption layers (LALs) and hole transporting layers (HTLs) on a large area (4 x 4 cm2) through a single step process which is fundamentally based on polar and nonpolar interfacial induced self-vertical phase separation between perovskite and HTLs. This process is highly saving material which is 3% Spiro-OMeTAD and 7.5% perovskite used compared to the traditional spin-coating process, it is dozens of times for the cost saving. Moreover, The specific gradient phase separation construction based on the doped-free Spiro-OMeTAD shows specific energy level and device construction, leading to efficient carrier transportation and higher power conversion efficiency (PCE). We further systematically studied the origin of stability in this phase separated film compared to the traditional layer by layer spin-coating film, it suggested that the gradient HTLs embed in perovskite crystal boundary which can effectively restrain ion migrate and moisture at the crystal boundary, providing an excellent environmental stability and retains 95% of the initial efficiency even after 68 days being stored in ambient condition without encapsulation. We believe that our strategy will pave a new way for simple, economical, efficient, stable, large-area and commercialized perovskite solar cells (PSCs) preparation, and provide more understanding on the nature of ion migrate in the PSCs devices.

ES16.05.03
Single-Step Solution-Processed CH3NH3PbBr3 Perovskite Active Layer for Enhanced Efficiency of Light-Emitting Diodes Musunik Oh, Bhaskar Parida, Seonghoon Jeong, Keum-jin Ko, Jae-Wook Kang and Hyunsoo Kim; Chonbuk National Univ, Jeonju, Korea (the Republic of).

Organic-inorganic hybrid perovskites are emerging as highly attractive materials for optoelectronic applications due to their high color purity, broadly tunable optical bandgap, facile solution process, and efficient narrow band emission. Due to these features of merits, perovskite materials are highly utilized in the field of light-emitting diodes (LEDs) used as an active layer and have been successfully demonstrated to overcome the disadvantages of organic LEDs such as complex synthesis procedure, poor color purity, and high-cost processing. Because of these efforts, perovskite LEDs have recently reached external quantum efficiencies (EQEs) about 10 % for green and near-infrared emissions through the grain size of the perovskite active layer. However, it still has the problem that increase the number of grain boundaries causing exciton quenching and nonradiative recombination, while reduce the grain size of the perovskites.

In this study, we investigated single-step solution-processed methylammonium lead-bromide (CH3NH3PbBr3, MAPbBr3) perovskite active layer for enhanced efficiency of LEDs. The single-step process contributed to strong exciton confinement inside the perovskite grain for improves the radiative recombination of the LEDs by achieving small grain size through a nanocrystal pinning method. In addition, the single-stepped perovskites can effectively reduce exciton quenching to the metallic Pb atoms by passivating the perovskite grain boundaries due to the MABr-rich molar proportion. As a result, the LED fabricated with single-step-processed MAPbBr3 perovskite active layer (SSP LED) exhibited 33.8 % stronger maximum luminance (202 cd/m2) and 17.6 % higher EQE (4.0 %) compared to LED fabricated with double-stepped perovskites (DSP LED). The SSP LED also showed a 11.5 % reduction in series resistance (1.31 Ωcm2) and a 7.3 % improvement in current efficiency (9.53 cdA−) compared to DSP LED, which was attributed to reduced Joule-heating than the double-stepped perovskite layer. The both LEDs consisting of ITO/PEDOT:PSS/MAPbBr3/PCBM/Ag structures with a peak emission wavelength of 538 nm.

ES16.05.04
Interface Control for Perovskite Solar Cells Using GaN Thin Film Deposited by PEALD Huixun Wei, Peng Qiu, Mingzeng Peng and Xintie Zheng; University of Science and Technology Beijing, Beijing, China.

In a perovskite solar cell (PSC), charge generation, transport and collection layers are stacked together, producing several interfaces, which have significant influences on the charge processes. At present, the interfaces in PSCs have been carefully manipulated by controlling the compositions, or introducing interfacial buffers and passivation layers.
Here, unlike the widely-reported electron transport layers (ETLs) consisting of monolayer or multilayer metal oxide (TiO$_2$, ZrO$_2$, SnO$_2$, etc.), group-III nitride GaN work as ETL is explored to improve the electron transport and interfacial property. Benefiting from the self-limiting reactions of plasma enhanced atomic layer deposition (PEALD), the GaN thin films are conformal and pin-hole free with an accurate thickness control (<10 nm), which thus in favor of the deposition of high quality perovskite film on GaN and suppression of charge recombination between GaN and perovskite layers. The results indicate that GaN thin-film thickness have significant effects on the electron transport and collection of the photovoltaic cells, and the devices based on a 5 mm thick GaN ETL can achieve the highest cell efficiency of 15.18% with $J_{sc}$ of 22.56 mA/cm$^2$, $V_{oc}$ of 0.977 V and $FF$ of 0.689.

**ES16.05.05**

**Dion-Jacobson Type Tin-Based Halide Perovskite Solar Cells**

Min Chen, Zhenghong Dai, Yuanyuan Zhou and Nitin P. Padture; Brown University, Providence, Rhode Island, United States.

Perovskite solar cells (PSCs) based on lead-based halide perovskites (MAPbI$_3$, FAPbI$_3$, etc.) have achieved surprisingly high power conversion efficiencies (PCEs). However, lead-toxicity and intrinsic instability of these PSCs are major hurdles in the path towards the commercialization of PSCs. Typically, lead-free PSCs suffer from the low PCE (<10%) and poor stability. Therefore, we introduce a series of Dion-Jacobson type 2D tin-based perovskite materials, and realized a promising PCE of up to 4.5% in hole-transport-layer-free PSCs. These PSCs show high stability, with >10% PCE decay after 200 hours under continuous one-sun illumination. Thus, this work provides a new direction in the design and development of stable Sn-based perovskite solar cells.

**ES16.05.06**

**Water Effect on Cesium Doped Triple-Cation Hybrid Perovskite Solar Cells**

Zhang Weiwei and Walid Daoud; School of Energy and Environment, City University of Hong Kong, Hong Kong, Hong Kong.

The effect of water on the performance of perovskite solar cells has been intensively studied in recent years. However, the conflicting conclusion derived from different studies makes it impossible to fully understand the mechanism involved. Besides, all studies on water effect thus far have concentrated on single methylammonium cation perovskite materials. As a consequence, the effects of water on formamidinium and cesium perovskites are still unclear. Herein, we introduce water during the fabrication of triple-cation formamidinium and cesium based perovskites (abbreviated as Cs/FA/MA). By carefully controlling the water content, we demonstrate that water additive plays a significant role on the crystallization of the hybrid Cs/FA/MA perovskite film. More interestingly, the studies of the optical properties of the films indicate that water content determines the phase of the perovskites. Further, thermogravimetric analysis (TGA) and X-ray photoelectron spectroscopy (XPS) characterizations are applied to analyze the components and the chemical environments of the films. Finally, By finely tuning the concentration of water, a more stable device with a significant enhancement in PCE could be fabricated. The findings in this work contribute to the understanding of the effect of water on hybrid perovskites. It is suggested that further theoretical and experimental studies should be carried out to gain full understanding of the mechanism of water on hybrid perovskites.

**ES16.05.07**

**Grain-Boundary Functionalization for Highly Stable and Efficient Perovskite Solar Cells Based on Formamidinium Lead Iodide**

Zhenghong Dai, Yuanyuan Zhou and Nitin P. Padture; School of Engineering, Brown University, Providence, Rhode Island, United States.

Formamidinium lead iodide (FAPbI$_3$) perovskites have great potential for their used in perovskite solar cells (PSCs) due to their near-ideal bandgaps. However, FAPbI$_3$ perovskite (α-phase) tends to crystallize in a hexagonal non-perovskite structure (δ-phase) at room temperature which is thermodynamically more stable yet photo-inactive. Herein, we report a novel method to stabilize the α-phase FAPbI$_3$ via chemical functionalization of grain boundaries. By protecting the α-phase FAPbI$_3$ from the ingress of moisture from the atmosphere, the resulting PSCs show significantly improved stability. This method also boosts the power conversion efficiency by affording higher phase-purity of as-crystallized α-phase FAPbI$_3$ and defects passivation. This work points to a new route for designing high-performance PSCs with long-term durability.

**ES16.05.08**

**Strategic Synthesis of Ultra- Small NiCoO$_2$ NPs as Hole Transport Layer for Highly Efficient Perovskite Solar Cells**

Onyung Dan, Junyan Xiao, Fei Ye, Zhanfeng Huang, Hong Zhang, Lu Zhu, Jian Chen and Wallace C. Choy; Hong Kong University, Hong Kong, Hong Kong.

In this work, we synthesize ultra-small ternary oxide nanoparticles (NPs), NiCoO$_2$, by a novel strategy of controllable deamination of Co-NH$_3$ complexes in a system containing Ni(OH)$_2$. Through this approach, 5 nm NiCoO$_2$ NPs without exotic ligands are obtained and could be dispersed well in aqueous, which enables the formation of uniform and pin-hole free films. We apply the tightly covered NiCoO$_2$ film as hole transport layer in perovskite solar cells, and the corresponding devices reach a high power conversion efficiency of 18.23% and a promising stability (maintained ~90% PCE after 500 h light soaking) due to the formation of large perovskite grains and the reduction of film defects [1]. Besides improving device performance and stability, the newly synthesized NiCoO$_2$ film with the interesting features of low-cost, low-temperature, simple and green solution process expose the opportunities of ternary oxides for the applications of emerging photovoltaic devices. To the best of our knowledge, it is the first time that spinel NiCoO$_2$ NPs are applied as hole transport layer in perovskite solar cells successfully. In summary, this work not only demonstrates the potential applications of ternary oxide NiCoO$_2$ as HTLs in PVSCs but also provides an insight into the design and synthesis of ultra-small and ligand-free NPs HTLs to enable cost-effective photovoltaic devices.

**ES16.05.09**

**Suppressing Phase Segregation of Mixed-Halide Perovskite for Highly Light-Stable Perovskite/Perovskite/Si Multi-Junction Tandem Solar Cells**

Su Geun Ji, Ik Jae Park, Deok Ki Cho and Jin Young Kim; Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

During the last years, inorganic-organic hybrid perovskite materials have been received attention as next-generation photovoltaics because of its excellent photovoltaic properties for solar cells. Currently, the power conversion efficiency (PCE) of single-junction perovskite solar cells has raised to 23.3% within a short period. In addition, double-junction tandem solar cells with perovskite materials have been developed such as perovskite/Si, perovskite/thin-film and perovskite/perovskite. The monolithic perovskite/Si tandem cells with double-side textured silicon substrate exhibit the PCE of 25.2%. However, realizing an efficient and stable perovskite-based triple-junction tandem solar cell remains challenging despite their very high theoretical PCE (~49%). The critical issue is the poor stability of perovskite solar cell against the light because large bandgap perovskite (over 1.9 eV) with mixed halide could be easily segregated to I-rich and Br-rich material under the continuous light. For a highly efficient and stable triple-junction tandem solar cells, therefore, the perovskite absorber that exhibits the highly stable under the operating condition is essential.

Here, we report a highly durable large bandgap (1.9 eV) perovskite solar cell under continuous light. Perovskite absorber containing triple cation (FA/MA/Sc) was prepared by two-step sequential deposition method. We added trimethylaluminum triacrylate (TMTA) as an additive into perovskite layer and cross-linked it by annealing process. By photoluminescence and X-ray diffraction analyses, we confirmed that a TMTA additive retarded the phase segregation of mixed halide. We assumed that the additive prevents the ion migration at the grain boundaries, which improves the light stability. As a result, the devices with the additive-added perovskite exhibited outstanding stability under continuous light with negligible PCE drop during 1 hour in ambient condition. Finally, we successfully fabricated solution process-based perovskite/perovskite/Si/mono-junction tandem solar cells on one-side textured Si substrates.

**ES16.05.10**

**The Influence of Guanidinium Cations on the Performance of Perovskites Solar Cells**

Mohammad Haval Alotabi, Yahya A. Alzahrani, Neha Arora, Ahmed Alyamani, Abdulrahman Albadri, Hamad Albritten$^{1}$, Ibrahim H. Allehyan$^{1}$, Ali Z. Alansari, Fahad S. Alghamdi, Shafik M. Zakeeruddin$,^{1}$ M. Ibrahim Dar$^{2}$ and Michael Graetzel$^{2}$; King Abdullah City for Science and Technology (KACST), Riyadh, Saudi Arabia; Institute of Chemical Sciences and Engineering, Laboratory of Photonics and Interfaces (LPI), Lausanne, Switzerland; $^{1}$Physics Department, Science College, King Saud University, Riyadh, Saudi Arabia.

Perovskites solar cells (PSCs) showed a dramatic improvement in their power conversion efficiencies (PCE) from 3.8 to 22.7% within a short period and are approaching commercialization. Such an outstanding advancement was realized by simply tuning the composition of the perovskite absorber layer. This compositional diversity allows tailoring of their photophysical properties, such as absorption coefficient, photoluminescence yield, and charge-carrier dynamics, which critically influence the PCE of a resulting device. In
this direction, we explored different sources of guanidinium cations to improve the photophysical properties, specifically, photoluminescence and charge-carrier dynamics of perovskite structures for their application in the fabrication of efficient solar cells. The effect of different sources of the guanidinium cations was systematically investigated by exploring various characterization techniques, including x-ray diffraction, scanning electron microscopy, steady-state absorption and emission spectroscopy, and time-resolved photoluminescence. The insights gained through these techniques helped us to understand the influence of guanidinium cations on the performance of PSCs. In my presentation, I will discuss structural, morphological and detailed photophysical characteristics of different perovskite films, and will correlate them with the photovoltaic performance of PSCs.

ES16.05.11 Ambient-Processed Perovskites for Broadband, Ultrafast and Efficient Flexible Photodetectors

Ivy Asuo1, 2, Paul Fourmont2, Ibrahim Ka2, Dawit M. Gedamu2, Soraya Bouzidi1, Alain Pignol1, Riad Nechache1 and Sylvain G. Cloutier1; 1INRS, Varennes, Quebec, Canada; 2Electrical Engineering, École de technologie supérieure (ETS), Montréal, Québec, Canada.

Organic-inorganic halide perovskites have shown exceptional semiconducting properties and microstructural versatility for inexpensive, solution-processable photovoltaic and other optoelectronic devices. The emerging solution-processed perovskite photodetector technologies show promising optoelectronic properties1–4 and generate a growing interest for large-area and flexible optoelectronic device production. In this work, we present a simple route for synthesizing efficient and reproducible halide perovskites under ambient conditions (>40%RH) by tailoring their physical and microstructural properties via mixed-anions and solvent additives. We fabricate an all-solution-based photodetector using high crystal quality perovskite nanowires grown on FTO and flexible Kapton substrates. The optimized photodetectors exhibit a high responsivity, a maximum specific detectivity of 10^12 cmHz^1/2/W and a rise time as low as 55 µs for devices on the rigid substrate and 320 µs for devices on the flexible substrate. It also shows remarkable photocurrent stability after multiple bending cycles. Moreover, due to the hygroscopic nature of halide perovskites, a deposition of poly(methyl methacrylate) (PMMA) as a protective layer on the perovskite yields significantly better stability under ambient air operation: the PMMA-protected devices are stable for over one month. This work demonstrates a cost-effective fabrication technique for high-performance flexible photodetector and will open opportunities for research advancements on broadband and large-scale flexible perovskite-based optoelectronic devices.

ES16.05.12 High-Efficiency Perovskite Solar Cell Fabricated by Slot-Die Coating Through Near-Infrared Heating in Ambient

Shih-Han Huang and Wei-Fang W. Su; Department of Materials Science and Engineering, National Taiwan University, Taipei, Taiwan.

Low cost, solution processable perovskite solar cell has potential for large-scale fabrication. The slot-die coating is one of the solution process that uses less amount of material as compared with spin coating. Currently, the power conversion efficiency (PCE) of perovskite solar cell has reached to 18% by slot-die coating. However, the uniformity of perovskite film is determined by the rate of solvent evaporation that increase with gas quenching, vacuum quenching and thermal heating in the slot-die coating. In this work, we successfully fabricate the uniform perovskite film using near-infrared heating in 6 seconds. The highest PCE of 14.26% is reached for perovskite device without post annealing in ambient.

ES16.05.13 Thermionic Emission-Based Interconnecting Layer Featuring Solvent Resistance for Monolithic Tangent Solar Cells with Solution-Processed Perovskites

Can Li1, Zishuai Wang1, Lu Zhu1, Di Zhang1, Jiaqi Chen1, Hong Lin1, Dan Ouyang1 and Wallace C. Choy1; 1Department of Electrical and Electronic Engineering, The University of Hong Kong, Hong Kong, Hong Kong; 2Department of Sustainable and Renewable Energy Engineering, University of Sharjah, Sharjah, United Arab Emirates; 3Centre for Advanced Materials Research, University of Sharjah, Sharjah, United Arab Emirates.

Inorganic-organic perovskite is a promising material with unique high absorption coefficient, long carrier diffusion length, tunable bandgap, and simple preparation techniques for future photovoltaic development. The power conversion efficiency (PCE) of perovskite single-junction solar cells increases rapidly from 3.8% since 2009 to 22.7% in 2018. However, the PCE is ultimately limited by the Shockley-Queisser limit. All-perovskite tandem solar cell has been considered as the potential candidate for bring the PCE beyond the Shockley-Queisser limit of single-junction device and yet retaining the advantages of earth-abundant materials and solution processability. It is still a challenge to fabricate such solution-processed perovskite tandem device owing to the lack of robust interconnecting layers (ICL). The ICL should simultaneously achieve good electrical property for carrier transport and recombination, and high optical transmission. Meanwhile, the ICL should protect the bottom perovskite film against the damage of the solvent from the upper perovskite film because the solution process usually involves the same type of polar solvents. Here, a new thermionic emission-based ICL with enhanced solvent-resistance feature is demonstrated for monolithic tandem cells with solution-processed perovskite films. Fundamentally, the thermionic emission assisted solution-electron transport mechanism is confirmed through both experimental and theoretical studies. Meanwhile, the new ICL protects the underlying perovskite film from the solvents of the upper perovskite by introducing a fluoride silane-incorporated polyethylenimine ethoxylated (FSIP) hybrid system. Besides the solvent resistance function, this novel FSIP hybrid system passivates perovskite to reduce nonradiative recombination leading to considerable enhanced performance. With optimized ICL, the tandem cells demonstrate high PCE up to 17.9%, which is the highest among solution-processed all-perovskite tandem cells with indium free ICL. Consequently, this work contributes to not only understanding the fundamental mechanism of ICL but also to promoting robust and low-cost photovoltaics.

ES16.05.14 Diboron-Assisted Interfacial Defect Control Strategy for Highly Efficient Planar Perovskite Solar Cells

Yongguang Tu; State Key Laboratory for Artificial Microstructure and Mesoscopic Physics, Department of Physics, Peking University, Beijing, China.

Metal halide perovskite films are endowed with the nature of ions and polycrystalline.1 Formamidinium iodide (FAI)-based perovskite films, which include large cations (FA) incorporating into the crystal lattice, are most likely to induce local defects due to the presence of the unreacted FAI species.2,3 Here, we demonstrate a diboron assisted strategy to control the defects induced by the unreacted FAI both inside the grain boundaries and at the surface regions. The diboron compound (C₂H₃B₂O₃) can selectively react with unreacted FAI leading to reduced defect densities. Nonradiative recombination between a perovskite film and a hole-extraction layer was mitigated considerably after the introduction of the proposed approach and charge-carrier extraction was improved as well. We therefore obtained a champion power conversion efficiency of 21.11% with a stabilized power output of 20.83% at maximum power point for planar structure perovskite solar cells.4 The optimized device also delivered negligible hysteresis effect under various scanning conditions. This approach paves a new way for mitigating defects and improving device performance.

ES16.05.15 Enhanced Performance of Perovskite Solar Cells by Micro-Structuring the Mesoporous TiO₂ Layer

Jingsong Sun1, 2, 3, Chang Liu2, 3, 4, Anthony Chesman3, 4 and Jacek Jasieniak2, 3, 4; 1Materials Science and Engineering, Monash University, Melbourne, Victoria, Australia; 2Monash Energy Materials and Systems Institute, Monash University, Melbourne, Victoria, Australia; 3ARC Centre of Excellence in Exciton Science, Melbourne, Victoria, Australia; 4Chemical Engineering, Monash University, Melbourne, Victoria, Australia.
Hybrid organic-inorganic halide perovskite solar cells (PSCs) have recently received tremendous attention and achieved high power conversion efficiency (PCE). However, efficient optimization of the PSC configuration is still key to further performance improvements. In this work, we report a facile method to develop high-efficiency PSCs by micro-structuring a mesoporous TiO$_2$ layer formed from directly from a TiO$_2$ nanoparticle dispersion. The micro-structuring is achieved through the controlled crystallization of additives in the dispersion, which are subsequently thermally fused following coating. This micro-structure enables for a more efficient charge extraction, achieving current densities of up to 24 mA cm$^{-2}$, some 5% higher than for pristine meso-porous TiO$_2$ layers. The PSCs using this modified TiO$_2$ mesoporous layer show the highest PCE of 19.6% compared to 18.6% for the controls. These results highlight that achieving high-performance PSCs relies not only on the nanoscale structure of charge extraction layers, but also their extended microstructure.

ES16.05.17  
Sustainable Pb$^0$ and Pb$^4$ Defects Elimination for Stable and Efficient Perovskite Solar Cells  
Lipeng Wang$^{1, 2}$, Ling-Dong Sun$^3$, Chun-Hua Yan$^1$ and Huaping Zhou$^2$; $^1$College of Chemistry and Molecular Engineering, Peking University, Beijing, China; $^2$College of Engineering, Peking University, Beijing, China.

Due to the soft nature of components in the metal halide perovskite absorber, it inevitably generates Pb$^+$ as not only recombination centers to deteriorate device efficiency, but also degradation starting point to hamper the device lifetime eventually. Herein, we demonstrate a sustainable Pb$^0$ and Pb$^4$ defects elimination method for the controls. These results highlight that achieving high-performance PSCs relies not only on the nanoscale structure of charge extraction layers, but also their extended microstructure.

ES16.05.18  
Analysis for Non-Radiative Recombination in Perovskite and Perovskite/Si Tandem Solar Cells  
Masafumi Yamaguchi, Ken-Hua Lee, Kenji Araki and Nobuaki Kojima; Toyota Technological Inst, Nagoya, Japan.

Remarkable recent advances in perovskite solar cells with efficiencies of over 23% have drawn world-wide as high-efficiency and low-cost solar cells. However, there are some problems to be solved in perovskite solar cells in order to develop high-efficiency, highly reliable and large-area solar cells and modules. Therefore, understanding and reducing non-radiative recombination losses in those materials and solar cells and resistance losses is necessary. In this paper, we introduced perovskite solar cells and perovskite/Si tandem solar cells is discussed by using external radiative efficiency (ERE), open-circuit voltage loss and fill factor loss and non-radiative recombination losses based on our previous analytical results for high-efficiency solar cells [1] and Si tandem solar cells [2]. One of problems to attain the higher efficiency perovskite solar cells is to reduce non-radiative recombination loss. The open-circuit voltage drop compared to bandgap energy (\(E_g\))/Vo(c) is expected to depend upon non-radiative voltage loss (Voc, rad) that is expressed by external radiative efficiency (ERE). Open-circuit voltage is expressed by

\[
V_{oc} = \frac{E_g}{1 + \frac{E_R}{E_g}}
\]

where the second term shows non-radiative voltage loss, and is radiative open-circuit voltage and 0.28V was used as the value for perovskite solar cells in this study. Correlation between Voc values for perovskite solar cells in the references estimated by eqs. (1) suggests that perovskite solar cells have still non-radiative loss and further improvements in efficiency are though to be possible by improving minority-carrier lifetime. In addition, reduction in resistance loss is suggested to be decreased. The perovskite solar cell have efficiency potential of 26% by improving ERE from around 0.3-1% to 20%. As one of non-radiative recombination loss issues in perovskite solar cells, effects of grain size upon minority-carrier diffusion length in perovskite solar cells are discussed. In order to improve ERE in perovskite solar cells, effects of photon recycling are also discussed. Recently, Si tandem solar cells including perovskite/Si tandem solar cells have become as one of hot topics. Most recently, 25.24% and 27.3% efficiency with perovskite/Si 2-junction tandem solar cells have been demonstrated by EPFL and Oxford Univ., respectively. Based on our analytical procedure [1,2], efficiency potential of perovskite/Si tandem solar cells is also analyzed in this paper. From the point of view of material quality, the ERE of perovskite/Si tandem solar cells are less than 10-5, which is several order-of-magnitude lower than that of III-V/Si tandem solar cells. This suggests that the material quality of perovskite/Si tandem cells still have large room to improve. By improving ERE from around 10 to 0.01, high efficiency of more than 33% is expected to be realized for perovskite/Si tandem solar cells. For this purpose, improvements in material quality, optimization of layer structures to reduce optical and resistance losses, and effective usage of light-trapping are suggested.

Side-Chain Polymer-Based Hole-Transporting Materials for High-Efficient Perovskite Solar Cells  
Yanyong Tian, Jianchang Wu, Chang Liu and Baomin Xu; Southern University of Science and Technology, Shenzhen, China.

In recent few years, the efficiency of organic-inorganic metal halide perovskite-based solar cells (PSCs) has been improved rapidly, because of the significant efforts in materials development and device fabrications. Hole transporting materials (HTMs) play an important role to the PSCs in charge extraction and interface modification. Currently, the most extensively studied and applied HTM for perovskite devices is 2,2',7,7'-tetrakis(N,N'-di-p-methoxyphenylamine)-9,9'-spirobifluorene (Spiro-OMeTAD). However, the spiro-OMeTAD possesses relatively low intrinsic conductivities, which need dopants like lithium bis(trifluoromethanesulfonyl)-imide (Li-TFSI), cobalt complexes, or 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ) to enhance the material conductivity. Thus, for simplifying the device fabrication, reducing the cost, and solving some trade-off between photovoltaic properties and long-term stability and to circumvent the tight control of doping level and oxidation duration in the fabrication procedure, numerous dopant-free HTMs including small molecules and conjugated polymers have been vigorously explored. Side-chain polymers play important roles in the polymer and materials science with abundance structures, flexibility, and moisture protection ability. However, only a few side-chain polymers like the poly(9-vinylcarbazole) (PVK) derivatives were studied in the PSC fields with moderate efficiency of around 16\%$^{[4, 5]}$. Herein, we designed new side-chain polymer structures by integrating a methoxytriphenylamine-conjugated-thiophene moiety as the HTM repeating unit on a poly styrene side-chain. The polymer (Poly-HTM) was synthesized by the radical polymerization of its relevant monomer (Mono-HTM). The results showed that with similar device preparation and measurement conditions, the hole mobility of polymer was about 3 times of that of its small molecular monomer. PSCs based on Poly-HTM as the dopant-free HTM afford an impressive highest power conversion efficiency of 17.2%, which is much higher than those obtained from Mono-HTM (9.7%). Moreover, the devices based on the Poly-HTM presented significantly higher stability than the device based on its monomer. Hence, this study demonstrates that the side-chain polymer strategy is an effective approach to achieve high efficiency and highly stable PSCs using dopant-free HTMs.

Development Large Area Flexible Perovskite Solar Cells Using Embedded-Type Cu Mesh Transparent Conductive Electrodes Bu-Jong Kim1, Jincheol Kim2, Ekyu Han1, Jae-Sung Yun2 and Nochang Park1;1 Electronic Convergence Material & Device Research Center, Korea Electronics Technology Institute, Seong-Nam, Korea (the Republic of); 2Photovoltaic and Renewable Energy Engineering, University of New South Wales, Kensington, New South Wales, Australia.

In recent years, research on organic-inorganic hybrid halide perovskite has been rapidly progressing due to its excellent photovoltaic materials having a large absorption coefficient, high carrier mobility, high carrier diffusion length, and direct band gap. Up to now, power conversion efficiencies (PCE) of perovskite solar cells (PSCs) have reached over 22%. The highest certified PCE of PSC has been achieved 22.7% on a small area. Despite a rapid increase in the performance, research for improving flexibility and large-scale PSCs that are advantageous in fabricating module and realizing commercialization are still insufficient. In order to fabricate flexible and large area PSCs, it is important to reduce the resistance and ensure flexibility of transparent conductive electrodes (TCEs). Meanwhile, Indium-tin oxide (ITO) or Fluorine doped tin oxide (FTO) thin films have been widely used due to their exceptional electrical properties, but we have disadvantages in the application for flexible devices, such as a brittle nature, a high processing temperature, and low adhesion to flexible substrate materials. For these reasons, studies on the electrode materials for replacing ITO and FTO, such as metal meshes, silver nanowires, conductive polymers, graphene, and carbon nanotubes, are actively progressing. Among these materials, metal meshes may be the leading candidates for commercialization due to their relatively low electric sheet resistance and high visible transmittance. However, a thick layer of metal mesh on the substrate, as required to achieve a sufficiently high conductivity in many applications, may easily cause electrical short circuiting. Furthermore, the flexibility of the embossed-type metal meshes was generally poor due to low adhesion between the flexible substrate and the metal mesh.

In this study, we present a fabrication method and properties of flexible and large area PSCs based on embedded-type Cu mesh. This is accomplished as follows: The Cu meshes are fabricated on glass substrates and then transferred to 5 cm x 5 cm Norland Optical Adhesive (NOA) as the flexible substrate. The opposite surface of NOA is patterned with a microstructure to improve the transmittance. Finally, the PSCs are deposited on embedded-type Cu mesh TCEs. The surface morphologies, cross section, and thickness profiles of the Cu mesh specimens are measured to confirm the thicknesses are well embedded in the NOA substrate, and their electrical and optical properties are characterized. Electroeluminescence (EL), quantum efficiency (QE), J-V, and Dark J-V are also measured for PSC fabricated on Cu mesh. Finally, the inner and outer bending tests are also performed to inspect the flexibility.

CHNH3PbI3 Exhibits Distinct NIR Sub-Gap Absorption Features in Response to AC Anodic and Cathodic Electrochemical Modulation Timothy Pollock and Cody Schlenker; University of Washington, Seattle, Washington, United States.

While lead halide-based perovskites have received an incredible amount of attention over the past several years as an emerging photovoltaic material, one aspect that has received minimal attention is their spectroelectrochemical responses in part to their relative instability under applied potentials while immersed in an electrolyte solution. We identify new spectrally distinct sub-gap NIR absorption features when we subject model CHNH3PbI3 perovskite solar cell materials to AC anodic and cathodic electrochemical potentials. First, we resolve a new differential absorption band with an onset near 850 nm under cathodic conditions, which is absent under anodic conditions. We find the electronic transition energy for this absorption to be commensurate with the energy separation that has been predicted and determined experimentally for the E1/2 and F1/2 conduction band minima in CH3NH3PbI3. Additionally, our AC spectroelectrochemical signals appear to be spectrally coincident with NIR transient absorption features that we observe on picosecond to nanosecond timescales. Deconvoluting these spectra by target analysis shows the correlation in temporal evolution between the photogenerated conduction band electron and trap state bleaching. The kinetics of the species associated spectra we model based on charge extraction, bimolecular recombination, charge trapping, and Auger recombination processes. The AC nature of our spectroelectrochemical detection also allows us to virtually eliminate the film degradation that has plagued DC electrochemical studies of halide perovskite materials. These results are relevant to device performance metrics as we see through kinetic modeling simulations that an extended electron lifetime observed in films made with 1-step fabrication procedure is due to a decreased trap state density compared to those made with a 2-step procedure, which also correlates to improved device performance due to increased fill factor.

ES16.05.22
Effects of Strain Modulation on the Charge Carrier Transport in 2D/3D Hybrid Formamidinium Perovskite Solar Cell Sungwon Song and Kilwon Cho; POSTECH, Pohang, Korea (the Republic of).

For commercialization of perovskite solar cell, suppression of ion migration and reduction of trap states is highly needed. Recent works has proposed that 2D perovskites with layered structures can be mixed with 3D perovskides due to its low defect density and superior ambient stability. Despite diversity of long organic cation, correlation of molecular structure and structural features and finally electrical properties have been neglected. Here, we systematically investigated the effect of the size of the phenylalkylammonium ions focusing on charge transport and defect passivation. The results show that defect density was reduced regardless of the type of phenylalkylammonium ion, however carrier accumulation and recombination loss in the perovskite crystals were increased with larger ion. Ionocation with steric hindrance induced tilting of lead-halide octahedra which affected charge collection efficiency. Finally, we could obtain highly efficient and stable (PCE=20.5%) low band gap (1.48eV) formamidinium perovskite solar cell.

High-Efficiency Perovskite Solar Cells Prepared by Low-Temperature Solution-Process for Commercialization Shih-Hsuan Chen, Ming-Chung Wu and Yen-Tung Lin; Chemical and Materials Engineering, Chang Gung University, Taoyuan, Taiwan.

With the shortage of energy, developing the alternative energy sources becomes an important issue. Solar energy is considered as one of the most important alternative energy source because it is inexhaustible. Among many types of solar cells, the metal halide perovskite solar cells (PSCs) is the most promising solar cells due to its high power conversion efficiency (PCE). The PCE of PSCs has rapidly increased from 3.8% to 23.3% since 2009. However, the high-efficiency PSCs typically required high-temperature-sintered mesoporous (over than 450°C) TiO2 (HT-TiO2) as electron transport layer (ETL) and the high-temperature to process often limits fabrication process. Furthermore, it can't be used on the flexible substrate and it will spend more energy on fabrication process. Based on above reasons, high-temperature to process is not suitable for commercialization. In this study, all the fabrication processes were under low temperature. The HT-TiO2 nanoparticles (LT-TiO2) were synthesized by non-hydrotalcite sol-gel method under 150°C and the spray-coating method was employed for the deposition of LT-TiO2 ETL. Moreover, we used spray-coating method and blade coating for large area (over 25 cm²) module. In order to go into commercialization, the perovskite active layer should be fabricated in the air. Therefore, we controlled different ratio of perovskite precursor solution (dimethyl sulphoxide:Butylacetone) to obtain large grain size, high crystalline, pinhole-free and uniform perovskite active layer with blade coating method under various relative humidity. We used scanning electron microscope and atomic force microscope to investigate the correlation between perovskite crystallization and various relative humidity. We also used the photo-assisted Kelvin probe force microscopy (KPFM) to explore the charge transport efficiency in active layer which were prepared under various relative humidity. Toward future commercial application, a large size module is essential. Hence, the 5x5 cm² PSCs module was fabricated based on the low-temperature process. Finally, we successfully developed PSCs without the need of high-temperature sintering process and obtained higher PCE than the mesoporous PSCs. The large area PSCs module also demonstrated the high PCE with the continuous process.

ES16.05.24
Ferroelectric, Photoconductivity and Photovoltaic Properties of Bi1−xCa2xF3−y/2O5/3u Thin Films Subhaist Nandy and Sudakar Chandran; Indian Institute of Technology Madras, Chennai, India.

The demand for renewable energy is escalating in recent years due to a dire need to address the global warming. Solar energy is one of the reliable alternative energy resources. Direct conversion of solar energy to electrical energy is a process known as photovoltaic conversion. Si based p-n junction solar cells with efficiency around 22% have captured commercial market despite high cost. Other solar cells based on semiconductor thin films, dye sensitizers, quantum dots, and organic inorganic perovskites are evolving to reduce the solar cell production cost while keeping up the efficiency similar to Si solar cells. Most of these devices are hampered by their long-term stability. In this front, all oxide photovoltaic devices are seems to be promising. Recently, ferroelectric oxides have captured significant attention in solar cell community due to demonstration of existence of unique anomalous photovoltaic effect, in which photovoltage (Voc) is found to be larger than the bandgap of the materials [1]. Most of the ferroelectric materials have larger bandgap – 3 eV which inhibits the material to absorb entire solar spectrum. Short circuit current density (Jsc) observed in ferroelectric oxide based solar cells is in the range of nA.
to μA which severely limits efficiency of the devices [2].

BiFeO₃ (BFO) is a room temperature ferroelectric oxide which exhibits lower bandgap ~ 2.5 eV in bulk. Bandgap of BFO can be tailored over a wide range from 2.32 eV to 1.5 eV [3], which is promising for solar cell application. In this report we show the effect of oxygen vacancies (Oᵥ) on ferroelectric, photoconductivity and photovoltaic properties of solar cells. The devices were made using BiₓCaₓFe₂₋ₓTiO₃⁺₀.₅ (BCFTO) [x = 0, (BFO); x = 0.1 and y = 0, (BC10FO); x = 0.2 and y = 0, (BC20FO); x = y = 0.1 (BC10FT100); x = y = 0.2 (BC20FT200)] thin films. All thin films are coated on FTO-glass substrates by simple spin coating. A mask having circular hole of 2 mm diameter is used to coat Au on top of the films. FTO/BCFTO/Au devices in capacitor configuration are used for photoconductivity and photovoltaic measurements. We observed an enhancement in photoconductivity of 3 orders in BC10FO and 5 orders in BC20FO compared to pristine BFO devices when illuminated with 1 Sun (~100 mW/cm²) power. Enhancement of photoconductivity in BC10FO and BC20FO is attributed to the Oᵥ present in the system. It is observed that Jsc is increased but Voc is reduced with increasing Ca doping concentration in pure BFO. FTO/BC20FO/Au and FTO/BC10FO/Au devices show Jsc = 3 mA/cm² and 30 μA/cm², respectively which are four and two orders larger than the Jsc observed in FTO/BFO/Au devices (~0.3 μA/cm²). Voc observed in pure BFO devices are ranging from 0.35 V to 3 V. In case of BC10FO devices, this lies in between 0.2 V to 0.8 V and it is found to decrease further for BC20FO devices (~0.1 V to 0.3 V). A reduction in ferroelectric domain size is observed with increasing Ca content. Ferroelectric switching gets diminished in BC10FO and BC20FO is attributed to the Oᵥ present in the system. It is observed that Jsc is increased but Voc is reduced with increasing Ca doping concentration in pure BFO.

In this work, we show our study on how the efficiency of the Perovskite solar cells depend on the conductivity and work function of PEDOT:PSS. A series of PEDOT:PSS solutions with different conductivity and work function were used to make the Perovskite solar cells. We will also report the interface processing we did in the p-i-n structure PSCs, which optimize device properties and charge transfer. In this work, all materials were prepared at low temperatures, showing potential for low-cost, scalable production of large-scale perovskite solar cells on flexible substrates.

ES16.05.25 Perovskite Solar Cell—The Effect of PEDOT:PSS on Its Efficiency Hongkun Cai¹, Patrick Milan¹, Madison Guerrero¹, Jose Peralta¹ and Weining Wang¹, 1Seton Hall Univ, South Orange, New Jersey, United States; 2Electrical Science and Engineering, Nankai University, Tianjin, China.

The efficiency of Perovskite solar cells (PSC) has increased from 3% to 22% in less than eight years. Because of its rapid rise in efficiencies in recent cost fabrication process, the perovskite solar cell technology has been studied extensively and was named as one of the biggest scientific breakthroughs in the year of 2013 by Science. In the PSC structure, poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) is usually used as the hole transport layer (HTL) on top of ITO. It was found that interface engineering at electrodes is very important for increasing the performance of PSCs.

In this work, we study on how the efficiency of the Perovskite solar cells depend on the conductivity and work function of PEDOT:PSS. A series of PEDOT:PSS solutions with different conductivity and work function were used to make the Perovskite solar cells. We will also report the interface processing we did in the p-i-n structure PSCs, which optimize device properties and charge transfer. In this work, all materials were prepared at low temperatures, showing potential for low-cost, scalable production of large-scale perovskite solar cells on flexible substrates.

ES16.05.26 Study of Perovskite Thin Films Obtained by Conversion of Lead Iodide (PbI₂) Deposited by RF Sputtering Using Formamidinium and Methylammonium Solutions Nelson F. Villegas¹, José Maria C. Silva Filho¹, Rodrigo Szostak¹, Jean Carlos Da Silva², Ana F. Nogueira² and Francisco C. Marques², 1Gleb Wataghin Physics Institute, Unicamp, Campinas, Brazil; 2Chemistry Institute, Unicamp, Campinas, Brazil.

Perovskite materials have been used in the fabrication of solar cell with efficiency exceeding 22%. Some of the proposed perovskite structures uses solution process of lead iodide (PbI₂) as precursor. Here we propose the production of perovskite by using sputtered PbI₂. The films were deposited by sputtering a PbI₂ target prepared by compression of PbI powder and deposited at room temperature. The use of the sputtering technique allows the deposition of uniform films in large area. The films were converted in perovskite by using two routes: 1) spin coating the film with a solution of methylammonium iodide (MAI) and 2) dipping the film in the same solution. We also investigate the effect of using formamidinium iodide (FAI) and cesium iodide (CsI) solutions. X-ray measurements revealed that the PbI₂ films contain a small concentration of segregated lead (Pb) and that the perovskite films have (112) preferential orientation and some residual PbI₂. However, after conversion of the PbI₂ in perovskite we do not observe presence of segregated lead. Optical and structural properties were investigated through UV-Vis spectroscopy, SEM and AFM. Preliminary study of fabrication of perovskite solar cells supplied devices with efficiency of 2.5%. Optimization of the fabrication process is currently under way.

ES16.05.28 Effects of Environmental Factors on the Performance and Stability of Perovskite Solar Cells Iyotika Chakraborty and Lihong (Heidi) Jiao, Electrical Engineering, Grand Valley State University, Grand Rapids, Michigan, United States.

Perovskite solar cells (PSCs) are based on organo-metallic halides (perovskites) that act as a light-sensitive compound which produces excitons when placed under light. The general formula for a perovskite compound used in a PSC is expressed as ABX₃, where A is an organic/inorganic cation, B is a divalent metal cation and X are halide ions. The most common compound used in a PSC is methylammonium lead halide, CH₃NH₃PbI₃ (A = CH₃NH₃+, B = Pb²⁺; X = I⁻). The mesoporous TiO₂ layer. These materials possess optical and electronic properties that are required for high efficient photovoltaic devices. However, PSCs have a limited operating lifetime due to the degradation of the perovskite layer. There are many factors that lead to the degradation of the perovskite layer.

This study aims to investigate the environmental factors that affect the performance and long-term stability of the PSCs. The structure of the PSC is used in this study is the regular structure containing the TiO₂ perovskite absorber, hole transport layer and the carbon layer. The PSCs were fabricated using two different methods, the spin coating method. These solar cells were investigated under various environmental conditions like humidity (0 to 70%), with oxygen, without oxygen (nitrogen), normal environmental conditions, and longtime light soaking at elevated temperatures. The properties under investigations are the optical absorption of the perovskite absorber, the open circuit voltage (Voc), short circuit current (Isc), fill factor (FF), and efficiency of the PSCs. It was found that the PSCs do not degrade with the presence of oxygen in a dry and dark environment. The complete study of the effects of these environmental factors will be reported in this paper.

ES16.05.29 Investigating Viable Sn-Based Perovskite Solar Device by Utilizing a Cu₂O Hole Transport Layer (HTL), a Cu Back-Electrode and by In Situ Optimization of Component Layer Thickness Jalen Harris¹, Jon Shaffer², Michael Pham², Saqib Ahmed² and Sankha Banerjee¹, ¹Mechanical Engineering, California State University, Fresno, California, United States; ²Mechanical Engineering, Buffalo State College, Buffalo, California, United States.

This investigation has applied simulation work to elucidate the photovoltaic performance of non-Pb based perovskite devices, utilizing Sn. In an effort to address additional key criteria that impede the commercial realization of this technology, we have investigated Cu₂O (instead of the traditional spiro-OMeTAD) as an HTL that is cheap and easily synthesized, deposited and fabricated to form a fully functional device. Also, in an effort to reduce cost, in place of Ag as the back electrode, we have incorporated Cu. By optimizing each layer thickness, this work showcases not only a maximal efficiency device, but by critical analyses of Jsc, Voc and FF trends that manifest due to each component layer thickness modulation, we present key charge mobility and transfer kinetics within the structure of the cell. These optimal numbers and trends are critical when fabricating a physical device in the lab, and even more so once these components are investigated as viable ingredients in an industrial setting.

ES16.05.30 Simulation Studies on Optimizing Sn-Based Perovskite Solar Cell by Excluding Electron Transport Layer (ETL) and Modulating Device Component Thickness Jon Shaffer¹, Jalen Harris², Michael Pham³, Sankha Banerjee⁴ and Saqib Ahmed⁵, ¹Mechanical Engineering, Buffalo State College, Buffalo, New York, United States; ²Mechanical Engineering, California State University, Fresno, Fresno, California, United States; ³Mechanical Engineering, California State University, Fresno, Fresno, California, United States.

In this research, we have utilized simulation studies to probe non-toxic Sn-based perovskites with a goal to explore optimal fabrication methodologies. To that end, we have
investigated a device structure with and without an ETL and assessed the impact on critical photovoltaic parameters. Our ETL of choice has been the traditional TiO2 matrix, which has a wide bandgap, and good transport properties. We have also in-situ performed optimization of individual layer thicknesses, thereby ultimately fabricating a device with the highest possible theoretical efficiency. The analyses provide critical insight into charge mobility and charge transfer kinetics within this non-Pb based device; by observing the effects on Voc, FF, and FF as individual layer thicknesses are modulated, and doing comparisons of devices with and without an ETL, we present results of a structure that is not only optimal from an efficiency standpoint, but also from a technology viability and sustainability standpoint.

ES16.05.31
Planar Perovskite Solar Cells with SnO2; Electron Transporting Layer Deposited by Atomic Layer Deposition (ALD) Seonghwa Jeong, Seongrok Seo, Hyojeong Min Park and Hyunjung Shin; Department of energy science, Sungkyunkwan University, Suwon-si, Gyeonggi-do, Korea (the Republic of).

Recently, SnO2 has received a great deal of attention in normal perovskite solar cells with its excellent optical and electrical properties, wide bandgap, good chemical stability and can be grown by low temperature processing as an electron transporting layer (ETL). Among various deposition methods, SnO2 thin films used as ETL are deposited by Atomic Layer Deposition (ALD). ALD has the advantage of being able to control the film thickness with nanometer precision and to produce high quality thin film without any pinholes. Also, SnO2 has a a lower conduction band, compared to TiO2, which has energy level mismatch with MAPbI3, thus energetic alignment of SnO2 is more appropriate for extracting photogenerated electrons than TiO2. Thin films of Zn doped SnO2 also prepared in this study and showed enhanced conductivity compared to undoped ones, as a result, photovoltaic performances were improved in the normal planar structure (FTO / SnO2 / Perovskite / Spiro-OMeTAD / Ag) perovskite solar cells.

Optically Controlled Two-Terminal Mechanical Perovskite/Silicon Tandem Solar Cells with Transparent Conductive Adhesives In Young Choi, Chan Ul Kim and Kyong Jin Choi; Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Solar cell technology is evolving into solar cells that increase efficiency, reduce cost, or have special functions such as transparent or flexible solar cells. Silicon solar cell technology, which has a market share of more than 90% of the entire solar cell market, has a wide spectrum of BSF, PERC, HIT and IBC in terms of efficiency and price. However, it is difficult to meet the efficiency and price of silicon solar cell at the same time, and breakthrough technology is needed to overcome it. Among these breakthrough technologies, the most promising technique is a tandem cell strategy in which two or more solar cells with different band gap energies are stacked. In particular, perovskite solar cell is an ideal material for tandemization with silicon solar cells because it is easy to control the bandgap by adjusting the chemical composition of perovskite. Thanks to these advantages, perovskite/silicon tandem solar cells have been actively studied and some results with high efficiency above 20% already have been reported. However, Most of the reported perovskite/silicon tandem cell are based on the high-cost SI planar silicon solar cell due to the problem of uniform perovskite top layer. Here, we demonstrate a simple, low-cost, 2-terminal, silicon/perovskite mechanical tandem solar cell, which was fabricated by bonding a p-type silicon cell upside down on an n-i-p perovskite cell using a transparent conductive adhesive (TCA) layer. The TCA layer consists of Ag-coated poly(methyl 2-methacrylate) (PMMA) particles embedded in a polymer adhesive. The Ag-coated PMMA particles have the role of electrical current path and the polymer adhesive bond two sub-cells mechanically. The specific contact resistance and transmittance of the TCA layer was determined to be 5.46 x 104 ohm cm2 and > 97.0%, respectively. Because this TCA is flexible and soft, our tandem structure can use a conventional textured silicon solar cell compared to the other structures. Using optical simulations and experiments, the optimal current matching was achieved at a perovskite layer thickness of 150 nm for the CH3NH3PbI3 solar cell in n-i-p structure and Al BSF p-type Si cells. The tandem cell fabricated under the optimal current matching condition exhibited a current density of 15.43 mA/cm2, an open-circuit voltage of 1.59 V, and a fill factor of 79%, resulting in a steady-state PCE of 19.4%. To the best of our knowledge, the tandem cell efficiency of this study corresponds to the highest efficiency among all tandem cells based on Al-BSF silicon cells. The unique structure of this tandem cell showed excellent long term stability without encapsulation in a humid environment (100 h in RH 85%).

ES16.05.34
Effects of Urea Addition on Photovoltaic Properties of Perovskite Solar Cells Lingwei Li1, 2, Yuanqing Chen1, 2, Yang Song1, 2, Aditya S. Yerramilli1, Yuxia Shen1 and Terry Alford1, 2; 1SEMTE, Arizona State University, Tempe, Arizona, United States; 2Materials Physics and Chemistry, Xi'an University of Technology, Xi'an, China; 3Materials Science, African University of Science and Technology, Abuja, Nigeria.

The power conversion efficiency (PCE) of perovskite solar cells (PSC) continuously break new records; however, there are still big challenges for large perovskite fabrication. Two of these being the solar cell’s grain growth and stability. In this investigation, Urea additions to the perovskite precursor solution prepared using lead acetate precursors show improved device performance. The results show that the best content of Urea is 0.5 wt. %, when compared with the samples with and without Urea. The presence of Urea in the PSC increases the PCE of from 15% to 17%. X-ray diffraction analysis indicates that the addition of Urea promotes grain growth and also improves the grain’s orientation. This study reveals that the PCE is also closely related to the anneal time of the perovskite layer. Our findings show that the addition of Urea and proper anneal times enhance the crystallization process of the perovskite films and results in the resulting in larger and more orientated grains. This is the reason for the device’s improved carrier transport and conversion efficiency.

ES16.05.35
Long-Term Thermal and Operational Condition Stable Perovskite Solar Cells with Inorganic Charge Transport Layers Grown via Atomic Layer Deposition (ALD) Seongrok Seo, Seonghwa Jeong, Hyojeong Min Park, Nam-Gyu Park and Hyunjung Shin; Sungkyunkwan University, Suwon, Korea (the Republic of).

Despite the high power conversion efficiency (PCE) of perovskite solar cells (PSCs), poor long-term stability is one of the main obstacles preventing their commercialisation. Two of these being the solar cell’s grain growth and stability. In this investigation, Urea additions to the perovskite precursor solution prepared using lead acetate precursors show improved device performance. The results show that the best content of Urea is 0.5 wt. %, when compared with the samples with and without Urea. The presence of Urea in the PSC increases the PCE of from 15% to 17%. X-ray diffraction analysis indicates that the addition of Urea promotes grain growth and also improves the grain’s orientation. This study reveals that the PCE is also closely related to the anneal time of the perovskite layer. Our findings show that the addition of Urea and proper anneal times enhance the crystallization process of the perovskite films and results in the resulting in larger and more orientated grains. This is the reason for the device’s improved carrier transport and conversion efficiency.

ES16.05.36
Perovskite solar cells (PSCs) have attracted attention due to tremendous rise in the power conversion efficiencies (PCEs) over the past decade and their possibility to replace traditional silicon solar cells has become realistic [1]. Although high life time is key requirement, the research has been mainly focused on improving the efficiency. A few studies have been performed to improve the stability of PSCs by synthesizing new hole or electron transport layer [2]. In the inverted PSCs, poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) is the widely used hole transport layer (HTL), however, its acidic nature has been continuously raised as a concern for the long-term stability of PSCs. Therefore, there is an urgent need for other HTLs. Inorganic transport layers have been used in organic photovoltaics e.g. nickel oxide (NiOx), copper iodide (CuI), copper thiocyanate (CuSCN) which have found successful in improving the stability. These HTLs can potentially improve the stability of PSCs having an impact on bulk transport and interfacial charge collection properties.

In this study, we have tested six HTLs: PEDOT:PSS, NiOx, CuI, CuSCN, molybdenum oxide (MoOx) and vanadium pentoxide (V2O5) in the inverted perovskite solar cell structure. The used device structure was ITO/HTL/perovskite/Pc60BM:LiF/Ag, where FAxMxACryBBrxICy (M= Pb,Sn) (FMC) was the used as perovskite absorber layer. Stability tests were performed under continuous light exposure using an AM1.5G spectrum as well as using dark storage tests. Both the Power Conversion Efficiency (PCE) and lifetime were found dependent on the HTL material which was applied for the tests. PSCs with PEDOT:PSS showed the efficiency of 10.1 % which degraded to 60 % in 180 hours. PSCs with NiOx showed the highest efficiency (<12 %) and lifetime. NiOx based solar cell maintained the efficiency for more than 180 hours. Additionally, the PSC with NiOx also showed hysteresis free photovoltaic characteristics. CuSCN, MoOx and V2O5 based devices were also found to be more stable than PEDOT:PSS based device but with lower PCEs. To understand the degradation in more detail, slow-discharge mass spectroscopy was used to analyse the films before and after degradation. The results will be presented in this talk. Additionally, atomic force microscope and X-ray diffraction was used to support the results and compare between different HTLs. Morphology of perovskite was found to be extremely homogenous on inorganic HTLs supporting the solar cell performance which yielded the best performance. Overall, the results on inorganic perovskite is found to be the crucial factor affecting the stability of solar cell.

In conclusion, the inorganic transport layers shows improved stability for perovskite solar cells. NiOx was found to be the most efficient and stable hole transport layer.

High-Performing Perovskite Solar Cells Using Gallium Nitriles as Electron Transporting Layer by PEALD Xinhe Zheng, Huiyun Wei, Pen Qiu, Mingzeng Peng, Sanjie Liu, Yingfeng He, Yinneng Song and Yunlai An; University of Science and Technology Beijing, Beijing, China.

The self-limiting reactions of atomic layer deposition (ALD) enable conformal-coatings/ interface layers with molecular-level control of thickness and composition, which has been found great benefit in tuning the interfacial structure and properties in solar cells. So far, various metal oxides (TiOx, AlOx, ZrOx, SnOx, etc) deposited by ALD have been used in some new generation solar cells, however, few group-III nitriles (AlN, GaN, InN, etc) are reported to explore their application. Here, we study the application of GaN thin-films in perovskite solar cells (PSCs). The nitrides thin films are deposited via plasma enhanced atomic layer deposition (PEALD) by reaping the benefits of the lower deposition temperature and precise thickness control. The GaN thin film here serves electron transport layer (ETL) for PSCs. The results indicate that GaN thin-film thickness has a significant effect on the electron transport and collection of the photovoltaic cells. It is found that the devices based on the 50-cycle GaN thin-film (~5 nm) show the best cell efficiency with performance of 15.2%. The introduction of group-III nitrides has shown promise for improving solar cell performance, and further enhancement of cell efficiency via improving the nitrides quality.

Dopant-Free High-Performing Perovskite Solar Cells Using Gallium Nitriles and Grain Boundary Passivation in Highly Efficient and Stable Organic-Inorganic Hybrid Perovskite Solar Cells Aung Ko Ko Kyaw1, Fei Meng2, Xue Lai2, Xianqiang Li1, Wenhui Li1 and Gongqiang Li1; 1Southern University of Science and Technology, Shenzhen, China; 2Nanjing Tech University, Nanjing, China.

Hole transport layer (HTL), where photogenerated holes are extracted from perovskite and transported to the back-metal contact, plays an important role in enhancing the power conversion efficiency (PCE) as well as improving the stability, which is a major bottleneck for commercialization of perovskite solar cell (PSC). Currently, the state-of-the-art PSCs use the small molecule 2,2',7,7'-tetrakis[N,N-diphenylamino]-9,9'-spirobifluorene (Spiro-OMeTAD) or poly[bis(4-phenyl)(2,6-dimethylphenyl)amine](PTAA) doped with common additives, such as Li-TFSI and rib, which usually cause a serious degradation of device performance. Therefore, the development of dopant-free HTL becomes an essential requirement in the field of PSC. In this work, we designed and synthesized small-molecule-based dopant-free hole transporting material (HTM) called α, β-COTH-OMeTAD by fusing two strong electron donating moieties; saddle-shaped cyclooctatetrathiophene (COTh) and triphenylamine, to obtain sufficiently high hole transporting properties without additional dopants. The α, β-COTH-OMeTAD exhibits a deep highest occupied molecular orbital energy level (HOMO) of -5.3 eV and a high hole mobility of 2.88 × 10⁻⁶ cm²/V·s. The thermal decomposition temperature of this small molecule is 308 °C and the phase transition temperature is 121.5 °C, showing a good thermal stability. It also exhibits a good solubility in several common organic solvents, which is favourable for easy processability and device fabrication. The solar cell fabricated with our small molecule HTM in the structure of FTO/compact TiOx/perovskite/HTL/Au gives a PCE of 15.66% with Jsc = 21.05 mA cm⁻², Voc = 1.04 V and FF=71.79%, which is comparable to the device based on doped Spiro-OMeTAD as HTL, whose PCE is 16.96% (Jsc=20.24 mA cm⁻², Voc=1.10 V, FF=74.62%). In addition to functioning as HTM, α, β-COTH-OMeTAD also serves as an interfacial layer to passivate the grain boundaries of perovskite crystals. During the crystallization of perovskite film, solvent such as chlorobenzene (CB) or toluene is usually poured into the perovskite precursor solution under spinning to produce a uniform and high-quality perovskite film. Herein, we observed that incorporating a small amount of α, β-COTH-OMeTAD (10 mg/mL) in CB anti-solvent further improves the efficiency of solar cell. Using α, β-COTH-OMeTAD as both interfacial layer and HTL improves the PCE to 17.22% with Jsc = 21.51 mA cm⁻², Voc = 1.05 V and FF=76.37%. SEM image of perovskite film treated with α, β-COTH-OMeTAD exhibits less apparent grain boundaries and denser film because of the passivation effect. Time resolved photoluminescence (TRPL) measurement also reveals that the faster decay lifetime τ, which corresponds to the quenching of the photogenerated free carriers transporting from the perovskite to HTL becomes shorter but the slower decay lifetime τ, which represents the radiative recombination of free carriers becomes longer, suggesting the efficient charge transfer between the perovskite and HTL and good passivation effect of the α, β-COTH-OMeTAD. Besides the hole transporting and passivating properties, α, β-COTH-OMeTAD also improves the stability of the device due to the hydrophobic nature of the material which prevents moisture from penetrating into the perovskite film, and deep HOMO level which prevents from reaction with iodine in the perovskite compound. We also employed the commercially available conjugated polymer called PDHTBDT-FBT in a separate study. Different from α, β-COTH-OMeTAD, the PCE of device is very low when PDHTBDT-FBT is used as HTL but it is functioning well as interfacial layer to passivate the perovskite film. The PCE of 18.03% is obtained when PDHTBDT-FBT dissolved in CB is used as anti-solvent and spiro-OMeTAD as HTL.

Interfaces in Efficient and Stable Organic-Inorganic Hybrid Perovskite Solar Cells Ying-Chiao Wang, Takaaki Taniguchi and Kazuhiro Tsukagoshi; International Center for Young Scientists (ICYS) & International Centre for Materials Nanotechnologies (ICAMN), National Institute for Materials Science, Tsukuba, Ibaraki, Japan.

Since Prof. Miyasaka’s group first reported the organometal halide perovskite-sensitized photoelectrochemical cells in 2009,1 perovskite-based light harvesters have launched the photovoltaics revolution due to their key advantages of low cost and low processing temperature. Moreover, some superior material properties, such as the high absorption extinction coefficient in the visible-near infrared wavelength region and excellent photocarrier separation/transport characteristics,2,3 encourage the progressive development of organic-inorganic hybrid perovskite solar cells (PSCs).

After years of development, the power conversion efficiencies of PSCs have been dramatically increased to more than 20%, however, the instability issues are remain the obstacle to commercialization. In this seminar, I will discuss the relationship between interface engineering and the reliability of efficient PSCs. In addition, I will also introduce several strategies of designing the device interface and controlling the perovskite grain interface to achieve bendable and durable PSCs.

Although methyl ammonium lead halide (MAPbX$_3$) perovskites exhibit unprecedented photovoltaic potential with excellent optical and carrier transport properties; but the toxicity of lead and intrinsic instability are the main issue hampering commercialization of MAPbX$_3$ solar cells. Therefore, photovoltaic community giving great attention to bismuth halide perovskite material which has advantages of non-toxicity, ambient stability along with low-temperature solution-processability. Here, we prepared thin films of cesium bismuth iodide (Cs$_4$Bi$_2$I$_9$) materials using novel one-step spray coating method. Spray deposition technique is a versatile coating strategy that can be used to deposit thick layers of different materials over large areas at speed. An electric field generated by employing high DC voltage supply while spray deposition method. Applied voltages built-up the electric field to create negative ions. The resulting electric field helped to create charged nanoparticles that adhered to the substrate while depositing onto it. Thus, the ions and electrons got onto the substrate through the electric field. The ions then got converted into thick films of perovskite material.

Perovskite solar cells are especially promising when considering the technology lifespan. The advantages of using perovskite for the active layer include but are not limited to broad a light absorption spectrum, tunable band gaps, long charge carrier diffusion, and low fabrication cost. The current work involves the design, fabrication, and simulation of different configurations of Tin iodide active layer based lead-free perovskite solar cells. The goal of the project is to develop a configuration that is non-toxic as well as stable in natural open air environments with a specific resistance to moisture. This design incorporates the use of organic and inorganic materials, as well as the efficient use of the perovskite crystalline structure that is produced by using the properties of the active layer. Different economical hole transport layers has also been explored to evaluate the impacts on opto-electronics, and photon-to-current conversion efficiencies. The stacking structure is further modulated within the cell by progressively including a recombination-inhibiting thin TiO$_2$ or a ZnO layer with the FTO, followed by an electron-transport layer (various oxides) and a combination of CuOx/Cu as the hole transport layer and back contact electrode. This work is intended to build up to a broader project of selecting the most optimal low-toxicity perovskite cell to stack onto a Si or FTO bottom cell for tandem configurations.

Perovskite Solar Cells Using Low Temperature-Processed Nb:SnO2 Electron Transport Layer
Tae Hee Song, Kyoung Jin Choi, In Young Choi and Hyungmin Lee; Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Recently, the development of solar cells using perovskite has been studied for past 10 years. In perovskite solar cells (PSCs), the electron transport layer (ETL) is an important component, which extract and convey electrons from perovskites to the cathode. This property has a direct influence on the efficiency of the cell. Since TiO2 has superior charge extraction and injection characteristics, most of high-efficiency PSCs use TiO2 and mesoporous TiO2 as ETL materials. However, TiO2 has several disadvantages such as vulnerable light stability against ultraviolet (UV) and low electron mobility which requires mesoporous TiO2 with high-temperature process (~450°C) so that there is limit of using in flexible substrates. As a result, studies on metal oxide as ETL that can be synthesized at low temperature and capable of planar structure have been actively researched. Among them, SnO2 has high mobility so that it enables fast transport of electrons and hysteresis-free can be obtained even in a planar structure. Also, SnO2 has a wide bandgap which leads stability against UV, and low photocurrent so that reduces current loss. For these reasons, SnO2 has been reported to be as efficient as a cell using TiO2. Moreover, since SnO2 is easily doped with various materials unlike TiO2, open circuit voltage (Voc) can be enhanced through bandgap alignment. Not only high efficiency, but also easy doping process could make SnO2 one of the most promising electron transport materials for planar perovskite solar cells.

In this work, we present a novel approach to engineer, and device design that has enabled these advances; and will review remaining challenges and paths forward for the field.

Machine Learning to Tackle Perovskites’ Recovery and Degradation from the Macro- to the Nanoscale
Marina S. Leite; University of Maryland, College Park, Maryland, United States.

This talk will focus on the dynamic optical and electrical behavior of perovskites, from the macro- to the nanoscale. We investigate a series of hybrid perovskites, including MAPbI3, MAPbBr3, Cs2xFA1−xPb(IyBr1−y)3, and triple cation CsxFASnI3−xPbxBr1−yI3. To elucidate the contribution of humidity, oxygen, temperature, light, and bias on materials’ properties and devices’ performance, we combine advanced scanning probe methods based on photoluminescence (PL) microscopy and atomic force microscopy (AFM). Through environmental PL microscopy we identify a humidity-induced PL hysteresis that strongly depends on the Cs/Br ratio [1]. Using fast Kelvin-probe force microscopy we quantify a dynamic open-circuit voltage (Voc) response as a function of perovskite chemical composition and illumination treatment, as will be discussed in details during the presentation [2,3]. The individual and combined effects of each intrinsic and extrinsic parameter is analyzed in terms of a machine learning approach (ML), key to elucidate the device conditions that can prevent degradation, and enable rest and recovery. Our functional imaging platform [4–6], combined with ML [7], can be leveraged to identify the recovery conditions of emerging perovskities, including Pb-free options.

Next Generation Interface Modification Strategies for High-Performance Perovskite Optoelectronics
Nakita K. Noel; Princeton University, Princeton, New Jersey, United States.

Within the past few years, metal halide perovskites have been attracting significant interest due to their and their versatile use in a wide range of applications. These materials have been used in lasers, photodetectors, and most commonly, in photovoltaic devices and light emitting diodes. Despite the use and simple fabrication methods by which these materials are deposited, the resulting perovskite films are effectively high-quality semiconductors, and the power conversion efficiencies of lead halide perovskite solar cells are now exceeding certified values of 23%. However, perovskite-based devices are yet to achieve their full potential. One of the major hindrances to achieving this is an incomplete understanding of perovskite surfaces and interfaces. Deficiencies at these interfaces may be responsible for the largest losses in perovskite-based optoelectronic devices; limiting charge extraction, increasing non-radiative recombination rates and leading to hysteresis, and significantly increasing the voltage loss in perovskite photovoltaics. Herein, we will present interface modification strategies to mitigate these deficiencies. We utilise charge-transfer dopants to dope the perovskite at the interface, resulting in the formation of narrow homojunction. These homostructures result in reduced interfacial recombination, suppressed hysteresis and improved device performance, yielding steady-state device efficiencies of over 21%. We also explore the use fluoride-containing ionic liquids at the metal-oxide perovskite interface and show that not only do they affect the work function of the metal oxide, but also interact strongly with the perovskite, significantly improving the quality of the perovskite film. The utility of these interface modification strategies extends beyond perovskite solar cells and can also be used to further improve the performance of perovskite-based light-emitting diodes.

The Perovskite/Transport Layer Interfaces Dominate Non-Radiative Recombination in Efficient Perovskite Solar Cells
Martin Stolterfoht1, Pietro Caprioglio1, Christian Wolff1, Jose Marquez Puyol2, Ioleik Nordmann1, Shanshan Zhang1, Daniel Rothhardt1, Ulrich Hörmann2, Alex Redinger1, Lukas Keigelmann1, Steve Albrecht1, Thomas Kirchartz2, Michael Saliba2, Thomas Unold2 and Dieter Neher1; 1Institute of Physics and Astronomy, University of Potsdam, Potsdam-Golm, Germany; 2Department of Structure and Dynamics of Energy Materials, Helmholtz-Zentrum-Berlin, Berlin, Germany; 3Young Investigator Group Perovskite Tandem Solar Cells, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Berlin, Germany; 4Institut für Energie- und Klimaforschung, Forschungszentrum Jülich GmbH, Jülich, Germany; 5Soft Matter Physics, Adolphe Merkle Institute, Fribourg, Switzerland.
Charge transport layers (CTLs) are key components of diffusion controlled perovskite solar cells, however, they can induce additional non-radiative recombination pathways which limit the open circuit voltage ($V_{OC}$) of the cell. In order to realize the full thermodynamic potential of the perovskite absorber, both the electron and hole transport layer (ETL-HTL) need to be as selective as possible. By measuring the quasi-Fermi level splitting (QFLS) of perovskite/CTL heterojunctions [1], we quantify the non-radiative interfacial recombination current for a wide range of commonly used CTLs, including various hole-transporting polymers, spiro-OMeTAD, metal oxides and fullerenes [2]. We find that all studied CTLs limit the $V_{OC}$ by inducing an additional non-radiative recombination current that is significantly larger than the loss in the neat perovskite and that the least-selective interface sets the upper limit for the $V_{OC}$ of the device. The results also show that the QFLS equals the internal QFLS in the absorber layer of pin and nip-type cells with selective CTLs and power conversion efficiencies of up to 21.4% (in pin). However, in case of less selective CTLs, the $V_{OC}$ is substantially lower than the QFLS which indicates additional losses at the contacts and/or interfaces. The findings are corroborated by rigorous device simulations which outline several important considerations to maximize the $V_{OC}$. This work shows that the real challenge to suppress non-radiative recombination losses in perovskite cells on their way to the radiative limit lies in the suppression of carrier recombination at the perovskite/CTL interfaces.

material electronic properties and stability. Furthermore, we determine the ideal Cl-incorporation ratio for stability increase without detrimental bandgap modification. The increased material stability induced by chlorine incorporation is verified by performing photoelectron spectroscopy on a device architecture. Our findings provide an important direction for the fabrication of stable perovskite devices.

Structural and Theoretical Studies of Black Phases of CsPbI₂ — Influence of the Anharmonicity
Pedesseau Laurent1, Arthur Marronnier2, Guido Romani1, Soline Boyer- Richard3, Jean-Marc Jancu1, Yvan Bonnassieux2, Claudine Katn1, Costas Stoumpos2, Mercouri G. Kanatzidis3 and Jacky Even1; 1Univ Rennes, INSA Rennes, CNRS Institut FOTON - UMR 6802, Rennes, France; 2LPICM, CNRS, Ecole Polytechnique, Université Paris-Saclay, Palaiseau, France; 3DEN - Service de Recherches de Metallurgie Physique, CEA, Université Paris-Saclay, Gif sur Yvette, France; 4Univ Rennes, ENSCR, CNRS, ISCR (Institut des Sciences Chimiques de Rennes), UMR 6226, Rennes, France; 5Department of Chemistry and Argonne-Northwestern Solar Energy Research (ANSER) Center, Northwestern University, Evanston, Illinois, United States.

In less than 10 years, hybrid organic-inorganic perovskites have emerged as a new generation of absorber materials for high-efficiency and low-cost solar cells [1], [2]. More recently, fully inorganic perovskite quantum dots (QD) also led to promising efficiencies [3], [4] and then become a serious alternative to hybrid organic-inorganic perovskites. Currently, the record efficiency for QD solar cells is obtained with CsPbI₂. High resolution in-situ synchrotron XRD measurements have been performed on CsPbI₂ as a function of the temperature and revealed a highly anisotropic variation of the lattice parameters. Moreover, CsPbI₂ can be temporarily maintained in a perovskite-like structure down to room temperature, stabilizing a metastable perovskite polytype (black-phase) crucial for photovoltaic applications. Structural, vibrational and electronic properties of the three experimentally observed black phases are further scrutinized using theoretical approaches revealing the importance of the anharmonicity of the lattice [5], [6]. A symmetry-based tight-binding model, calibrated with self-consistent GW calculations including spin-orbit coupling, affords further insight into their electronic properties. A Rashba effect is thus predicted for both cubic and tetragonal phases when using the symmetry breaking structures obtained through frozen phonon calculations.

The ab initio simulations have been performed on HPC resources of CINES under the allocation 2017-J2017096724 made by GENCI (Grand Equipement National de Calcul Intensif).

Use of Meso-Structured PbI₂ for Two-Step Deposited Hybrid and All-Inorganic Perovskite Solar Cells
Bin Li1, Jianfeng Lu1, Jingsong Sun1, Liangchong Jiang1, Yi-bing Cheng1 and Jacky Jusienak2; 1Monash University, Clayton, Victoria, Australia; 2Wuhan University of Technology, Wuhan, China.

The so-called one-step and two-step sequential deposition methods are the most used in the fabrication of perovskite films suitable for deployment within solar cell structures. The one-step deposition approach relies on mixed metal and halide precursor solutions being processed under stringent conditions to control the extent of precipitation and, thus, to ensure high quality perovskite thin films. Whilst useful for small-scale devices, this approach is challenging to scale, which has prompted us to further explore the two-step method. In two-step sequential deposition, a high-quality perovskite film can be achieved by exposing a near lead halide film to a solution of an appropriate halide salt. In this work, we explore the role of solvent engineering to achieve microstructural control of the lead iodide (PbI₂) layer such that it is suitable for two-step sequential deposition. Through this modification, the diffusion of methylammonium iodide (MAI) into the structure to form methylammonium lead iodide perovskite during the second step is accelerated. Moreover, it enables for the formation of ultra-smooth thin perovskite films with large grains and photo-conversion efficiencies (PCE) of > 15% under planar configurations. The versatility of the approach is demonstrated also for all-inorganic CsPbBr₃Iₓ, with PCEs of > 10%.

Achieving Long-Term Thermal, Atmospheric and Operational Stability in Low Band Gap Tin-Lead Halide Perovskite Solar Cells
Rohit Prasanna1, 2, Tomas Leijtens2, Sean P. Dunfield2, James A. Raiford1, Eli Wolf2, 3, Giles Eperon1, Axel F. Palmstrom2, Maikel van Hest1, Stacey F. Bent1, Glenn Teeter1, Joseph Berry1 and Michael D. McGehee1; 1Stanford University, Stanford, California, United States; 2National Renewable Energy Laboratory, Golden, Colorado, United States; 3University of Colorado Boulder, Boulder, Colorado, United States.

Widespread adoption of renewable solar power requires the production of solar cells of improved power conversion efficiency at low cost. As conventional single-junction silicon solar cells approach their fundamental limits in efficiency, the use of tandem solar cells based on multiple semiconductors to absorb complementary parts of the solar spectrum offers a proven way to increase efficiency past 30%. Metal halide perovskite semiconductors, with their strong absorption, tunable band gaps, and defect tolerance under a variety of low-temperature processing methods offer the promise of fabricating such tandem solar cells at low cost. Specifically, all-perovskite tandems, which use perovskites for all active absorbers in the stack, promise to attain high efficiencies while keeping these benefits for all subcells. Over 20% efficient monolithic tandem solar cells have recently been demonstrated using a lead iodide-bromide perovskite for the wide-gap absorber and a tin-lead iodide perovskite for the low-gap absorber. While the use of tin at the B-site of the ABX₃ perovskite is crucial to achieving low band gaps required of the rear subcell, tin-containing perovskite solar cells have conventionally been thought to be unstable due to the propensity of tin to oxidize upon exposure to air. We show that tin can be drastically stabilized by alloying with lead, which leads the facile oxidation pathway that pure tin perovskites undergo. We identify two different reaction pathways by which tin-containing perovskites can be oxidized. The pathway that mixed tin-lead perovskites (with 50% tin or lower at the B-site) are forced to take involves breaking more Sn-I bonds, which makes it unfavorable, therefore stabilizing these perovskites toward oxidative breakdown.
We show that PEDOT:PSS, the hole transporter most commonly used so far for tin-containing perovskites, adversely reacts with them upon aging at elevated temperature (85°C). This results in poor thermal stability, with charge extraction being severely reduced upon 100 - 200 hours of aging at 85°C. By designing a heterojunction with upward band bending in the perovskite, we achieve selective extraction of holes without using the unstable PEDOT:PSS.

We proceed to study the effect of morphology on the rate of oxidation, and find that increasing compactness and size of nanoscale morphological domains significantly improves stability in air. Combining these results, we fabricate a mixed tin-lead perovskite using a hole-selective heterojunction, processed in a way that yields a compact and large-grained film, and show that this device maintains 95% of its initial efficiency after 1000 hours of aging at 85°C in ambient air without any additional encapsulation, and maintains 95% efficiency after 1000 hours of aging in damp heat (85°C with 85% relative humidity) with encapsulation. Further, the solar cell stays above its initial efficiency when operated at maximum power point under illumination for over 1000 hours. These results represent the first demonstration of the benchmark 1000-hour stability tests being passed by low band gap tin-lead perovskites. Our work removes the main perceived hurdle to the implementation of single junction and tandem solar cells based on tin-lead perovskites.

Perovskite solar cells (PSCs) have become a competitive photovoltaic (PV) technology with rapid progress of efficiencies reaching above 23%. Uniquely, PSCs have the highest efficiencies when they are solution processed, so one can envision solar cells printed in a similar manner and scale as newspapers. Bandgap tunability through perovskite composition engineering is attractive for developing high-efficiency multijunction devices, including perovskite/perovskite, perovskite/silicon, or perovskite/thin-film absorber (e.g., CIGS). In this talk, we will discuss our recent progress in the development of perovskite-based tandem solar cells. For wide-bandgap (~1.7–1.8 eV) PSCs, the challenge is to reduce the voltage deficit. Developing strategies to reduce defect density is critical. For low-bandgap (~1.2–1.3 eV) PSCs based on Sn-Pb mixed perovskite films, key challenges lie at both the material and device levels. At the material level, the high defect density associated with oxidation of Sn2+ to Sn4+ and formation of Sn vacancies significantly limits carrier lifetime and charge collection. At the device level, it is difficult to synthesize uniform, pinhole-free, Sn-based thin films because of the rapid crystallization of Sn-based perovskite films. We will show our recent progress on solution chemistry engineering to reduce defect density in perovskites with a wide composition range covering both low- and wide-bandgap perovskite films. The precursor chemistry and growth conditions affect significantly the physical and optoelectronic properties of perovskites. Finally, I will also discuss some of our recent efforts on upscaling PSCs. These results demonstrate a promising path towards commercialization of the perovskite photovoltaic technology.

Thin film tandem photovoltaic (PV) devices fabricated with commercially viable Cu(In,Ga)Se2 (CIGS) device as narrow bandgap bottom cell and emerging perovskite technology devices as wide bandgap devices for the top cell can offer low-cost and environmentally friendly solution processed route towards high efficiency devices. Another advantage in perovskite/CIGS tandems lies in variability of both top and bottom cell bandgaps. While multiple experimental and computational studies have optimized the perovskite/silicon tandem solar cells, the option of variability in the bottom cell material has been overlooked. In this study we have simulated performances of the perovskite/CIGS tandem solar cells in two-terminal and four-terminal configuration while varying both top and bottom cell bandgaps and perovskite layer thickness. To this end we use actual measured reflective indices for all the layers including the absorber layers within transfer matrix method calculations to determine the optimal bandgap combinations for the top and bottom cells. These devices are also examined for their energy yields in the context of real-world conditions. For this part of the study we generate annual hourly solar irradiance spectra using updated National Renewable Energy Laboratory’s typical meteorological year data while accounting for sunlight’s angles of incidence, PV device temperature and anisotropy in diffused horizontal irradiance for multiple locations in the USA. Our results show that certain combination of bandgaps for top and bottom cells do not perform as well under real-world conditions as they do for laboratory conditions. We explore the monthly spectral shifts due to seasonal climatic changes and demonstrate correspondence between the shifts in the solar irradiance spectra and functions of tandem devices.

2:30 PM BREAK

3:30 PM *ES16.07.04 Interfacial Design of Highly Efficient Vacuum-Deposited Perovskite Solar Cells Pablo Boix, Daniel Pérez-del-Rey, Chris Dressen, Ana Igual, Benedikt Dänekamp, Jorge Avila, Michele Sensollo and Henk J. Bolink; Instituto de Ciencia Molecular, University of Valencia, Paterna, Spain.

Vacuum-deposition of halide perovskites and charge-selective materials enables a wide range of variations in the device architecture [1]. This technique permits an accurate control on the layer thickness and stacking sequence, which is particularly suitable for applications such as tandem devices. Here, we use the intrinsically additive nature of vapor-based processes to carry out a detailed study of the solar cell interfaces and perovskite optoelectronic properties. We analyze the main processes determining the performance of both nip [2] and pin configurations [3]. The use of optical and electrochemical spectroscopies allows distinguishing the role of band alignment and recombination, and how these affect the open circuit voltage and overall performance of the devices. As a result, CH3NH3PbI3-based solar cells with open circuit potential close to the thermodynamical limit and power conversion efficiency >20% are achieved.

4:00 PM ES16.07.05 CdTe-Perovskite Tandem Photovoltaics Timothy Siegel, Tushar Shimpi, Walajabahad Sampath and Brian A. Korgel; McKetta Department of Chemical Engineering and Texas Materials Institute, The University of Texas at Austin, Austin, Texas, United States; Next Generation PV Center, Department of Mechanical Engineering, Colorado State University, Ft. Collins, Colorado, United States.

Hybrid organic-inorganic perovskites (HOIPs) have garnered significant interest as absorber layers in tandem photovoltaic devices (PVs) due to their low-temperature solution processability, high performance, and widely tunable band gap. Perovskites have been coupled in tandem devices with silicon, CIGS, and other perovskites, to boost the efficiency of the single-junction devices. However, they have yet to be employed in tandem with CdTe. One of the reasons for this is the need for a perovskite with either a very low or very high band gap to couple efficiently with the 1.5 eV band gap (Eg) of CdTe. Here, we show that tandem PVs can be made by coupling CdTe with wide band gap CH3NH3PbBr3 (MAPbBr3) in a four-terminal device architecture to improve efficiency. We find that MAPbBr3 films tend to exhibit a significant amount of haze, depending on the processing conditions of the film. This haze is a result of a “wrinkling” in the film, which is observed using polarized light microscopy and scanning electron microscopy. By simulating device performance with a MAPbBr3 top cell and a CdTe bottom cell using the Semiconductor Capacitance Simulator (SCAPS) software package, we identify the amount of haze that can be tolerated by the tandem device to still improve the performance relative to the CdTe device layer. We did this by applying optical filters to a simulated 15.5% power conversion efficiency (PCE) CdTe device and comparing simulated CdTe device PCE before and after the filter was applied. We see for a perfect MAPbBr3 top cell (100% transmittance E>2.3 eV, 0% transmittance E<2.3 eV), a MAPbBr3 device efficiency of 4.2% is required for the PCE of 4-terminal MAPbBr3-CdTe tandem to exceed 15.5%. Simulating instead a film with high haze, we show a MAPbBr3 top cell with 50% sub-band gap transmittance would require a PCE of at least 9.8% for break even. Finally, optimizing the MAPbBr3 top cell morphology, optical quality, and performance via solvent-antisolvent engineering and additive engineering, we construct and characterize HOIP-CdTe tandem devices.
Perovskite solar cells have shown tremendous improvement in their power conversion efficiency (PCE) in a short period of time reaching up to 23.3% [1]. Owing to excellent optical properties (sharp band-edge, high IR transmittance) and ability to tune their bandgap to wide energy range, make perovskites attractive candidates for top-cells in tandem applications [2].

We have previously demonstrated a 23.6% efficient monolithic, two-terminal perovskite/silicon tandem using 1.63 eV Cs$_{0.75}$FAPb$_{0.25}$Br$_3$ (CsFA) perovskite top-cell [3]. This PCE value is still below the 30% that is achievable with two junctions in two-terminal devices with silicon as a bottom sub-cell [2]. Reasons for low PCE include high reflectance loss due to planar front surface and parasitic absorption in layers other than perovskite and silicon. Additional way to improve PCE is to reduce the thermalization losses in tandem by using a perovskite top-cell of higher bandgap. Perovskite/silicon tandems are multi-layered devices, thus a comprehensive optical modeling is required to tune the thickness of perovskite top-cell to current-match it with silicon bottom-cell. To perform this analysis optical constants of wide-bandgap perovskites are required. So we first determined the optical constants using multi-angle spectroscopic ellipsometry and spectrophotometry of two CsFA perovskites having different bandgaps of 1.63 and 1.68 eV, and also of a common absorber, CH$_3$NH$_3$PbI$_3$. Then we showed that the complex refractive index of CH$_3$NH$_3$PbI$_3$, can be used to generate approximate optical constants for an arbitrary wide-bandgap perovskite (in the range of 1.56 eV to 1.68 eV) by translating the data along the wavelength axis. Lastly, we used these optical constants to map the short-circuit current density of perovskite/silicon tandems with a range of different bandgap perovskites and textures to determine the top-cell thicknesses necessary to achieve current matching for varying top-cell bandgap. Our results show that ~28% PCE tandem is achievable with 1.68 eV perovskite, and even higher efficiency is possible by minimizing parasitic losses.

In the end we fabricated a two-terminal perovskite/silicon tandem by employing a 1.68 eV Cs$_{0.75}$FAPb$_{0.25}$Br$_3$ (CsFA) perovskite top-cell, rear textured silicon bottom-cell and textured polydimethylsiloxane (PDMS) anti-reflection foil at the front achieving 25% PCE [4].

an impressive photovoltaic performance of 17.27% as compared to the standard spiro-OMeTAD-based device (18.01%). In addition, the SGT-421-based device exhibits improved long-term stability which is originated from the combination of various contributions such as larger water contact angle, good film-forming ability and trap passivation effect toward the perovskite films via Lewis acid-base interactions. Eventually, we believe in that the structure-property relationship study of the terminal acceptor units offer detailed understanding about their behaviour obtained from optical-electrochemical profiles with respect to the valence band of the perovskites. The apparent demonstration of multifunctional features together with high intrinsic hole mobility and excellent PCE by SGT-421 from the A-D-A-based HTMs shows that they can be a cost-effective and promising alternative to the expensive spiro-OMeTAD for PSCs applications. The facile synthesis of the HTMs from commercially available cheap starting materials opens up a new avenue for the commercialization of perovskite solar cells through the development of efficient and low-cost HTMs with multifunctional features.

An Investigation of Decomposition in Lead Halide Perovskites via In Situ Absorption Spectroscopy and Grazing Incidence Wide Angle X-Ray Scattering Soumya Kondu and Timothy Kelly; Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan, Canada.

Moisture degradation is a serious hurdle for the commercialization of perovskite solar cells. Recently, mixed cation perovskites (MCPs) have shown promise in achieving relatively longer stability and consistently higher power conversion efficiency than single cation counterparts. Increased stability is due in part to the large grains created through the use of the mixed cation material, which leads to fewer pathways for the penetration of moisture. Furthermore, it has previously been shown that trapped charges are likely the core origin for degradation of perovskite material. Using MAPbI3/Br as control and CsFAMAPbI3/Br as the mixed cation perovskite, we measured trap density of states (tDoS) along the grain boundaries through KPFM and capacitance sweeps. These measurements were performed at 0%, 25%, 50%, and 75% relative humidity conditions for comparison. The mixed cation samples showed lower tDoS under moisture exposure, pointing to the reason for prolonged stability. Through this work, we can further understand the degradation pathway of mixed cation perovskite and the effect MA may play in the moisture stability of the device, moving one step closer to the commercialization of perovskite solar cells.

ES16.08.04
Carrier Cooling in Perovskite Under Hydrostatic Pressure Probed by Transient Absorption Spectroscopy Loreta A. Mascarella, Jan Versluis, Huib Bakker and Bruno Uhrer; FOM Institute AMOLF, Amsterdam, Netherlands.

The rise of the efficiency of perovskite solar cells from 3.8% to 23.3% in less than 10 years has shaken up the scientific photovoltaic community. A comprehensive understanding of fundamental properties of these intriguing materials is paramount for further progress in device applications. In this work we investigate how the charge carrier cooling dynamics in MAPbI3 thin films is affected by hydrostatic pressure up to 400MPa. In particular, charge cooling is probed by pump-probe transient absorption spectroscopy. We find a dramatic increase of carrier temperature at the picosecond timescale when the pressure is increased. We also investigate the effect of pressure on cooling timescales, as recently the slow cooling in those materials has sparked significant interest. Furthermore, we present a first insight on how the cooling is influenced by the phase transition, which occurs at around 325 MPa for this perovskite. Our findings will contribute to the understanding of ultrafast carrier dynamics of metal halide perovskites.

ES16.08.05
Perovskite Thin Films with Sub-Millimeter Grains Formed via Solvent Engineering Over Surface Modified Substrates Ricas Ahmad1,2, Tuck Ming Koh1, Nripsan Mathews1,3, Subodh Mhaisalkar1,3 and Maria-Elisabeth Michel-Beyerle4; Energy Research Institute @ NTU, Singapore, Singapore; 1-Interdisciplinary Graduate School, NTU Singapore, Singapore; 2-School of Materials Science and Engineering, NTU Singapore, Singapore; 3-School of Physical and Mathematical Sciences, NTU Singapore, Singapore, Singapore.

Improving the crystallinity is considered to be one of the most promising ways to enhance the efficiency as well as stability of lead halide perovskite photovoltaic (PV) devices. A typical high efficiency PV device employs perovskite thin films with grain sizes of the order of a few hundreds of nanometers. Even though there are reports showing the growth of perovskite monocrystalline thin films over substrates, these techniques cannot be scaled up to grow and fabricate devices beyond a few millimeters in lateral dimensions. Thin films with grain sizes of hundreds of microns is an attractive alternative to monocrystalline thin films as the device performance offered by such a film approaches monocrystalline device characteristics. Here we show that the substrate surface has a crucial role to play on the morphology and orientation of spin coated perovskite thin films. By tuning the substrate surface and engineering the precursor solution we were able to grow highly crystalline thin films of MAPbI3, and MAPbBr3, over different substrates. Typical lateral dimensions of individual crystal grains were found to be of the order of hundreds of microns (1000 times larger than conventional thin films) and were pin hole free. The thickness of these thin films were lesser than 1 microns and hence these films can be used to fabricate PV devices with excellent device stability and efficiency.

ES16.08.06
Superhydrophobic Perovskite Based on the Alkylamine Compound for High Efficiency Solar Cells Mi Hee Jung; Department of Nanotechnology and Advanced Materials Engineering, Sejong University, Seoul, Korea (the Republic of).

Hybrid quasi-two dimensional perovskites (2D) have attracted significant scientific interest because they have demonstrated excellent light absorbing materials in the photovoltaic devices. However, the quasi-2D perovskite still suffers in high humidity even though it exhibits greatly improved stability compared to their three-dimensional (3D) counterpart. This is the biggest obstacle to the realistic implementation of perovskite solar cells toward commercial viability. Herein, we used the hexylamine (CH3(CH2)6NH2) for quasi-2D, HA(CH3NH3)2PbI4 (n = 1, 2, 3 and 4) perovskites, has have enough long alkyl chain to maintain the chemical stability of perovskite. As the number of layers of quasi 2D HA(CH3NH3)2PbI4 perovskites was increased, it exhibited an appropriate band gap as a light absorber to be applied to solar cells. The perovskite solar cell based on the 2D HA(CH3NH3)2PbI4 perovskites shows superior power conversion efficiency of 11.5% with a 11.6% conversion efficiency of 23.4 mA cm-2, one open circuit voltage of 0.94 V and a fill factor of 71% as well as stability of solar cell to ambient air. The long alkyl chain of hexylamine cation prevent the degradation of the solar cell from the atmosphere by the passivation of perovskite films due to its highly hydrophobic property. This investigation highlights the role of organic cation to maintain the quality of perovskite film and provides a critical solution for the poor stability of perovskite in ambient air.

ES16.08.07
The Exploration of the Two-Dimensional Perovskites Incorporating Methylenammonium for the High Performance Solar Cell Mi Hee Jung; Department of Nanotechnology and Advanced Materials Engineering, Sejong University, Seoul, Korea (the Republic of).

In this study, we investigated the structural and optical properties of 2-dimensional (2D) perovskite according to the various cations, and synthesized mixed perovskites by incorporating them into the 3-dimensional (3D) perovskite (CH3NH3PbI3) in order to complement the disadvantages of the existing 3D perovskite. First, to prepare the 2D perovskites, we used the ammonium cations [butylammonium (BA), benzylammonium (BZA), ethylammonium (EA), guanidinium (GA), imidazolium (IM) and phenethylammonium (PEA)] as an organic component between inorganic layers based on a lead (II) iodide unit. When BZA, BA, and PEA were employed, we obtained

Enhancing Air Stability of Sn-based Metal Perovskite Materials by Chemical Doping
Myeongjung Lee1,2 and In Chung1,2
1School of Chemical and Biological Engineering, Seoul National University, Seoul, Korea (the Republic of); 2Center for Nanoparticle Research, Institute for Basic Science (IBS), Seoul, Korea (the Republic of).

Since the emergence of photovoltaic devices based on metal halide perovskite material, there has been extensive studies on replacing Pb for environmentally friendly technology. CsSnI3, a representative Pb-free halide perovskite material, suffers from critical problems. When exposed to air, it is immediately oxidized from Sn3+ to Sn4+, prompting rapid spontaneous phase transition from the perovskite (black phase) to the non-perovskite (yellow phase) structure. This air-instability prohibits its practical applications. Herein, we demonstrate a new strategy to improve the air stability of the black perovskite phase of CsSnI3, by chemical doping. We investigate structural changes of the undoped and doped black phase under various conditions, and find that moisture mainly causes the phase transition of the black phase. We reveal that specific dopants suppress the formation of competitive yellow phase by changing formation energy of Sn4+, and oxidation of Sn2+ in doped samples occurs at a significantly lower rate in air. As a result, doped CsSnI3, maintains the black phase over a week under air. These dopants induce an unusual shift in optical band gaps in Sn-based perovskite materials, in contrast to Pb-based materials. Ab initio density functional theory calculations show that band gap tuning effect is attributed to the p orbitals of the dopants.

ES16.08.09
High Performance and Long-Term Stability-Reduced Perovskite Solar Cells Based on Mesoscopic Zn-TiO2 Electron Transport Layer
Mine-Chung Wu, Shun-Hsiang Chan and Yi-Ying Li;
Department of Chemical and Materials Engineering, Chang Gung University, Taoyuan City, Taiwan.

Organic-inorganic lead halide perovskite solar cells (PSCs) have attracted great interest due to its rapid progress in power conversion efficiency (PCE) within a few years, which is from 3.8% to the present record of 23.3%. However, this type of solar cell still exists some challenges to overcome. First, the toxicity issue of lead drags the PSC from commercialization. To advance the technology of PSC, the development of lead-free or lead-reduced perovskite is imperative. Second, the current density-voltage hysteresis (J-V hysteresis) is an important issue for PSCs. Especially, hysteresis effect often occurs in planar n-i-p structured PSCs. The hysteresis effect can lead to misjudgment of photovoltaic performance because the forward and reverse scans show different results. In order to solve these problems, we developed mesoscopic zinc-doped TiO2 (meso-Zn:TiO2) electron transport layer (ETL) and barium-doped perovskite (Ba-perovskite) active layer. The mesoscopic zinc-doped TiO2 (meso-Zn:TiO2) as ETL of PSC is synthesized by combining sol-gel and hydrothermal method. Surface morphology, electron mobility, charge carrier dynamic and electrical conductivity of various meso-Zn:TiO2 ETL are systematically studied. To understand the electron extraction behavior between perovskite active layer and meso-Zn:TiO2 ETL, the band levels and surface potentials of perovskite active layers are analyzed by ultraviolet photoelectron spectroscopy (UPS) and photo-assisted Kelvin probe force microscopy (KPFM), respectively. To achieve high PCE lead-reduced PSC, the stability of perovskite structure should be considered. By introducing formamidinium (FA) to Ba-perovskite, the crystallinity can be enhanced, which allows long-term stability for PSCs. The Ba-perovskite films are stable which can be fabricated in the atmosphere. In this study, we combined meso-Zn:TiO2 with Ba-perovskite to fabricate high-performance lead-reduced PSCs. By combining the benefits of both MAFA mixed-cation perovskite and Ba-perovskite, the acceptable doping amount of Ba2+ can be increased to >10.0 mol%, and the device performance is better than the MAPIPbI3 PSCs, indicating that mixed-cation perovskite is able to enhance the performance of lead-reduced perovskite and reduce the lead pollution to the environment. Obviously, when Ba-perovskite combines with meso-Zn:TiO2 ETL, the J-V hysteresis effect can be completely eliminated. These results show that the ETL-perovskite interface optimization could enhance PCE and eliminate J-V hysteresis.

ES16.08.10
Water Induced Defects Suppression for Efficient Inverted Perovskite Solar Cells
Ankur Solanki, Swee Sien Lim and Tze Chien Sum; Nanyang Technological University, Nanyang Link, Singapore.

Low power conversion efficiencies and material instability caused by moisture effects under ambient conditions are the pertinent issues for perovskite solar cells. Herein, an optimal small amount of water additive into methyl ammonium lead iodide (CH3NH3PbI3) solution helps to improve perovskite crystalization and stability of perovskite films. Addition of optimal fraction of water into N, N-dimethylformamide (DMF) results in controlled perovskite growth due to the higher vapour pressure and lower boiling point of water compared to DMF. The optimal water concentration of 1% by volume was found to yield preferential crystallization in the (110) plane, together with improved grain size, small amount of pin holes and defects compared to non-water added film. The device performance improved from 10.1% to 12.3% in 1% water added perovskite films, but decreases upon further inclusion of water content. Pump fluence dependent photoluminescence shows the reduced trap density from 4.8×1010/cm2 to 3.2×109/cm2 on inclusion of 1% water to the perovskite film. The presence of the optimal amount of water enhances the charge carrier lifetimes and diffusion lengths in blend film confirmed by the transient measurements and hence improved device performance. We conclude that these defects in perovskite are dominated by surface trap states and inclusion of an optimal amount of water as an additive help to passivate these traps. This study correlates the device performance, thin film morphology with transient dynamics and provide a route to control the growth of crystal perovskites and new insights for improving the stability of organic–inorganic halide perovskites.

Organic-inorganic hybrid halide perovskite solar cells (PeSCs) have risen as promising candidates for photovoltaics due to their superior properties such as outstanding performance, low cost and facile processability from solution state. In order to obtain higher power conversion efficiency of PeSCs, the suitable engineering of charge transport layers as well as the interlayer is needed. Herein, we first reported the application of a novel organic-inorganic based metal-organic frameworks (MOFs) as an interlayer for PeSCs which are porous coordination polymers exhibiting long-range ordered metal clusters connected with organic linkers. There are some reports expecting that MOFs could be utilized to optoelectronics, but a few reports regarding to MOF includes optoelectronics have also appeared. By using the rapid self-assembly process between metal source and organic linker to build MOFs structures, brushing method from precursor solution under hot-substrate condition was employed to prepare the thin MOFs films, incorporated into p-i-n structured PeSCs. By this straightforward strategy, the transparent and thin MOF films were deposited, film development and properties were analyzed by various methods and found to be appropriate for charge injection and transfer between perovskite and MOF layer. This result indicates MOFs could be novel and good hole transport materials for PeSCs.

ES16.08.12
Low Temperature Processed High Efficiency Flexible Perovskite Solar Cells with Additive-Induced Morphology Control
In-Bok Kim1,2, Soo-Young Jang1, Yunseul Kim4, Dongseong Yang1, Jeong-Eun Kim1,2,3, School of Materials and Science and Engineering, Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of); 2Research Institute for Solar and Sustainable Energies, Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of).

Perovskite solar cells have been actively studied due to their great light absorption ability and a long excursion diffusion length (~ 1.0 μm). The cell efficiency has rapidly grown up to ~25% using mesoporous TiO2 layer which required a high temperature sintering processes. Such device structure with high temperature treatment is not compatible with flexible solar cells due to degradation of flexible substrate above 120°C. Therefore, low temperature process below the Tg of flexible substrate (PEN 120 °C, PET 80 °C) is necessary for the application to the flexible substrate. So we adopt planar type device structure of substrate/TiO2/polymer hole transport layer/amphiphilic conjugated
polyelectrolyte/MAPbI3(PCBM/BCP)/Ag with low temperature solution process (except BCP/Ag electrode). Also, we investigate the effect of various additives on crystal growth and grain size of perovskite films at different thermal annealing temperatures. The reasonably high efficiency of 18% and 17% fabricated at low temperature were obtained on glass and flexible substrates, respectively.

Eliminating Artifacts Resulted from Preferential Sputtering of Metal Halide Perovskite by Using Proper Sputter Source During ToF-SIMS Analysis Li-P. Jhong, Research Center for Applied Science, Academia Sinica, Taipei, Taiwan.

Recently, metal halide perovskite appears to be the most promising material in the photovoltaic devices. Despite the dramatic increase in the certified device efficiency, the lack of a comprehensive understanding of the fundamental properties, such as the real elemental composition and distribution in the perovskite film, greatly limits the technological progress. Time-of-flight secondary ion mass spectrometry (ToF-SIMS) is a powerful analytical tool which can provide one-dimension (depth profile), two-dimension (image mapping) and three-dimension (3D tomography) compositional information and it was used to probe the perovskite film or the entire perovskite solar cell. However, we found out that, during the sputtering period, the organic group locates at the A site in the perovskite lattice was removed at a much higher rate than the inorganic species when using the commonly utilized O2− sputter source. The unequal sputter rate of the components, which is also known as preferential sputtering, can misguide researchers to a false conclusion and stall the scientific advance. In this study, we demonstrated that by substituting C4H9+ for O2− as the sputter source, the preferential sputtering of organic species can be eliminated, yielding a depth profile without anomalous concentration gradient. We also investigated the 3D tomography of the perovskite film by using ToF-SIMS with C4H9+ sputtering. By comparing our results with those reported in the previous studies, the importance of using C4H9+ sputter source was highlighted for obtaining artifact-free information of metal halide perovskite via ToF-SIMS analysis.

ES16.08.14

Stability of Perovskite Photovoltaic Devices as a Function of Cation Composition Under Controlled Environmental Conditions Ramez Hosseinian Ahammadnejad, Zhaooning Song, Zahrah S. Almutawah, Adam Phillips, Yanfa Yan and Michael Heben; University of Toledo, Toledo, Ohio, United States.

Perovskite photovoltaic (PV) devices have demonstrated power conversion efficiencies above 23% within nearly a decade after their introduction. With such a remarkable rate of progress in performance and low manufacturing cost perovskite PV devices are expected to have a substantial share in the future PV industry. However, one of the major drawbacks of perovskite PV that hinders commercialization is lower stability compared to reliable and robust technologies such as Silicon and CdTe. While many methods such as employing multi-cation perovskite composition, mixed 3D-2D perovskite, and encapsulation have demonstrated enhanced lifetime for the perovskite PV devices, fabrication of durable perovskite solar cells remains a challenge. As a result, we introduced a new solution (named as solution B). Compared to the solution A, we used titanium isopropoxide (TiO2) as a metal source, which is a right choice to fabricate high stability perovskite solar cells. Finally, a highly reproducible fabrication procedure of PSCs with an average PCE of 16.5%, and a maximum PCE of 17.43% for an active area of 0.08 cm2 was achieved.

Efficient Perovskite Solar Cells Using Atomic Layer Deposited Ti-Doped ZnO as a Transparent Contact Louise Ryan1, Arnaud Walter2, Matthias Bräuning2, Scott Monaghan1, Melissa M. McCarthy1, Shane O'Brien1, Mircea Medeoiu1, Martyn E. Pembble1,4, Sylvain Nicolay1 and Ian M. Povey1; Tyndall National Institute, Cork, Ireland; 1;Centre Suisse d’Electronique et de Microtechnique (CSEM), Neuchâtel, Switzerland; 2;École Polytechnique Fédérale de Lausanne (EPFL), Neuchâtel, Switzerland; 3;University College Cork, Cork, Ireland.

Power conversion efficiencies of perovskite (PK) solar cells have rapidly improved in recent years obtaining efficiencies in excess of 20% [1]. Good absorption properties in the visible and infrared spectrum, high efficiencies and low fabrication costs have brought PK solar cells to the forefront. With single junction PK solar cells soon reaching theoretical efficiency limits a requirement for tandem cells, where materials of differing absorption characteristics create a wider spectral range, is in demand. However, such tandem solar cells introduce fabrication complexities due to the thermal budget restrictions imposed by the complex layer structure [2].

Indium-tin oxide (ITO) is widely used as a transparent contact in PK cells. However, due to the high deposition temperatures or energetic process used in production ITO is not viable for tandem solar cells. Here we discuss the replacement of this transparent contact using atomic layer deposited (ALD) Ti-doped ZnO as a candidate material. ALD has the ability to be scaled and offers excellent uniformity even at low temperatures. We focus on the optimum deposition conditions of Ti-doped ZnO to optimize it and compare those to the commonly used ITO. Solar cells with Ti-doped ZnO transparent contacts were successfully fabricated and their performance, with respect to power conversion efficiency, evaluated and compared to state of the art PK solar cells.

The Key Processing Issues and Their Solutions for High-Quality Perovskite Solar Cells Hojjatollah Sarvari, Mohsen Nasseri, So Min Park, Douglas Strachan, Kenneth R. Grahan, Vijay Singh and Zhi Chen; University of Kentucky, Lexington, Kentucky, United States.

Here, we report the critical processing issues and the solutions for the fabrication of cesium-doped mixed cation PSCs consisting of FTO/c-TiO2/mp-TiO2/Perovskite/spiro-OMeTAD/Au. Perovskite precursor with a final formula of C8H6[(MAPbBr3)x[(FAPbI3)y]1-x]0.5 is used. The perovskite film is deposited using the anti-solvent method through spin-coating and shows a smooth, shiny, and dark film. First, deposition of a pinhole-free c-TiO2 layer on a smooth surface is critical in the fabrication of high-efficiency planar perovskite solar cell structures. The conventional c-TiO2 solution for spin-coating a metal oxide is a mildly acidic solution of Diisopropanoxotitanium bis(acetylacetonate) (75% in 2-propanol) in ethanol named as solution A here. One needs to repeat the spin-coating of the c-TiO2 solution A two-three times to get rid of pinholes in the film. Thus, it uses extra effort, cost, time, and equipment into account, and the film will not be perfect. To tackle this issue, we introduced a new solution (named as solution B). Compared to the solution A, we used titanium isopropoxide (TiO2: 99.99%), hydrochloric acid, and anhydrous ethanol in solution B. We optimized this solution toward fabrication of a quick, pinhole-free, and efficient hole-blocking layer. Highly reproducible PSCs with an average power conversion efficiency (PCE) of 15.4% are fabricated using this solution compared to the conventional solution utilizing both spin-coating and spray pyrolysis with average PCEs of 10.6% and 13.78%, respectively.

The anti-solvent method was usually used with chlorobenzene (CBZ), but CBZ cannot dissolve the Li-TFSI particles which may be present on the surface of mp-TiO2 after Li-ion doping. In this case, we should use a solvent that can dissolve the Li-TFSI particles completely. Both diethyl ether (DEE) and the mixed solvent consists of CBZ and DEE with a volume ratio of 4:1 can dissolve the Li-TFSI powders easily. Perovskites with larger particles (from CBZ:DEE) show a lower density of defects in the film compared to the one with smaller particles. Thus, the performance of the PSCs with CBZ:DEE is improved. The overall PCE is enhanced to 15.9% for samples with CBZ:DEE compared to the PCE of 14.76% for samples with CBZ in the same processing conditions. Also, to improve the adhesion of Au to the HTL, a thin layer of silver (Ag) is introduced as the interlayer between the hole transport layer (HTL) and the Au. We deposited a 2-5 nm of Ag on top of the HTL followed by 80 nm of Au. In this way, the adhesion of the Au layer to the HTL is improved according to our simple tweezer tool test. A pure Au film can easily come off from the surface of HTL. However, the Au films with 2-5 nm silver buffer layer showed strong adhesion to the HTL. Interestingly, it improved the current density and, finally the PCE of the devices by both enhancing the adhesion of the back electrode onto the organic HTL and increasing the light reflection in the PSC.

Finally, a highly reproducible fabrication procedure of PSCs with an average PCE of 16.5%, and a maximum PCE of 17.43% for an active area of 0.08 cm2 in reverse bias direction is achieved.

ES16.08.17

Reducing Trap-Assisted Recombination in Pb-Less Perovskite Solar Cells by Combined Compositional and 2D/3D Engineering Deepak Thirumurahassery Gangadharan;
Halide perovskites have been dominating solution-processable photovoltaic research with remarkable power conversion efficiency of over 23%. The presence of toxic lead in state-of-the-art halide perovskite, however, shackles the marketability of this technology. Although by completely replacing lead with elements such as tin, germanium, etc. lead-free halide perovskite solar cells can be achieved, they show much lower efficiency and stability. Moreover, partially replacing lead with other metals helps to reduce the lead content in perovskite solar cells while without significant efficiency loss. But, we identify that trap-assisted recombination at grain boundaries and on the perovskite film surface associated with Sn vacancies limit the efficiency of three-dimensional (3D) Sn-Pb alloyed perovskite devices. By designing two-dimensional (2D/3D) alloyed perovskites, we passivated the non-radiative recombination channels and thus improved the efficiency of alloyed perovskite solar cells. Here, 2D/3D alloyed perovskites are synthesized by substituting small organic cations in 3D alloyed perovskoids with bulkier phenylhexylammonium cations. We optimized the content of lead and phenylhexylammonium cations for achieving the highest photovoltaic performance in resultant 2D/3D alloyed perovskite solar cells. Consequently, an enhancement of 39% was achieved in tin-rich alloyed perovskites (7.66 % versus 4.78 %) and a 15% enhancement in lead-rich alloyed perovskites (13.60 % versus 11.49 %) was achieved as compared to 3D alloyed perovskites in p-i-n planar solar cells. Also, the current-voltage hysteresis originating from the ion migration in perovskite almost fully vanishes in 2D/3D alloyed perovskite devices, once again attributed to the passivation of trap states, which is in clear contrast to the large hysteresis displayed in 3D alloyed perovskites. Last but not the least, 2D/3D alloyed perovskite devices showed much better moisture stability and photostability. The work demonstrates that a 2D/3D engineering strategy is an effective approach towards realizing Sn-based high-performance perovskite solar cells.

Rational Design of Low-Cost Hole Transport Materials for Highly Efficient Perovskite Solar Cells Yang Cao 1,1, Valerie A. Chiykowski 2 and Curtis Berlinguette 1,2; 1Department of Chemistry, The University of British Columbia, Vancouver, British Columbia, Canada; 2Department of Chemical and Biological Engineering, The University of British Columbia, Vancouver, British Columbia, Canada.

Expensive hole transport materials (HTMs) such as Spiro-OMeTAD and PTAA hinder the commercial deployment of high-efficiency perovskite solar cells (PSCs). We report an iterative approach to developing highly efficient HTMs from inexpensive organic scaffolds that give rise to high-efficiency PSCs without sophisticated device engineering. Candidate molecules with some structural variations were made within three synthetic steps. The structure-property relationship of these compounds was revealed by interrogating their physical (e.g., crystallinity and glass transition temperature) and electrical properties (e.g., work function and charge extraction from perovskite layer). This knowledge informs molecular modifications to achieve optimal parameters in thin-film devices. As the result, device PCE above 20% have been achieved in both direct and inverted device configurations.

Facile Synthesis of Composite Metal Nanostructures for High-Performance Planar Perovskite Solar Cells Chih Wei Chiu 1, Mriganka Singh 1 and Gang Li 2; 1Academia Sinica, Taiwan, Taiwan; 2Department of Electronic and Information Engineering,, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong.

Metal oxide carrier transporting layers have been investigated widely in organic/inorganic lead halide perovskite solar cells (PSCs). Tin oxide (SnO2) is a promising alternative to the titanium dioxide commonly used in the electron transporting layer (ETL), due to its tunable carrier concentration, high electron mobility, amenability to low-temperature annealing processing, and large band gap energy. In this study, a facile method was developed for the preparation of a room-temperature-processed SnO2 electron transporting material that provided a high-quality ETL, leading to PSCs displaying high power conversion efficiency (PCE) and stability. A novel physical ball milling method was first employed to prepare ground SnO2 nanoparticles (G-SnO2), and then a sol–gel process was used to prepare a compact SnO2 (C-SnO2) layer. The effects of various types of ETLs (C-SnO2, G-SnO2, G-SnO2/C-SnO2) on the performance of the PSCs are described. The composite SnO2 nanostructure formed a robust ETL having efficient carrier transport properties; accordingly, carrier recombination between the ETL and mixed perovskite was inhibited. PSCs incorporating C-SnO2, G-SnO2, and G-SnO2/C-SnO2 as ETLs provided PCEs of 16.60, 17.92, and 20.12%, respectively. In addition to their high efficiency, the devices featuring the composite SnO2 (G-SnO2/C-SnO2) nanostructures possessed excellent environmental stability—they maintained 99% (with encapsulation) and 93% (without encapsulation) of their initial PCEs after 105 days (~2500 h) and 60 days (~1400 h), respectively, when stored under dry ambient air (20 ± 5 RH %).

High Performance Planar Solar Cells Based on Quasi 2D Perovskite with Mixed Binary Organic Spacer Shi Chen and Baomin Xu; Southern University of Science and Technology, Shenzhen, China.

Ruddlesden-Popper layered quasi-two-dimensional (Q-2D) perovskites have shown promising stability, but the intrinsic insulating organic spacer layer mainly blocks the vertical charge transport and thus significantly depresses device power conversion efficiency (PCE). Moreover, most of the reported open-circuit voltage (VOC) values of Q-2D perovskite devices are still much smaller than 1.2 V. Herein, we design and fabricate a series of (PEA1-xBAx)2MAxPb3I13 (x ≤ 0.3, PEA = phenylhexylammonium, BA = n-butylammonium, MA = methylammonium) Q-2D perovskite films, and reveal that, compared to either BA or PEA unitary material, the mixed PEA-BA binary organic spacer leads to more intensified film surface quality, preferable vertical orientation of crystals and improved optoelectronic properties in respect to charge transfer dynamics, trap density and hole mobility. Consequently, (PEA0.75BA0.25)2MA0.3Pb1.7I3.3 based devices yield a maximum PCE of 14.1%, which is the highest efficiency for Q-2D perovskite (x ≤ 5, PEA or BA) devices so far. More importantly, a peak VOC of 1.21 V is achieved due to a small non-radiative recombination loss of ~100 mV, the lowest reported loss value for Q-2D perovskite devices. In addition, significant enhancement of PEA-BA based device performance parameters are also supported by obviously decreased recombination losses. These findings provide an effect strategy towards the rational design of Q-2D perovskite materials and device performance improvements.

**ES16.08.21**

Perovskite solar cell (PSC) has emerged as a promising photovoltaic technology in lab scale with a short time of research due to their high power conversion efficiency, simple device fabrication, all-solid-state structure and the possibility to integrate the traditional device into fiber format. The flexible electrode material is a key to develop the next perovskite solar cells devices. Therefore, we employed carbon nanotube yarn as working and counter electrode material in order to fabricate flexible perovskite solar cell. To achieve maximum photocurrent, we employ the most efficient and simple carbon nanotube yarn (CNT) synthesized using chemical vapor deposition to fabricate perovskite solar cell with carbon nanotube yarn as working and counter electrode. The electrical, optical and optoelectronic properties of the perovskite/carbon nanotube yarn device were measured and reported in this study.

**ES16.08.22**
Organic-Inorganic Bismuth (III)-Based Material—A Lead-Free, Air-Stable and Solution-Processable Light-Absorber Beyond Organolead Perovskites Miaoqiang Lyu; School of Chemical Engineering, Brisbane, Queensland, Australia.

Solar cells based on organolead halide perovskites have recently seen rapid progress as one of the most promising photovoltaic technologies, owing to their solution-processability, low-cost and high efficiencies [1-5]. However, serious concerns on the use of toxic lead as well as the instability of these perovskites in humid conditions have triggered efforts towards developing non-toxic and stable organic-inorganic alternatives, which is critically important for their market acceptance in future commercialization [6-8]. To address the toxicity and stability issue of the tin/lead based perovskites in this research field, we presented the first demonstration of applying organic-inorganic methylammonium bismuth (III) iodide (MBI) in solution-processable solar cells [10]. The organobismuth material shows the advantages of non-toxicity, ambient stability and low-temperature solution-processibility, which may provide promising solution to address the toxicity and stability challenges in perovskite solar cells. Systematic study have been performed to understand the electrical, optical and optoelectronic properties of the organic-inorganic methylammonium bismuth (III) iodide. Crystallographic data as well as the crystal structure of the MBI single-crystal was achieved using single-crystal X-ray diffraction. First-principles electronic band structure calculations based on the density
functional theory was carried out as well to determine the theoretical energy band structure and density of states in this semiconductor. According to the both the theoretical and experimental results, the energy band levels of the MBI are well-aligned to be used in a typical perovskite solar cells in replacing tin/lead perovskite layers. Therefore, solar cells based on the MBI films were assembled and tested. The devices yielded a preliminary efficiency of ~0.190% with an open-circuit voltage of ~ 0.510 V in its planar structure (Fig. 1 (a-c)). The MBI film shows good long-term stability in the ambient air, which has been confirmed by monitoring the time-dependent XRD results (Fig 1 (d)). Reducing the background carrier concentration and its optical band-gap may be two effective strategies for further improving the device performance. Also, this is one of the earliest demonstrations of trivalent metal cation based, solution-processable organic-inorganic hybrid light-absorber for solar cell application, which may inspire more research work to develop and apply organic-inorganic hybrid materials beyond divalent metal cations (Pb (II) and Sn (II)) for solar energy utility.

ES16.08.23
Can We Make Oxide Perovskite/Halide Perovskite Interfaces Selective? Anat Frizbak; Adi Karna2, Shay Tirosh2 and David Cahen1; 1Materials and Interfaces, Weizmann Institute of Science, Rehovot, Israel; 2Chemistry, Bar Ilan University, Ramat Gan, Israel.

Metal oxide perovskites (MOPs) are wide bandgap materials. Some MOPs are likely to have electron affinities (EAs) that make them suitable as Electron-selective Transport Layers (ETLs) in halide perovskite (HaP)-based solar cells. The rich substitution possibilities of oxide perovskites (regarding the A and B cations in these materials with ABO3 stoichiometry) allow tuning the EA to optimize them for use as ETL with HaPs. Sr- and Ba-based MOPs are particularly interesting as SrTiO3 has energy band positions similar to those of TiO2, the most commonly used ETL today. For BaTiO3 and BaSnO3, the EA is just 0.1 eV smaller and 0.3 eV larger than that of SrTiO3, respectively. We deposit MOPs solid solutions with a compositional spread by pulsed laser deposition as ETLs and measured the resulting distribution of lattice parameters and energy band positions. Onto this library, a uniform layer of mixed halide perovskite (HaP) absorber is deposited, and the effect of the different ETL compositions on the interface with the HaP absorber and transport across it is characterized. We will present results showing to which extent we achieve control over the interfacial energy band alignments. These data and conclusions then serve to find in how far the electronic energy level and structural measurements of separate layers can be used to optimize electron transport processes across the interfaces in complete solar cells (i.e., limits of vacuum level alignment).

ES16.08.24
An Upscaled Chemical Vapor Deposition Process (CVD) Claudiu Mortan; Energy Science and Engineering, Material Science and Surface Science Group, Technische Universität Darmstadt, Darmstadt, Germany.

An upscaled chemical vapor deposition process (CVD) for methylammonium lead iodide (MAPI, CH3NH3PbI3) and formamidinium lead iodide (FAPI, CH3NH2PbI3) used in thin film perovskite solar cells has been built-up and optimized. The procedure uses exclusively gaseous precursors to transform the inorganic salt, i.e. lead iodide (PbI2) to the respective perovskite films. The mechanism of formation has been confirmed using XPS and XRD. Further characterization techniques include SEM and solar simulator measurements.

SESSION ES16.09: Upscaling and Industrial Considerations
Session Chairs: Kylie Catchpole and Martin Stolterfoht

8:00 AM *ES16.09.01
The Challenge of Pilot Scale Manufacturing Trials for Perovskite Solar Cell Modules via Sheet to Sheet and Roll to Roll Processing Trystan Watson, Jenny Baker, Daniel Barkitt, Simone Meroni, Katherine Hooper, Peter Greenwood, David Beynon, David Richards, Rahul Patidar, Dimitrios Raptis, Carys Worsley, Francesca De Rossi and Vassil Stoichkov; SPECIFIC, Swansea University, Swansea, United Kingdom.

Lead halide perovskite materials are particularly suited to solution processing and have been used extensively in coating processes combined with electron and hole transporting materials to produce multilayer solar cell devices with photovoltaic conversion efficiencies over 23%. The versatility of perovskite materials means that they can be applied to a range of substrates from glass to plastic and metal using a range of coating techniques from screen printing to spin and slot-die coating. This paper will consider the trials and tribulations of manufacturing perovskite solar cells at scale on glass and flexible PET substrates, in particular delivering an assessment on the matching of device architecture to deposition method to substrate with the view of unlocking scale-large production. The results will be discussed in the context of two recent pilot scale manufacturing trials on FTO coated glass and ITO coated PET.

In the first instance, the screen printing of glass mounted carbon perovskite solar cells (C-PSC), based on a triple mesoporous stack (titania, insulator, carbon) will be discussed. This structure represents likely the most promising architecture for successfully upsaling perovskite solar cells to modules and represents an exciting leap forward in the pursuit of industrial deployment with recent reports demonstrating 10,000 hours of continuous light soaking datausing inexpensive manufacturing processes. Alongside process improvements related to increasing throughput and mechanising manufacture, the performance and final cost of large area modules also depends on the ratio between the module’s active and total areas, the so-called geometrical fill factor, which has to be optimised to properly exploit the substrate available area and maximise the energy production. At present, series interconnected C-PSC modules are achieved through accurate registration of each of the patterned layers, using precision screen printing, however new developments will be presented using mechanical and laser scribing to increase the active area towards 90% for all printed modules.

Roll to roll processing of perovskite on PET requires a different approach primarily due to the temperature limitations of the substrate combined with the continuous non-batch deposition processes required. Here meniscus guide slot-die coating is used. Slot-die coating is a versatile technique able to coat a range of ink rheologies with little ink wastage. The paper will discuss the application of a meniscus guide to improving stripe definition, coating quality and reducing coating defects such as ribbing and discontinuous films. The lead iodide ink used in the perovskite layer is formulated in a non-toxic solvent and results in a film readily converted to perovskite through slot-die coating of methylammonium iodide without any other pre-treatments. The choice of solvent for the MAI ink is optimised by considering how the rheology and volatility of the formulation impacts on the conversion to perovskite. These developments allow us to demonstrate roll-to-roll coated perovskite solar cells.

Finally the paper will present the complex preparation required for the delivery of a pilot scale perovskite module trial. In order to transition from lab to module scale particular considerations for substrate and material handling are required. Extensive environmental monitoring was undertaken to understand and mitigate the potential for operator exposure and to ultimately ensure the safe delivery of these trials.

8:30 AM *ES16.09.02
Advances of Inverted Planar Heterojunction Perovskite Solar Cells Rui Zhu; Department of Physics, Peking University, Beijing, China.

Perovskite solar cells have attracted tremendous attentions in recent years due to the high device performance and the superior optoelectronic properties of perovskite materials. In this contribution, I will show our efforts on improving the device performance of inverted perovskite solar cells.[1-5] Research efforts, including the charge-carrier balance, composition optimization and in-situ dynamic observation of perovskite microstructure evolution, will be discussed.

REFERENCES
Organometal halide perovskites have powerful intrinsic potential to drive next generation solar technology, but their insufficient thermochanical reliability and unproven large-area manufacturability limit competition with incumbent silicon PV. The work addresses these limitations by leveraging large-area processing and robust inorganic hole transport layers (HTLs). We present inverted p-i-n perovskite solar cells utilizing NiO HTLs deposited by rapid aqueous spray-coating that outperform spin coated NiO and lead to a 5X improvement in the fracture energy ($G_c$), a primary metric of thermochanical stability. The morphology, chemical composition, and optoelectronic properties of the NiO films were characterized to understand and optimize compatibility with an archetype double cation perovskite, Cs$_2$FAPb$_{1-x}$Sn$_x$I$_{3}$)$_2$. Perovskite solar cells with sprayed NiO show higher photovoltaic performance, exhibiting up to 82% fill factor (FF) and 17.7% power conversion efficiency (PCE)—the highest PCE reported for inverted cells with scalable-processed charge transport layers—as well as excellent stability under full illumination and 4,000-hour aging. By utilizing open-air techniques and aqueous precursors, this combination of robust materials and low-cost processing provides a platform for scaling perovskite modules with long-term reliability.

9:15 AM

Mechanochemical Approaches to Inorganic-Hybrid Materials for Perovskite Solar Cells Daniel Prochowicz, Institute of Physical Chemistry, Polish Academy of Sciences, Warszawa, Poland.

The discovery of hybrid organic-inorganic metal halide perovskites led to a renaissance of thin film photovoltaics. The great diversity of hybrid perovskite compositions and preparation paths makes them an excellent candidate for novel photovoltaic materials with unique combination of properties, the potential for low cost and easy processing along with relatively high power conversion efficiencies.\textsuperscript{2} Crystallinity, density of defects and impurities are key factors for optoelectronic properties, and are also highly dependent on the materials formation processes, for most inorganic semiconductors. Understanding this behaviour and the structure/property relationship is crucial for fundamental understanding of perovskite materials, and for extending their properties to other process-tolerant systems. In that context, the synthetic approach induced by mechanical forces has appeared as a new emerging methodology in materials science.\textsuperscript{3} The mechanochemical reactions in solid state offer a significant advance by avoid the use of solvent, dramatically shortening synthesis times and simultaneously increasing the purity and amount of product.

Herein, we present a facile mechanochemical route for the preparation of various hybrid perovskite particles for high-efficiency thin-film photovoltaics.\textsuperscript{5} We also demonstrate that such approach applied for preparation of perovskite materials has advantage over a solution-based synthetic routes in terms of hysteresis and device performance. In addition, mechanochemistry allows the facile synthesis of large quantities of polycrystalline materials that is particularly well-suited for solid-state NMR studies, which can provide direct information about cation dynamics and atomic level phase compositions.\textsuperscript{5} These studies highlight the essential need for atomic-level characterization of photovoltaic materials and provide fundamental understanding of photovoltaic parameters in these systems and their superior stability.

High Photovoltaic for Inverted Planar Heterojunction Perovskite Solar Cells with Metal Oxide Hole and Electron Extraction Layers Xin Liu\textsuperscript{1} and Yanbo Li\textsuperscript{2}; \textsuperscript{1}Institute of Fundamental and Frontier Sciences, University of Electronic Science and Technology of China, Sichuan, China.

Organometal halide perovskite solar cells have been attracting increasing attention in recent years due to their excellent photovoltaic efficiencies, and that they possess the advantages of suitable optoelectronic attributes and simultaneously low-cost solution processibility. Recently, perovskite solar cells (PSCs) with inverted planar heterojunction structures, wherein a polycrystalline perovskite film is sandwiched between a hole and an electron-extraction layer, have gained attention due to its easy fabrication, compatibility with bending and greatly enhanced stability of energy-hand engine, and the possibility of fabricating multi-junction cells. Moreover, they have achieved power conversion efficiencies (PCE) exceeding 21%. Further improving their PCE is now mainly hindered by the relatively low open-circuit voltage ($V_{oc}$) and the relatively low short-circuit current density ($J_{sc}$) of perovskite solar cells.

In this work, we report an intense research on the optimization of the perovskite solar cells with NiO as hole extraction layer, in order to increase the open-circuit voltage ($V_{oc}$) and the short-circuit current density ($J_{sc}$). We found that the CsPbX$_2$ halides and favored by previous ball-milling of CsX and PbX$_2$ precursors. When bigger halides were used and/or CsX and PbX$_2$ precursors were simply mixed without previous post-deposition thermal annealing, as well as previous mechanosynthesis of perovskite powders. It is known that metal oxide demonstrate much higher carrier mobility and superior stability than organic materials. Here, we report a vacuum-deposition-based p-i-n type planar perovskite solar cell that uses metal oxide as hole and electron transport layers, respectively. This device structure shows a high $V_{oc}$ of 1.16 volts and 1.18 volts, corresponding to a voltage deficit of 0.45 volts at a bandgap of 1.61 electron volts and a voltage deficit of 0.47 volts at a bandgap of 1.65 electron volts, respectively, which derives from reducing nonradiative recombination.

9:45 AM

Single-Source Vacuum Deposition of Mechanosynthesized Inorganic Halide Perovskites Yousra El Ajjouri, Francisco Palazon, Michele Sessolo and Henk J. Bolink; \textsuperscript{1}University of Valencia Institute of Molecular Science, Valencia, Spain; \textsuperscript{2}University of Electronic Science and Technology of China, Sichuan, China.

Fully inorganic cesium lead halide perovskites are of great interest in the field of photovoltaics due to their optical and electronic properties and thermal stability.\textsuperscript{1–3} The poor solubility of Cs-based perovskites, which is encountered in conventional solution processing, can be bypassed by the use of vacuum deposition.\textsuperscript{4–6} This technique allows the formation of CsPbX$_2$ halide perovskite thin films in a dry process without the need of extra chemicals (e.g., solvents) other than the salt precursors that form the perovskite compounds. In this study, single-source vacuum deposition (SSVD) is used as an easy, fast and dry process for the preparation of fully inorganic cesium lead halide perovskite thin films.\textsuperscript{7} We investigated the structural and optical characteristics of the so-formed films as a function of chemical composition (chloride, bromide and iodide films were formed), post-deposition thermal annealing, as well as previous mechanosynthesis of perovskite powders. We found that the CsPbX$_2$ perovskite was preferentially formed for the smaller halides and favored by previous ball-milling of CsX and PbX$_2$ precursors. When bigger halides were used and/or CsX and PbX$_2$ precursors were simply mixed without previous mechanosynthesis, PbX$_2$-rich compounds such as CsPb$_2$X$_5$ were preferentially formed in the thin films. We demonstrate that single-source vacuum deposition of ball-milled perovskites represents an easy, fast and dry process to form high-quality thin films of fully inorganic perovskites. We will also present the preliminary implementation of these films into different optoelectronic devices such as light-emitting diodes or solar cells.

Perovskite photovoltaics has emerged as a new thriving technology for solar conversion due to the rapidly increasing power conversion efficiency (PCE). Although great progress has been made to push the PCEs of perovskite solar cells (PSCs) up to over 23% at laboratory scale, the practical conversion of solar energy to electricity via PSCs requires the development of large-area, low-cost, and stable high-efficiency PSCs. This presentation will introduce our recent efforts on the exploration of: 1) air blading as a new fully spin-coating-free and anti-solvent-free processing for scalable high-efficiency PSCs; 2) high-efficiency electron-transport-layer-free PSCs with simpler device configurations for low-cost and convenient device processing; 3) new low-cost and readily-available organic hole-transporting material for PSCs with efficiency over 20%; and 4) new insights into the stability of all-inorganic CsPbI3 photovoltaic. These results may contribute to develop practical perovskite photovoltaics.

**What’s the Story with Shockley and Queisser**

Chris Case, Oxford Photovoltaics, Oxford, United Kingdom.

Schokley and Queisser knew the absolute efficiency limit of single junction silicon long before technology caught up to within 90% of their 30% power conversion efficiency glass ceiling. The multijunction concept offers a roadmap for mass deployment of photovoltaic technology beyond 30%- raising the fundamental limit to 45% for silicon tandem and 40% for triple junction. In a few short years the perovskite technology has reached 23.3% in single junction and in tandem with silicon achieved 27.3% - exceeding for the first time the very best silicon single junction. Theoretical combination of existing best-in-class single junctions predict obtainable tandem and triple junction efficiencies of 34% and 39% respectively. So what is between us and the 34% efficient perovskite-silicon tandem? We discuss the specific challenges to overcome and our progress on the tandem roadmap beyond 30%, addressing fundamental loss mechanisms in the perovskite absorber and its contact heterojunctions as well as aspects of optical design and deployment in mono or bifacial format. We will address how these solutions can be delivered at the full wafer-scale in a production environment at rates of tens of thousands of wafers/hr.

11:15 AM ES16.09.09
**High Performance, Robust, and Stable Compound Perovskite Solar Cells with a Low-Cost Lens Array for Passive Tracking and Photon Management**

Oliver Zhao, Amprintz, Nicholas Rolston, Stephen Hamann, Reinhold D. Auskardt and Olav Solgaard; Stanford University, Stanford, California, United States.

Organic-inorganic metal halide perovskites have emerged as the most promising candidate for low-cost solar cells based on their compatibility with solution processing and rapid progress in device efficiency. Despite this remarkable potential, perovskites suffer from well-characterized chemical and thermal instability, as well as mechanical fragility; all of which are obstacles to achieve the required service lifetimes for commercialization. We previously introduced a new design concept of scaffold-reinforced compound solar cell (SCS), in which planar perovskite devices are partitioned into many smaller micrcells by a mechanically reinforcing scaffold. However, the introduction of scaffolds reduced device efficiency due to the parasitic absorption of the scaffold material, where the short-circuit current scaled inversely with the scaffold area (i.e., larger scaffolds resulted in lower current and efficiency).

In this work, we demonstrate a new low-cost lens array architecture which directs light away from the scaffold and into the perovskite micrcells, resulting in over 90% efficiency and current recovery. The microlens array is fabricated on the backside of the device substrate and uses light concentration to directly fabricate the scaffolds, thus making the scaffold self-aligned and removing the need for a photomask. In addition, both optical ray tracing simulations and light transmission experiments show that these lenses have passive light tracking capabilities up to angles of incidence greater than 30°, making them strong candidates for integration into low-cost, high-performance perovskite devices. Finally, we demonstrate the thermomechanical reliability of these lenses under accelerated aging conditions which is imperative for longer service lifetimes so that perovskite solar cells can ultimately compete with CIGS, CdTe, and e-Si solar technology.

11:30 AM ES16.09.10
**Perovskite Ink Chemistry—A Key for Scalable Anti-Solvent-Free Deposition Technique**

Benny Febriansyah, Teck Ming Koh, Nripun Mathews and Subodh Mhaisalkar; Energy Research Institute @NTU, Singapore, Singapore.

Lately, tremendous effort has been made, particularly in laboratory-scale spin-coating technique, to achieve unprecedented increase in power conversion efficiencies of perovskite solar cells (23.7%). However, the reported efficiency are mainly based on small-area perovskite solar cells (≤0.1 cm²). Scalable processing methods are still lagging behind the state-of-the-art spin-coated devices, primarily due to the complexity in perovskite casting, drying and crystallization from its precursor solution. It can be foreseen that the upcoming challenge for commercializing perovskite PV technology will be translation of high quality perovskite film from laboratory-scale spin coating technique to large-area coating or printing methods. Since the perovskite ink chemistry for scalable deposition was underexplored, we demonstrated new perovskite ink formulation for single step anti-solvent-free deposition for high efficiency perovskite solar cells and its potential of fabricating large-area devices.

**Photoluminescence Mechanisms in MAPbBr3 Films with Controlled Crystal Size**

Nikolaos Droseros 1,2, Giulia Longo 1, Jan Brauer 2, Michele Sessolo 1, Henk J. Bolink 1 and Natalie Banerji 1; 1 Dept. of Chemistry and Biochemistry, University of Bern, Bern, Switzerland; 2University of Fribourg, Bern, Switzerland; 3Instituto de Ciencia Molecular, University of Valencia, Paterna, Spain.
Organo-lead halide perovskites are excellent candidates for applications in light emitting diodes (LEDs). Methylammonium lead bromide (MAPbBr₃) is the most investigated perovskite for visible perovskite LEDs, but its use is still limited by a low photoluminescence quantum yield (PLQY). Efforts to increase the PLQY of this material mainly consist in fine-tuning the morphology and reducing the grain size of the polycrystalline perovskite to the micro- and nanoscale. However, the origins of the increased PLQY with reduced crystal size remain unclear. Here we elucidate the physical processes underlying the light emission of MAPbBr₃ thin films using time-resolved spectroscopy. A systematic correlation between the enhanced PL properties and the reduction of the crystal size, achieved by using different additives during solution-processing, is observed. The co-existence of free carriers and excitons at low excitation densities is shown in as-cast polycrystalline MAPbBr₃ (crystal size of the order of few μm), while only excitons are present at high excitation densities. Using the Burstein-Moss and Saha models, important quantities such as the exciton binding energy, the reduced exciton effective mass and the trap density are estimated. We then explain the increased PLQY upon crystal size reduction by the presence of a bright exclusively excitonic population even at low excitation densities, together with reduced surface trapping thanks to passivation by the additives. J. N. Droseros, G. Longo, J. C. Brauer, M. Sessoło, H. J. Bolink, N. Banerji. ACS Energy Lett. (2018), 3, 1458

1:45 PM ES16.10.02
Simulation Studies of Useable Perovskite Photovoltaic Devices—Non-Toxic, Cheap Material Alternatives That Have Been Optimized In Situ with Their Thicknesses Jalen Harris¹, Jon Shaffer², Michael Phant³, Sanhita Banerjee¹ and Sajib Ahmed²; Mechanical Engineering, California State University, Fresno, Fresno, California, United States; ²Mechanical Engineering, Buffalo State College, BUFFALO, New York, United States.

In this research, we have utilized simulation studies to probe non-toxic Sn and Pb-based perovskites with a goal to explore optimal fabrication methodologies. To that end, we have investigated a device structure with and without an ETL (both TiO₂ and ZnO have been explored) and assessed the impact on critical photovoltaic parameters. We have also explored Cu₂O as a viable hole transport layer (HTL) alternative to the traditional Spiro OMeTAD structure owing to ease of fabrication. Lastly, we have incorporated Cu as a viable back-contact alternative to the expensive Ag. We have performed optimization of individual layer thicknesses, thereby ultimately fabricating a device with the highest possible theoretical efficiency. The analyses provide critical insight into charge mobility and charge transfer kinetics within this non-Pb based device with cheap and easily fabricated materials. By observing the effects on Jsc, Voc, and FF as individual layer thicknesses are modulated, and doing comparisons of structures with and without the various ETL layers, we present results of a structure that is not only optimal from an efficiency standpoint, but also from a technology viability and sustainability standpoint.

2:00 PM *ES16.10.03
Encapsulating Perovskite Solar Cells to Withstand Environmental Stress Anita Ho-Baillie; Australian Centre for Advanced Photovoltaics, University of New South Wales, Sydney, New South Wales, Australia.

While energy conversion efficiencies of metal halide perovskite solar cells continue to improve (from 3.8 % to 23.7 % in merely 9 years), durability becomes an even more pressing issue especially for practical applications. In particular, solar cells need to endure environmental stresses such as moisture, heat and light. I will talk about some of the simple encapsulation schemes developed in my research group for moisture and heat stabilities. It is found that high quality barrier film when applied appropriately is sufficient for perovskite solar cells to pass IEC61215:201615 thermal cycling, damp heat and humidity freeze tests. The pressing pressure when applying barrier-film-based encapsulation and the design of the cell solar structures play a key role in module durability. Preliminary results of gas chromatography and mass spectrometry will also be presented to investigate trends of outgassing by perovskite solar cells which are useful information for designing appropriate encapsulation schemes.

2:30 PM ES16.10.04
Ionotronic Halide Perovskite Diffusive Synapses for Low-Power Neuromorphic Computation Rohit A. John¹, Natalia Yantara², Filippo De Angelis²,³, Subodh Mhaisalkar¹, Arindam Banu¹ and Nirpan Mathews³; ¹Nanyang Technological University, Singapore, Singapore; ²Energy Research Institute @ NTU (ERI@N), Nanyang Technological University, Singapore, Singapore; ³Computational Laboratory for Hybrid/Organic Photovoltaics (CLHYO), CNR-ISTM, Perugia, Italy; ⁴D3-Computation, Istituto Italiano di Tecnologia, Genova, Italy.

Emulation of brain-like signal processing is the foundation for development of efficient learning circuitry, but few devices offer the tunable conductance range necessary for mimicking spatiotemporal plasticity in biological synapses. An ionic semiconductor which couples electronic transitions with drift-diffusive ionic kinetics would enable energy-efficient analog-like switching of metastable conductance-states. Here, we utilize ionic-electronic coupling in halide perovskite semiconductors to create memristive synapses with a dynamic continuous transition of conductance-states. Co-existence of carrier injection barriers and ion migration in the perovskite films defines the degree of synaptic plasticity, more notable for the larger ionic ammonium and ammonium cations than the inorganic cesium counterpart. Optimized pulsing schemes facilitates a balanced interplay of short and long-term plasticity rules like paired-pulse facilitation and spike-time dependent plasticity, cardinal for learning and computing. Trained as a memory array, halide perovskite synapses demonstrate reconfigurability, learning, forgetting and fault tolerance analogous to the human brain. Network-level simulations of unsupervised learning of handwritten digit images utilizing experimentally derived device parameters, validates the utility of these memristors for energy-efficient neuromorphic computation, paving way for novel ionotronic neuromorphic architectures with halide perovskites as the active material.

2:45 PM ES16.10.05
Dual-Source Evaporation of Multidimensional Semiconductor Bismuth Halides for Planar Junction Solar Cells Maryam Khazaee contempt; Kasia Sanders²; Chang-Chang Chung¹, Jon-Paul Sun¹, Hanchun Zhou¹, Charlotte Clegg³, Eric Bergmann⁴, Wiley A. Dunlap-Shohl⁵, Qiwu Han⁶, Ian G. Hill⁷, Jacob L. Jones⁸, Dora C. Lupascu⁶ and David B. Mitzi⁸,¹; ¹Department of Mechanical Engineering and Materials Science, Duke University, Durham, North Carolina, United States; ²Institute for Materials Science and Center for Nanointegration Duisburg-Essen (CENIDE), Essen, Germany; ³Department of Materials Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States; ⁴Department of Physics and Atmospheric Science, Dalhousie University, Halifax, Nova Scotia, Canada; ⁵Department of Chemistry, Duke University, Durham, North Carolina, United States.

Despite the significant progress in fabricating hybrid organic-inorganic lead halide perovskite solar cells, their toxicity and low stability remain as major drawbacks, thereby hindering large-scale commercialization. Given the ionic/electronic nature of lead(II) and bismuth(III) ions, potentially stable and non-toxic alternatives for efficient light absorption in thin-film photovoltaic (PV) devices may be found among bismuth-based halide semiconductors. Recently, solution-based film fabrication approaches for several bismuth-based iodide semiconductors have been investigated. The current work reports on a facile and reproducible two-step coevaporation/annealing approach to fabricate AgBiI₃ (A = Cs, Rb, Ag₂BiI₇, Ag₃BiI₈ and Ag₅BiI₁₁) polycrystalline films with compact and pinhole-free morphology (Chem Mater., 2018, 30, 3338-3354). The structural, compositional, optical and electrical characteristics of the resulting thin films are studied by X-ray diffraction, scanning electron microscopy (SEM) energy-dispersive X-ray spectroscopy (EDX), optical spectroscopy and X-ray/UV photoelectron spectroscopy. A crystalllographic phase transition from rhombohedral to cubic structure silver bismuth iodide is investigated via temperature-dependent X-ray diffraction (TXRD). Planar-junction photovoltaic (PV) devices are prepared based on the coevaporated rhombohedral AgBiI₃ films, with titanium dioxide (TiO₂) and poly(3-hexylthiophene) (P3HT) as electron- and hole-transport layers, respectively. The best-performing device exhibited a power conversion efficiency (PCE) of as high as 0.9% with open-circuit voltage (Voc) > 0.8 V in the reverse scan direction.
Combining perovskites with well-established photovoltaic materials such as silicon or CIGS is an attractive option for producing cheap, high efficiency and high voltage solar cells. Perovskite-based tandem solar cells can potentially achieve over 30% tandem efficiency. We demonstrate a 4-terminal tandem perovskite/silicon configuration in which the efficiency is as high as 26%, with 23.9% for a perovskite/CIGS tandem. We also demonstrate a two-terminal monolithic tandem device with a perovskite top cell and a polysilicon passivated c-Si bottom cell, with an efficiency of over 24%, using a novel approach that avoids the need for a dedicated interconnection layer. Much of the success of these approaches has come from the reduction of optical losses, and we discuss the potential for further progress in this direction. In addition we have found that a combination of PMMA and PCBM can provide effective interface passivation for perovskite solar cells, resulting in a Voc of over 1.2 V for a 1.6 eV bandgap perovskite cell. Finally we show an efficiency of over 20% for a perovskite cell using a CuPc hole transport layer, which demonstrates excellent thermal stability. These results show the clear potential of perovskites in practical high efficiency devices.

Efficient Wide-Bandgap Perovskite solar cells and the limiting factors of tandem solar cells efficiency, as parasitic absorption, reflection losses.

All-perovskite tandem cell has been considered as the potential candidate for bringing the power conversion efficiency (PCE) beyond the Shockley-Queisser limit of single-junction device and yet retaining the advantages of earth-abundant materials and solution processability. However, a challenging issue of realizing such solution-processed devices is the fulfillment of complex and coupled requirements of the interconnecting layer (ICL) including solvent-resistance to protect underlying perovskite film, high electrical properties for carrier transport and recombination, and high optical transmission. In this work, a new thermionic emission-based ICL with enhanced solvent-resistance feature is demonstrated. Fundamentally, the thermionic emission plays a critical role in the electron transport process in the ICL, which is confirmed through both experimental and theoretical studies. Besides achieving high optical transmission and electrical properties, the new ICL chemically protects the underlying perovskite film by introducing a fluoride silane incorporated polyethyleneimine ethoxylated (FSIP) hybrid system which also passivates the surface defects to reduce electrical loss. Our monolithic all-perovskite tandem solar cells demonstrate highest PCE of 17.9% [1]. Consequently, this work contributes to only understanding the fundamental mechanism of ICL but also to promoting robust and low-cost photovoltaics.

Strategies to Improve Perovskite on Silicon Tandem Solar Cells Performances Amalisa Bruno1,2, Herlina A. Dewi1, Wang Hao1, Kurt Vergeer1, Li Jia1, Lin Fern2, Maung Thway1, Armin Aberle3, Niran Mathews4 and Subodh Mhaisalkar5; "ERIS@N, Nanyang Technological University, Singapore, Singapore; 'SERIS, National University of Singapore, Singapore, Singapore.

The energy demand is constantly growing worldwide and Paris Agreement requirements of a substantial de-carbonization of electricity generation by 2050 are very stringent. Renewable energy production efficiencies need to be maximized to meet these urgent needs. Since solar irradiance is the largest resource of globally available energy, thus photovoltaics (PV) is in a prime position to deliver energy at costs similar to the fossil generated. Developing solar cells able to deliver high efficiencies, keeping their production cost and environmental impact low, would therefore address these issues. Nowadays, PV market is dominated by silicon solar cells delivering high efficiency and long-term stability. However, Si solar cells are approaching their practical efficiency limits and new methodologies are required to enhance SC power conversion efficiency. Tandem solar cells are the most promising and viable option for drastically improving the efficiency of existing PV technologies keeping the production cost low and versatile. 1,2 Indeed, combining Si solar cells with a low-cost wide-band-gap absorber material, as perovskite, it is possible to create tandem solar cells that efficiently absorb light in complementary regions of the solar spectrum and overcome the transmission and thermalization losses of a single junction solar cells. Research on perovskite on silicon tandem SCs is picking up very fast and in just three years very promising results have been reported on both four-terminal (4T), mechanically stacked, and two-terminals (2T), monolithically integrated tandem, silicon-perovskite tandem SCs. The development of high efficiency semi-transparent perovskite solar cells is critical for the implementation of high performing tandem solar cells.

In this work, we present tandem structures including semi-transparent perovskite with different band-gaps as top-cells and both hetero-junctions and passivated emitter and rear cell (PERC) silicon solar cells as bottom cells. Semi-transparent perovskite solar cells with different architectures have been developed and efficiencies above 16.0% with average transparency >80% in near-infrared have been demonstrated. Semi-transparent electrode has been realize by using sputtered indium tin oxide (ITO) as semi-transparent electrode and a thin Ag/MoOx buffer layer to protect the organic layers below and to guarantee the contact to be resistant to delamination but still highly transparent. 3 We will also present different solar cells realized both by spin-coating and thermal evaporation and strategies to improve their specific efficiencies. We will also discuss the effects of different perovskite bandgap solar cells and the limiting factors of tandem solar cells efficiency, as parasitic absorption, reflectance losses.

Efficient Wide-Bandgap Perovskite Solar Cells Enabled by Combining Bulk and Surface Passivation Strategies Cong Chen1,3, Chunxiaxiao Xiao1, Zhaoning Song1, Guojia Fang1, Chun-sheng Jiang2 and Yanfa Yan1; 1The University of Toledo, Toledo, Ohio, United States; 2National Renewable Energy Laboratory, Golden, Colorado, United States; 3Wuhan University, Wuhan, China.

Wide-bandgap (-1.7 to 1.9 eV) perovskite solar cells have attracted substantial research interest in recent years due to their great potential to fabricate efficient tandem solar cells via combining with a lower bandgap (1.1 to 1.3 eV) absorber (e.g., Si, CIGS, and low-bandgap perovskite). However, wide-bandgap perovskite solar cells usually suffer from large open circuit voltage ( VOC) deficits caused by small grain sizes and photoinduced phase segregation. Here, we introduce a small amount of Pb(SCN)2 as an additive into wide-bandgap FASn0.47C0.53PbI2.85Br0.15 perovskite precursor solution and simultaneously employing the solvent annealing method to fabricate high-quality wide-bandgap perovskite thin films. The synergetic effects of combining Pb(SCN)2 additive and solvent annealing strategies lead to enhanced grain size from ~200 nm to ~2 μm and creation of excess PbI2 to passivate defect states at grain boundaries. This advance enables an increase in the Voc of the p-n type perovskite solar cells from 1.12 to 1.21 V. Further, we adopt guanidinium bromide (GuaBr) solution to tune the effective doping and electronic properties at the back surface of perovskite thin films, which further enhance Voc to 1.24 V. The enhancement is attributed to the formation of a stronger electric field, revealed by Kelvin probe force microscopy (KPFM) measurements. With the optimization of the device fabrication process, we demonstrate a champion power conversion efficiency of 18.9% with a decent stability under continuous illumination.

High Efficiency and Flexible All-Perovskite Tandem Solar Cells Axel F. Palmstrom1, Tomas Leijtens1, Giles Eperon1, Rohit Prasanna2, Sanjini Nanayakkara3,
The emergence of metal halide perovskites as high efficiency, cost-effective solar materials has led to significant interest for perovskite-based tandems. Of existing perovskite-based tandem technologies, pairing wide-gap and low-gap perovskites in a monolithic all-perovskite tandem arguably offers the greatest potential by enabling efficiencies beyond the single-junction Shockley-Queisser limit with low-cost solution processing on a flexible, lightweight substrate. As of yet, efficiency of all-perovskite monolithic tandems has lagged behind perovskites paired with silicon or CIGS despite significant improvement to low-gap perovskite materials. The state-of-the-art all-perovskite 2T tandems have been limited by several main factors: 1) relatively low fill factors, 2) shunting due to the use of a thick (100nm) and conductive recombination layer of indium tin oxide allowing lateral connectivity of shunt pathways in either subcell, and 3) large voltage losses in the wide gap subcell due to photoinduced halide segregation, resulting in lower than ideal voltages for the tandem overall. Here, we develop strategies to overcome all of these issues and attain record-efficiency all-perovskite tandem devices.

We have substantially improved the recombination layer with an ultra-thin nucleophilic surface modification to C60 for improved atomic layer deposition (ALD), enhancing the solvent/sputter barrier properties and mechanical stability of ALD-grown recombination layers. This strategy enables the fabrication of recombination layers that are thinner and less laterally conductive (reduced shunting) than currently reported strategies. Secondly, we improve the voltage of our wide-gap cell through A-site cation bandgap tuning. A combination of large and small A-site cations are used to tint the metal halide octahedral. This increases the bandgap and therefore reduces the amount of bromine needed to attain a certain bandgap. We achieved a band gap of 1.7eV with a solution bromide concentration of only 20%. We find that this strategy results in higher voltages and efficiencies 20%. We have also demonstrated two-terminal all-perovskite tandems with efficiencies over 23% for rigid devices and 21% for flexible devices.

Enhancement of Efficiency for Sn Perovskite Solar Cells (Pb free) by Reducing Lattice Strain
Kohei Nishimura1, Daisuke Hirotani1, Muhammad Akmal Kamarudin1, Satoshi Ikubo1, Qing Shen1, Minemoto Takashi2, Kenji Yoshino3 and Shuzi Hayase1,2,4,5
1Kyushu Institute of Technology, Kitakyushu, Japan; 2University of Electro-communications, Cho-fu, Japan; 3Ritsumeikan University, Kusatsu, Japan; 4Miyazaki University, Miyazaki, Japan.

Sn perovskite solar cell is one of the most expected Pb-free perovskite solar cells with high efficiency. We have already reported the efficiency of SnGe-perovskite with 7.9%. It has been also reported that Sn perovskite solar cell efficiency was enhanced to over 9% by inserting 2D structure partially. It is well known that the stability of perovskite structure is expected by Tolerance Factor. In the research on enhancing the Sn-perovskite solar cells, we focused on the relationship between the lattice strain of the Sn-perovskite calculated from XRD data and the solar cell efficiency. Sn perovskite solar cell is expressed as ASnI3, where A stand for cation. In this research, we employed (B0.1)(FA0.75MA0.25)0.9SnI3, where A cation is the mixture of (B0.1)(FA0.75MA0.25)0.9. In this report, B was varied was varied from small Na cation to large Butyl ammonium cations (Na cation, K cation, Et ammonium cation and Butyl ammonium cation). The lattice strain decreased with an increase in the ion radius from Na, K, Cs, Et ammonium, and Butyl ammonium. Replacement of FAA with Et ammonium cation gave smallest lattice strain. By introducing Bu ammonium cation, the lattice strain increased with keeping the 3D structure at 5 mol %. By the addition of 10, and 20% addition, the strain decreased with the formation of 2D structure as it is well-known in the literature. Therefore, estimation of lattice strain by XRD peaks was proved to be useful. The solar cell efficiency had good correlation with the lattice strain. Low lattice strain gave high efficiency when MAFA was partially replaced by from Na ion to Ethyl ammonium cation. Introduction of Et ammonium ion with the smallest lattice strain gave the best results. The relative lattice strain of FA0.75MA0.25SnI3 was 0.057 (Tolerance factor: 0.979). When 10 mol % of Et ammonium cation was introduced, the relative lattice strain decreased to 0.035 (tolerance factor:0.985), the efficiency of the solar cells was enhanced from 2.34% without adding Et ammonium cation to 3.72% with 10 mol% addition. The efficiency was saturated at 20mol % concentration (3.45%). XRD signal showed that 3D structure was held and the increase in the efficiency was not explained by the insertion of 2D structure which has been reported before. All of the FF, Jsc, and Voc increased with a decrease in the lattice strain. By introducing 10% of EtA cation, the efficiency of solar cells consisting of TIO/PTCDA/PSS:EA0.1[(FA0.75MA0.25)0.9SnI3](PCBM:60) was enhanced to 5.41 %. Sn perovskite solar cells with 7.9% is reported.

Bandgap Modulation in Cs-Pt-I-O Perovskites Based on Solvent Engineering
Dakota Schwartz1 and Shubhra Bansal1; University of Nevada, Las Vegas, Las Vegas, Nevada, United States.

Organic-inorganic hybrid perovskite solar cells have attracted immense attention because of excellent optoelectronic properties and record power conversion efficiency (PCE) has surpassed 23.3% within a few years. Despite the very high efficiency already attained by HPSCs (ABX3; A = MA, FA, Cs; B = Pb,Sn; X=I, Br, Cl) resulting from high absorption coefficient and electron-hole diffusion lengths, toxicity of Pb and stability of these materials are veritable issues. Composition space for Pb-free perovskite ABX3 is expected by Tolerance Factor. In the research on enhancing the Sn-perovskite solar cells, we focused on the relationship between the lattice strain of the Sn-perovskite calculated from XRD data and the solar cell efficiency. Sn perovskite solar cell is expressed as ASnI3, where A stand for cation. In this research, we employed (B0.1)(FA0.75MA0.25)0.9SnI3, where A cation is the mixture of (B0.1)(FA0.75MA0.25)0.9. In this report, B was varied was varied from small Na cation to large Butyl ammonium cations (Na cation, K cation, Et ammonium cation and Butyl ammonium cation). The lattice strain decreased with an increase in the ion radius from Na, K, Cs, Et ammonium, and Butyl ammonium. Replacement of FAA with Et ammonium cation gave smallest lattice strain. By introducing Bu ammonium cation, the lattice strain increased with keeping the 3D structure at 5 mol %. By the addition of 10, and 20% addition, the strain decreased with the formation of 2D structure as it is well-known in the literature. Therefore, estimation of lattice strain by XRD peaks was proved to be useful. The solar cell efficiency had good correlation with the lattice strain. Low lattice strain gave high efficiency when MAFA was partially replaced by from Na ion to Ethyl ammonium cation. Introduction of Et ammonium ion with the smallest lattice strain gave the best results. The relative lattice strain of FA0.75MA0.25SnI3 was 0.057 (Tolerance factor: 0.979). When 10 mol % of Et ammonium cation was introduced, the relative lattice strain decreased to 0.035 (tolerance factor:0.985), the efficiency of the solar cells was enhanced from 2.34% without adding Et ammonium cation to 3.72% with 10 mon% addition. The efficiency was saturated at 20mol % concentration (3.45%). XRD signal showed that 3D structure was held and the increase in the efficiency was not explained by the insertion of 2D structure which has been reported before. All of the FF, Jsc, and Voc increased with a decrease in the lattice strain. By introducing 10% of EA cation, the efficiency of solar cells consisting of TIO/PTCDA/PSS:EA0.1[(FA0.75MA0.25)0.9SnI3](PCBM:60) was enhanced to 5.41 %. Sn perovskite solar cells with 7.9% is reported.

Highly Stable and Efficient All-Inorganic Tin-Based Halide Perovskite Solar Cells
Min Chen1, Minggang Ju2, Xiao C. Zeng3, Yuan yuan Zhou1 and Nitin P. Padture1, 3Brown University, Providence, Rhode Island, United States; 2Department of Chemistry, University of Nebraska–Lincoln, Lincoln, Nebraska, United States.

The state-of-the-art high efficiency perovskite solar cells (PSCs) contain lead and organic cations in the perovskite light-absorber. However, the toxicity associated with the lead and the volatility of the organic cations are hurdles in the path towards the future commercialization of PSCs. While there has been effort towards replacing lead cation with less toxic cations, typical lead-free PSCs still suffer from the low power-conversion efficiency (PCE) and poor stability. Herein, we have utilized an alloying strategy in all-inorganic Sn-based perovskite materials, and realized PSCs with a promising PCE of up to 7.11%. Furthermore, the formation of a stable, robust native-oxide layer passivates the surface resulting in superior air-stability, with <10% PCE decay after 500 hours continuous operation under one-sun illumination. Thus, this work provides a new avenue for the design and development of high performance and stable Sn-based PSCs.

SESSION ES16.12: Reducing Lead and Perovskite-Inspired Materials
Session Chairs: Nakita Noel and Pankaj Yadav
Friday Morning, April 26, 2019
PCC North, 100 Level, Room 125 AB
Hybrid organic-inorganic perovskite (HOIP) solar cells – particularly those using $\text{APbX}_3$ [$\text{A} = \text{CH}_3\text{NH}_3$, HC(NH$_3$)$_2$, Cs$^+$ and X = I$^-$, Cl$^-$, Br$^-$] as the absorber layer – have already exceeded the 23% conversion efficiency milestone, surpassing the record efficiencies of well-established photovoltaic technologies based on multicrystalline silicon, c-Si, and cadmium telluride absorbers [1]. However, a major obstacle in the commercialization of HOIP-based solar devices continues to be their short operational lifetimes, with significant performance decreases observed within the first hours in service [2]. Because this deterioration is linked to the intrinsic instability of the HOIP [3], reducing their defect concentrations seems a key strategy towards improving the long-term stability of this type of absorber and, therefore, of solar devices produced from them. Recently, it has been shown that the addition of divalent cation halide salts (e.g., SrI$_2$ and MgI$_2$) to the HOIP precursor mixture yields thin-films with lower defect concentrations, leading to boosts in resulting solar device performance [4,5]. The additives are expected to increase halide content, thus effectively filling halide vacancies, however an understanding of the doping role of the divalent cation and the mechanism inducing the observed device improvements is, at best, incomplete.

Using hard x-ray photoelectron spectroscopy (HAXPES), we have investigated the chemical and electronic structure of a Sr-doped MAPbI$_3$ thin-film sample prepared by varying the concentration of SrI$_2$ additive within a 0 to 2 mol% range. Sr is detected in all Sr-doped samples, and depth-dependent measurements reveal a pronounced surface accumulation of Sr in samples with higher Sr-doping concentrations, suggesting a Sr lattice incorporation saturation. Moreover, significant reductions in defect states (i.e., Pb$^0$) are detected for all Sr-doped samples compared to (undoped) MAPbI$_3$. The effect of the Sr-doping concentration and detected Pb$^0$ defect changes on the electronic structure is discussed in this contribution, as well as a comparison of the chemical and electronic properties with the device performance (enhancements) of corresponding solar cells.

9:50 AM ES16.12.05

Lead-free double-perovskites (A$_2$M$^+$M$^-X_6$) have been recently proposed as a stable and environmental friendly alternative to lead-based perovskites. Among the vast number of possible double-perovskite compositions, Cs$_2$AgBiBr$_6$ has been the most investigated material, both from a theoretical and experimental point of view. To date, the majority of fundamental studies on this material have been conducted on single crystals or powders, which is due to the poor solubility of the material precursors and to difficulties in obtaining smooth and uniform films. Vapour deposition offers to be a promising alternative for the formation of Cs$_2$AgBiBr$_6$ films, overcoming the drawbacks of traditional solution chemical methods and time-consuming growth of single crystals. In particular, physical vapour deposition can produce high-quality films with various thicknesses and smooth surfaces. In this way, numerous spectroscopic techniques which require non-scattering surfaces (like TRPL or THz spectroscopy), as well as thickness- and temperature-dependent transient photoconductivity measurements can be conducted to get an insight in the optoelectronic properties of the material. Here, we disclose our recent findings on vapour-deposited Cs$_2$AgBiBr$_6$, demonstrating not only efficient double-perovskite solar cells, but also presenting a fundamental understanding of the carriers dynamics in the double-perovskite thin films, not achievable otherwise.

9:45 AM ES16.12.06

High Performance Low Dimensional Tin Perovskite Solar Cells Zhijun Ning, Fei Wang and Xianyuan Jiang; ShanghaiTech University, Shanghai, China.

The low toxicity and a near-ideal bandgap make tin (Sn) perovskite an attractive alternative to lead perovskite for next generation solar cells. However, the development of Sn perovskite is still an emerging field in which fundamental studies on this material have been conducted on single crystals or powders, which is due to the poor solubility of the material precursors and to difficulties in obtaining smooth and uniform films. Vapour deposition offers to be a promising alternative for the formation of Cs$_2$AgBiBr$_6$ films, overcoming the drawbacks of traditional solution chemical methods and time-consuming growth of single crystals. In particular, physical vapour deposition can produce high-quality films with various thicknesses and smooth surfaces. In this way, numerous spectroscopic techniques which require non-scattering surfaces (like TRPL or THz spectroscopy), as well as thickness- and temperature-dependent transient photoconductivity measurements can be conducted to get an insight in the optoelectronic properties of the material. Here, we disclose our recent findings on vapour-deposited Cs$_2$AgBiBr$_6$, demonstrating not only efficient double-perovskite solar cells, but also presenting a fundamental understanding of the carriers dynamics in the double-perovskite thin films, not achievable otherwise.

Improved Charge Carrier Lifetimes with Partial Substitution of Lead with Strontium in Perovskite Compounds Aditya S. Yerramilli1; Yuancheng Chen2; Yang Song1, 2 and Terry Alford1; 1Arizona State University, Tempe, Arizona, United States; 2Materials Physics and Chemistry, X’ian University, X’ian, China; 3Materials Science, African University of Science and Technology, Abuja, Nigeria.

Lead (Pb) based perovskite solar cells have come a long way since their inception. However, toxicity issues due to the presence of lead have adversely affected their commercial potential. Strontium (Sr) a relatively non-toxic element is a viable candidate to replace Pb, given the similar ionic radius (Sr$^{2+}$ = 132 pm, Pb$^{2+}$ = 133 pm). We have prepared samples using accurate-based precursors to make devices with different substitution percentages of Pb with Sr, of 10% and 20%. We have obtained a reasonable device efficiency of 8.9% and 5.7% for 10% and 20% substitution devices, respectively. Charge carrier lifetimes gave 117.91ns for 10% and 109.36ns for 20% samples which are higher compared to the 103.79ns for a complete Pb based control device. Higher order substitution of Pb with more than 20% Sr has however resulted in a poor performance which can be due to the formation of SrO, Sr$_2$(C$_2$H$_5$O$_3$)$_3$, and SrCO$_3$ compounds which act as barriers for smooth charge transport.

10:45 AM ES16.12.08

All-Solution-Processed Organic/ Inorganic Hybrid Perovskite Nanocrystalline Photodetectors Guodan Wei, Jingzhou Li1 and Feiuyu Kang1; 1Graduate School at Shenzhen, Tsinghua University, Shenzhen, China; 2Tsinghua-Berkeley Shenzhen Institute, Tsinghua University, Shenzhen, China.

Recently, inorganic lead halide perovskite nanocrystals show great potential in infrared, visible and multispectral photodetectors (PD) for sensing, security and electronics applications. Considerable progress has been obtained through solution-processed fabrication technique which combines ease of processing, tailorable optoelectronic properties, facile compatibility with flexible structures. However, the stability of the nanocrystals in ambient condition has always been a great challenge in as-prepared PDs. In this work, an air stable organic/inorganic hybrid lead halide perovskite nanocrystalline PD has been obtained from full solution processes, using Cs$_2$PbBr$_4$ quantum dots (QDs) as the photocative layer, Poly(N, N-hexyl-4-butylphenyl)-N,N'-bisphenyl benzidine (poly-TPD) and phenyl-C61-butyric acid methyl ester (PCBM) as the electron transport/hole blocking
layer (ETL/HBL). The resulting device has significantly suppressed dark current as low as 10 nA/cm². The responsivity of greater than 1 A/W was obtained for this unique hybrid structure, and it has been approved up to one order of magnitude enhancement when compared with the device without the organic combination layers of poly-TPD and PCBM. Especially, these as-prepared devices remain stable for more than one week even without encapsulation. In this solution process, hydrofluoroethers (MT700) was employed as an effective protective layer for QD nanocrystals. Further, we systematically studied the influence of different types of organic carrier transport layers on device performance.

11:00 AM ES16.12.09 Reducing Saturation-Current Density to Realize High-Efficiency Low-Bandgap Mixed Tin-Lead Halide Perovskite Solar Cells Chongwen Li, Zhaoning Song and Yanfa Yan; The University of Toledo, Toledo, Ohio, United States.

The unsatisfactory performance of low-bandgap mixed tin (Sn)-lead (Pb) halide perovskite subcells has been one of the major obstacles hindering the progress of the power conversion efficiencies (PCEs) of all-perovskite tandem solar cells. By analyzing dark-current density and distribution, we identified that charge recombination at grain boundaries is a key factor limiting the performance of low-bandgap mixed Sn-Pb halide perovskite subcells. We further found that bromine (Br) incorporation can effectively passivate grain boundaries and lower the dark current density by two-three orders of magnitude. By optimizing the Br concentration, we successfully fabricated low-bandgap (1.272 eV) mixed Sn-Pb halide perovskite solar cells with open-circuit voltage deficits as low as 0.384 V and fill factors as high as 78%. The best-performing device showed a PCE of >19%. Our results suggest an important direction for improving the performance of low-bandgap mixed Sn-Pb halide perovskite solar cells.

11:15 AM ES16.12.10 Efficient Defect Removal and Passivation of Pb-Sn Mixed Perovskites Enabling High Performing Solar Cells with High Charge Carrier Mobilities and Fill Factors of 83% Indrachapa Bandara R M, Imalka Jayawardana, Steven Hinder, Stephanie Adeyemo, Hannah Joyce, Radu Sperlea and Ravi Silva; 1University of Surrey, Guildford, United Kingdom; 2Engineering Department, University of Cambridge, Cambridge, United Kingdom.

In realizing new materials for low cost, high performance, solution processed photovoltaic (PV) devices, metal halide perovskites continue to show increasing potential. To enable solution processed tandem PVs by tuning the bandgap, as well as reducing the toxicity of conventional Pb-based perovskites solar cells (PSCs), Pb-Sn mixed perovskites have recently shown excellent capability (Eperon et al. Science 354, 861). However, one of the prevailing issues in these PSCs is the fast oxidation of Sn⁴⁺ to Sn²⁺ giving rise to a “self-doping” process (Noel et al. Energy Environ. Sci. 7, 3061). Sn²⁺ dopants play a major role in non-radiative recombination in Sn-based perovskites by acting as trap sites for mobile photo-generated charge carriers. This has made it difficult for these PSCs to have comparable efficiencies with Pb-only perovskites. Although there have been efforts to inhibit the oxidation process, most commonly with the addition of SnF₂ (Leijtens et al. ACS Energy Lett. 2, 2159), there are no known studies reported on the complete removal of Sn²⁺ defects.

Interestingly, it has been reported that the efficient extraction of Sn⁴⁺ from ionic mixtures in ores, alloys and food is dependent on the solvent system used. Based on this premise, we investigate a solvent extraction method to achieve the complete removal of Sn⁴⁺ through anti-solvent engineering for Sn-based perovskites, on a novel triple cation Pb-Sn mixed perovskite system with the formula CsₓPb₁₋ₓSnₓI₄ (Sn bandgap 1.26 eV). The THz photoconductivity studies show high charge carrier mobilities for solvents which enable the highest Sn⁴⁺ extraction resulting in a maximum of 23.52 cm² V⁻¹ s⁻¹, the highest observed for Sn-based PSCs. This trend continues in XPS surface analysis which indicates a clear dependence on the anti-solvent used. The most efficient Sn⁴⁺ extracting solvent also enables the highest grain sizes, lowest Urbach energies and highest PSC performance leading to champion PCE 11.62%. This is an 80% improved compared to other anti-solvents that extract Sn⁴⁺ less efficiently. Significant improvements were observed for the Jₚ, where the highest value observed is 28.05 mA cm⁻² for the best performing devices compared to the highest values for the other two solvents tested in this work, 22.10 mA cm⁻² and 21.48 mA cm⁻², while dark leakage current is minimal with when Sn⁴⁺ is more efficiently extracted. Sn²⁺ is seen to act as shallow traps, as evident from the dark current analysis. Further strengthening the argument that solvent engineering aids in Sn⁴⁺ removal, the Pb-only analogue of the PSCs did not show a performance dependence on the anti-solvent used.

Next, we introduce a mechanism by which Sn⁴⁺ is extracted through complex formation with the optimized solvent extraction medium used. Building on this foundation, the complete removal of Sn⁴⁺ was achieved by tuning the solvent engineering process and annealing temperature. Finally, the performance is further enhanced by defect passivation by fabricating a wide bandgap perovskite structure at the grain surfaces, leading to efficiencies towards 15%. Here, we achieve 83% fill factor, which is the highest achieved for a Sn-based perovskite and strongly competes with the Pb-only PSCs.

11:30 AM ES16.12.11 Solution-Processed Lead-Free Double Perovskites Exhibit Potential for Photovoltaics with Narrowed Bandgaps Yuan Liu, Li Zhang and Hongwei Zhu; 1Tsinghua University, Beijing, China; 2Key Laboratory of Photochemical Conversion and Optoelectronic Materials, Technical Institute of Physics and Chemistry, Chinese Academy of Sciences, Beijing, China.

To date, while solar cells (SCs) have been developed for years with striking advancement especially in silicon SCs and perovskite SCs, a new issue has been emerging in such progress: how to manufacture SCs in an environmental-friendly way with the help of non-toxic and durable materials. Taking such environmental consequences into consideration, recently, double perovskites AₓBCₓ₂ (A=Cs, Bi; Ag, Cu, In, C=In, Bi, Sb, X=Cl, Br, I) have provoked substantial interests among researchers, especially those who are eager to solve the toxic and unstable nature of lead halide perovskites. Since the capacity of the perovskite SCs for reaching high power conversion efficiencies has been widely revealed, it is of great potential that the AₓBCₓ₂ double perovskites would substitute the traditional perovskites for SCs in the future.

Continuous researches have revealed that Cs₂AgBi₂I₇, though the processability and stability of which are favorable, has a relatively wide and intrinsically indirect bandgap which seems unsuitable for photovoltaics. To solve such problem, we pick up Cs₂AgBi₂I₇, double perovskite as the matrix and, herein, report a feasible method for the synthesis of Cs₂AgSb₂Bi₁₋ₓBrₓ, through the solution process, where antimony serves as the alloying element for narrowing the bandgap. Apart from former synthetic method through a time- and energy consuming process at over 300°C, in this work, we successfully dissolved the precursors in the dimethylsulfoxide in a short time then fabricated double perovskites thin films directly and quickly on the prepared substrates. Meanwhile, we also tested the thermostability and reliability of the thin films under different conditions, as well as the photovoltaic properties and the band structure. Further, following a similar methodology of traditional perovskite SCs researches, we conducted an advanced study on the performance of the Cs₂AgSb₂Bi₁₋ₓBrₓ SCs. Conclusively, our results suggest that feasibility of controlled synthesis of Cs₂AgSb₂Bi₁₋ₓBrₓ thin films and indicate that Cs₂AgSb₂Bi₁₋ₓBrₓ double perovskites, benefited from its narrowed bandgap, would be more applicable as the photovoltaic layer in SCs or photodetectors.

11:45 AM ES16.12.12 Impact of Composition and Structure on Bismuth Halide Perovskites Rainie Nelson, Bradley J. Ryan, Atefe Hadi, Umar Hamdeh, Matthew Milot and Matthew G. Panthani; Iowa State University, Ames, Iowa, United States.

Bismuth halide perovskites have shown rapid advancements in power conversion efficiencies over a decade, leading to an increased focus in these materials for solar cells and other optoelectronics. However, stability issues and the unavoidable toxicity of lead prove potential barriers to large-scale applications and implementations of the lead halide perovskites. Bismuth has long been a replacement for lead in various applications, and some of the similarities in electronic properties make bismuth an interesting candidate to replace lead for optoelectronic materials. In this work, we describe bismuth halide perovskite and perovskite-inspired materials which demonstrate a wide range of properties. We show photoluminescence of bismuth halide precursor seeds in the synthesis of cesium bismuth halide nanocrystals, absorbance tunability of cesium bismuth halide nanocrystals based on halide composition, thermochromism of a layered double perovskite and the apparent sonocrystallization of nanocrystals from bulk crystals of layered double perovskites of various compositions. We identify promising properties of these perovskite materials and discuss major areas that require investigation in order to make bismuth halide perovskites viable materials for a variety of applications.
Lithium-Free Radical Triarylamine Dopsants for Small Molecule-Based Organic Hole-Transport Layers in Perovskite Solar Cells—Impact on Device Performance and Stability

Trapey H. Schloezer1,2, Timothy Gehan4, Jeffrey Christian3, Debbie Mitchell2, Alex Dixon2, Zhen Li3, Kai Zhu2, Joseph Berry3, Joseph Luther4 and Alan Sellinger3,5,6, Colorado School of Mines, Golden, Colorado, United States; 2Hope College, Holland, Michigan, United States; 3Northwestern Polytechnical University and Shaanxi Joint Laboratory of Graphene (NPU), Xi'an, China; 4National Renewable Energy Laboratory, Golden, Colorado, United States; 5University of Denver, Denver, Colorado, United States; 6University of Nova Gorica, Nova Gorica, Slovenia.

Within the PSC device stack, charge-selective contact selection has been shown to considerably impact PSC stability. Recently, a triarylamine-based hole-transport layer (HTL) doped with its oxidized organic salt analogue (EH44/EH44-ox) has been shown to bypass the need for hygroscopic lithium salt dopants, enabling high PSC stability in ambient conditions and room temperature. However, as the improved stability came with a power conversion efficiency (PCE) penalty, and stability suffered at elevated temperatures. Broadening the applicability and understanding of this under-utilized HTL dopant system, we report design criteria for stable, synthetically simple triarylamine-based organic hole transport materials (HTM) and their corresponding oxidized salts as HTL dopants for improved PSC efficiency and stability at elevated temperature. The triarylamine-based dopants must contain at least two para-electro donors for radical cation stabilization to prevent impurity formation (e.g., dopant reduction) which significantly reduces PSC fill factors (FF). Furthermore, these dopants can be interchanged with respect to the HTL matrix for improved PSC FF and PCE. The stability of devices (unencapsulated in ambient atmosphere under constant load and illumination) prepared with these three new HTLs considerably outperform both EH44/EH44-ox and Li1-doped spiro-OmeTAD controls at 50 and 70 °C. The ability to mix and match a dopant stable with a non-identical small-molecule-based HTL matrix for improved charge-transport properties has broadened the design scope for highly stable and cost-effective PSC without sacrificing performance. This is collaborative work with the National Renewable Energy Lab (NREL).

Highly Stable Carbon-Based Perovskite Solar Cell with an Efficiency of over 18% via Hole Transport Engineering

Qianqian Chu1,2, Xi'an Jiaotong University, Xi'an, China; 1Material science and engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Carbon-based perovskite solar cells show great potential owing to their low-cost production and superior stability in air, compared to their counterparts using metal contacts. The photovoltaic performance of carbon-based PSCs, however, has been progressing slowly in spite of an impressive efficiency when they were first reported. One of the major obstacles is that the free energy change for hole-extraction from the perovskite layer, while TPAs about the conjugated fluorene moiety increase the free energy change for hole-extraction from the perovskite layer, two orders of magnitude larger than pure P3HT. The improved charge transport and extraction provided by the composite HTL provides a significant efficiency improvement compared to cells with a pure P3HT HTL. As a result, we report carbon-based solar cells with a record efficiency of 17.8% (certified by Newport); and the first perovskite cells to be certified under the stabilized testing protocol. The stability of devices (unencapsulated in ambient atmosphere under constant load and illumination) prepared with these three new HTLs considerably outperform both EH44/EH44-ox and Li1-doped spiro-OmeTAD controls at 50 and 70 °C. The ability to mix and match a dopant stable with a non-identical small-molecule-based HTL matrix for improved charge-transport properties has broadened the design scope for highly stable and cost-effective PSC without sacrificing performance. This is collaborative work with the National Renewable Energy Lab (NREL).
systems for space applications is evidenced by the lack of any phase transition between 4.2 K and 300 K, which demonstrates the excellent stability of these mixed cation perovskites. Temperature and intensity dependent current density-voltage (J-V) measurements are used to probe the solar cells under conditions consistent with the environments around the outer planetary systems of Mars, Jupiter, and Saturn. At low temperature, a barrier impeding current flow is observed in the structure and results in a largely decreased fill factor under 1-Sun AM0 conditions. However, under low intensity and low temperature (LILT) conditions, the fill factor and the power conversion efficiency are recovered. At low temperature, thermionic emission is the limiting factor for carrier extraction over the barrier and as such the short photocurrent generated at LILT conditions provide the conditions for efficient carrier extraction, even in situations where sample degradation may have occurred in transit.

Perovskite Quantum Dot Photovoltaics—Ligand Chemistry, Optoelectronics and Charge Transport for High Voltage Solar Cells Mokshin Suri1, Abhijit Hazarika1, Lance Wheeler1, Bryon Larson2, Joseph Luther2 and Brian A. Korgel1; 1The University of Texas at Austin, Austin, Texas, United States; 2National Renewable Energy Laboratory, Golden, Colorado, United States.

Improving the open-circuit voltage (Voc) of photovoltaic devices (PVs) made with wide-bandgap (Eg≥1.8 eV) perovskites is a major goal in the development of low-cost, high-efficiency tandem solar cells that use these materials as a top cell. There is significant interest in using perovskite quantum dots (PQDs) for this application. PVs made with CsPbI, PQDs with Eg≥1.75 eV now hold the record power conversion efficiency (13.4%) for all quantum dot materials. PQD PVs show higher Voc than PVs made with similar bulk perovskite composition, and further, it is easy to manipulate the bandgap of the PQDs by synthetically tuning their size and composition. To date, however, PQD solar cells with Eg≥1.8 eV have exhibited poor device performance, due especially to high voltage loss. To alleviate these problems, we have sought to develop PQD ligand chemistry that enables high efficiency PQD device fabrication. We have found that the performance of wide bandgap PQD PVs correlates with the photoluminescence (PL) lifetime and carrier diffusion length of the PQD layer, and that the performance of wide bandgap PQD PVs can be significantly improved with appropriate modifications of the PQD composition and surface chemistry. For instance, the exchange of native oleate and oleylammonium ligands with acetic acid and formamidinium significantly increases the carrier mobility, enabling devices with high Voc. We found that PQD PVs made from CsPbI1-xBrx and FAPbI1-xBrx with sufficiently wide bandgap for tandem devices exhibit decreased Voc, short PL lifetimes, and decreased carrier diffusion lengths due to the high Br incorporation required for bandgap tuning. PL lifetime and carrier diffusion length of wide bandgap PQDs can be improved by mixing FA and Cs at the A-site, i.e., (FA1-xCsx)PbI3. Alloying of FA and Cs at the A-site balances Br incorporation at the X-site to yield wide bandgap PQD PVs with improved Voc. This work highlights potential strategies for producing the high-voltage, wide bandgap perovskite photovoltaic devices needed for a next generation of high efficiency tandem devices.

3:30 PM ES16.14.03
Design and Implementation of Information Pipeline for Robot-Ready Perovskite Experimental Data Acquisition Ian M. Pendleton1, Mansoor Ani N. Neillikal1, Zhi Li1, Emory M. Chau1, Alex Norquist1 and Joshua Schrier1; Haverford College, Haverford, Pennsylvania, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Fordham University, New York, New York, United States.

Design of new crystalline materials requires understanding the relationship between physical inputs of a system, such as chemicals, conditions, and molecular features, and the corresponding results. The chemical processes underlying crystallization in relatively simple systems can be confounded through small changes in solution concentrations, temperatures, or stochastic effects. Statistical models, such as machine learning, can aid in quantifying relationships between variations in chemical environment and reaction outcome. For success, statistical models targeting real-time data collection generally require data pipelines that assemble normalized datasets. Toward this end, we have developed a platform which brings together data storage, hardware/software interface, and simple experimental user interfaces into a single data pipeline. The key components of this pipeline include: generation of initial search parameters and robotic input files, accessible interfaces for data input by experimentalists, and in-line molecular feature calculations. Discussion topics will include the process for navigating the large initial experimental search space including automated physical constraints as well as user specifications, development of the technology stack to aid in data acquisition, and the resulting chemical ontology used to describe the underlying relationships between the chemistry and the data will be discussed. Particular attention will be given to what has emerged as ‘best practices’ for data curation, acquisition, and the development of a scalable workflow. An overview on the development and application to organohalide perovskite crystal formation will be discussed, and the work needed to implement similar processes for disparate chemical systems with moderate adjustment will be highlighted. This work provides an overview of the tools necessary for further development of real-time data capture in materials chemistry and outlines the first steps to construct larger databases for use in materials discovery.

3:45 PM ES16.14.04
High Performance Hybrid Perovskite Based Photodetector on Flexible Substrate for Wearable Sensor Applications Son Singh, Rahim Abdur, Md Abdul Kuddus Sheikh and Jaegab Lee; Kookmin University, Seoul, Korea (the Republic of).

Excellent flexibility with high mechanically stable of photonic devices are essential for next-generation integrated optoelectronic systems, wearable sensors and flexible consumer electronics. Here we describe hybrid perovskite based flexible photodetector for wearable sensor devices. The hybrid perovskites are excellent new materials with high carrier mobility, high photo conversion efficiency, tunable bandgap and excellent optoelectronic properties. These materials have advantage of low temperature and easy processing, and facile scale-up. In this study, we discuss the design and experimental demonstration of hybrid perovskite based photodetector integrated on flexible sensor platform. We have fabricated perovskite-based flexible photodetector consisting of ITO/CdS/perovskite/V1O5/Au, focusing on the conformal coating of perovskite on the planar CdS by addition of PbBr2 and PbCl2 to PbI2, which significantly increases the nucleation rate of perovskite-leading to highly smooth surface morphology of perovskite. This enhances the performance of photodetectors. The devices are fabricated on flexible PEN substrate which are withstand many bending cycles at a submillimeter radius without degradation of optoelectronic properties. Our findings provide a hybrid perovskite sensor platform for photonic devices to improve their role in the area of flexible and mechanically stable optoelectronic systems.

4:00 PM ES16.14.05
Photovoltaic Efficiency of CsPbI3 Quantum Dots-Based Solar Cell Exceeding 14% Yueli Liu; State Key Laboratory of Silicate Materials for Architectures, Wuhan University of Technology, Wuhan, China.

The emergence of organic-inorganic hybrid lead halide perovskites has received the impressive power conversion efficiency (PCE) over 22% within a few years [1]. However, the long-term stabilities of perovskite materials, including the durability under humid, thermal, UV radiation and other environmental conditions, are still poor due to the organic components, which are becoming to be the major challenges for their commercialization [2]. α-CsPbI3, as an all-inorganic lead halide, has been reported recently and exhibited excellent optoelectronic property and good stability, which is regarded as an outstanding alternative to organic-inorganic hybrid lead halide perovskites and a promising light-harvesting absorber for solar cell application [3]. Quantum dot-induced phase stabilization is believed to be an effective procedure to get α-CsPbI3 and suppress the formation of orthorhombic phase (6) CsPbI3. Protescu et al. have provided a hot-injection method for the preparation of high quality α-CsPbI3 quantum dots (QDs) [4]; α-CsPbI3 QDs based solar cells are reported by Luther and co-workers subsequently, which achieve a high PCE over 13% [5]. However, the short-circuit current density (JSC) is still low at present, which restricts the performance of CsPbI3 —based solar cells. In the work, α-CsPbI3 QDs were prepared by hot-injection method, and high performance inorganic perovskite quantum dot-based solar cells over 14.65% was fabricated, and the optimized device achieved a highly reproducible champion PCE of 13.05% with a high short-circuit current density (18.68 mA cm−2). This work provides an effective strategy for boosting high performance for all-inorganic lead halide PSCs.
Beyond Solar Cells—Perovskite Radiation Detectors and Light Emitting Diodes

Jinsong Huang; University of North Carolina-Chapel Hill, Chapel Hill, North Carolina, United States.

The excellent optoelectronic properties of halide perovskite materials and the easy growth of single crystals from solution make them ideal candidates for other electronic devices beyond solar cells. Here we will report the birth of perovskite radiation detectors, and advances in imaging detectors in terms of scaling up and integration with silicon read-out circuitry. Single photon detectors will also be presented to outline the challenges and opportunities for perovskite materials. Finally, we will present recent progress in making perovskite to be very efficient blue emitters.

Chemistry and Devices from Halide Perovskites Semiconductors

Merceauri G. Kanatzidis; Northwestern University, Evanston, Illinois, United States.

Two-dimensional (2D) metal halide perovskites have made an impressive entry in the field of solar cells and LEDs as highly promising semiconductors. They feature a high degree of structural flexibility and tunable optoelectronic properties. They have a general formula of (A’)3+(A)n–(MXy)3n+1, where A = Cs+, CH3NH3+(MA), H(CN)3H2+(FA), M = Ge2+, Sn2+, Pb2+ and X = Cl, Br, I, are the perovskite components and A’ = RNH3 is an organic spacer. There are four kinds of 2D organic inorganic hybrid perovskites so far: Ruddlesden-Popper, Cation-ordered, Jacobson-Dion and Diammonium Cation. These vary from one another in ways the inorganic slabs stack and the way the spacer cations interact with the inorganic slabs. Generally, 2D perovskites form from solution via the bottom-up self-assembly of individual, semiconducting perovskite sheets having an adjustable slab thickness of up to few nanometers, separated by insulating bulky organic molecules. As a result, they behave as natural multiple quantum wells (QWs) with the semiconducting perovskite layers representing the wells and the insulating organic spacers representing the barriers. The width of the barrier is fixed and depends only on the length of the A’ cation, while the width of the well can be adjusted by varying the thickness of perovskite slabs, which is defined by the n variable in (A’)3+(A)n–(MXy)3n+1. It is critical to understand the thermodynamic and chemical limitations of the maximum layer thickness that can be sandwiched between the organic bilayers while retaining the structural integrity of the 2D perovskite.

Novel Low-Dimensional Tin Halide Compounds—Structures, Properties and Perspective Applications

Maksym V. Kovalenko1, 2; 1Department of Chemistry and Applied Biosciences, ETH Zurich, Zurich, Switzerland; 2Empa-Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, Switzerland.

The spatial localization of charge carriers to promote the formation of bound excitons and concomitantly enhance radiative recombination has long been a goal for luminescent semiconductors. Zero-dimensional (0D) materials structurally impose carrier localization and result in the formation of bound Frenkel excitons. We present fully inorganic, perovskite-derived zero-dimensional Sn4+ material Cs8SnBr20 that exhibits room-temperature broad-band photoluminescence centered at 540 nm with a quantum yield (QY) of 10-20 % [1]. A series of analogous compositions following the general formula Cs8n-AnSnBr2n–1 (A=RnB; K; ≤1, ≤1) can be prepared. The emission of these materials ranges from 500 nm to 620 nm with the possibility to compositionally tune the Stokes shift and the self-trapped exciton emission bands.

We also present the synthesis, the structure as well as electronic and optical properties of a family of hybrid tin (II) bromide compounds comprising guanidinium [G, C(NH2)3]+ and mixed cesium-guanidinium cations: G2SnBr6, CSGSnBr6 and Cg2GSnBr6. G2SnBr6 has a one-dimensional structure that consists of chains of corner-shared [SnBr6]2– square pyramids and G cations situated in-between the chains. G2SnBr6 is a luminescent phase with a broad emission band resulting from trapped exciton states. Cs+ exhibits pronounced structure-directing effect: with a mixture of Cs+ and mixed cesium-guanidinium cations: G2SnBr6, CSGSnBr6 and Cg2GSnBr6 compounds. The related strong anisotropies of the halide perovskite lattice distortions have in turn a direct influence on their electronic and optical properties.

Understanding White-Light Emission from Layered Perovskites and Related Materials

Matthew Smith, Adam Jaffe, Aaron Lindenberg and Hemamala Karunadasa; Stanford University, Stanford, California, United States.

In 2014 we observed white-light emission from the inorganic sheets of layered lead-halide perovskites (1). Upon UV excitation, these bulk crystalline solids emit light that spans the entire visible spectrum, similar to sunlight. These hybrid phosphors have high color rendering indices and easily tunable chromaticity coordinates. They are promising as phosphors for solid-state lighting, especially as neat large-area coatings. Recently, a number of other white-light-emitting perovskites and closely related materials have been reported, making this a burgeoning field of study (2). However, the vast majority of layered perovskites display a narrow blue/green emission, and white-light emission remains rare, leading to the question: "what is special about the white-light emitters"?
Over the past several years, we have investigated the generality of obtaining broad photoluminescence from low-dimensional metal-halide lattices. We attributed the white-light emission mechanism to exciton self-trapping, or the trapping of photogenerated electron-hole pairs in transient lattice deformations (1,3), and showed that it is common to all Pb-Br perovskites, although it is highly temperature dependent (4). I will describe our most recent work that provides a more complete picture of the emission mechanism and highlights the generality of exciton self-trapping. Our studies provide design rules for obtaining both the broad white-light emission as well as the narrow blue/green-light emission from these materials. The understanding we have developed of perovskite white-light emitters can be applied to many other low-dimensional systems.

(4) Smith, Jaffe, Dohner, Lindenberg K. Rouznin and Tae-Woo Lee, Science and Engineering, Nanyang Technological University, Singapore, Singapore;

Metal halide perovskites (MHPs) have emerged as a very high promising materials for optoelectronics and photonics, mostly due to their large absorption coefficient and excellent quantum yield of emission at room temperature, among other electro-optical properties of MHPs. The most surprising fact is that these properties are not very different from monocrystalline (or epitaxial films) direct semiconductors, even if MHPs are prepared as polycrystalline thin films by simple deposition methods, as spin-coating, inkjet printing and thermal evaporation, for example. The absorption coefficient is dependent on the material electronic structure and hence mostly intrinsic, but other electro-optical parameters, as the emission quantum yield, will depend on radiative and non-radiative recombination channels for free (and bound) excitons and carriers. In this way, slow carrier recombination in MHPs is considered the origin of the observed large charge carrier diffusion length, whose origin would be the so-called "delayed luminescence" due to the existence of shallow non-quenching traps in these materials [1, 2]. In the talk a revision of recombination dynamics in MHPs will be presented. These materials have been successfully integrated in optical waveguides where stimulated emission is observed with very low thresholds both on rigid and flexible substrates [3-5]. Furthermore, perovskite-based photodetectors can be also integrated in the same platform paving the road towards wearable integrated photonics [5].

Finally, we will present the optical properties of MHP thin films using different organic cations alone or their mixture with methylammonium that produce multi-quantum-well structures (or 2D/3D perovskites). This is an emerging field of work within the scientific community of perovskites, because of the higher efficiency of photovoltaic devices based on these 2D/3D MHPs. Moreover, quantum confinement in these structures introduces a new way to tune the optical properties, especially useful for emitting devices.

Tunable Ferroelectricity in Ruddlesden-Popper Halide Perovskites Qiannan Zhang1, Ankur Solanki1, Mingjie Li2, Davide Giovanni3, Thomas L. Jansen1, Maxim S. Pshenichnikov1 and Tze Chien Sum1,3; 1School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore; 2School of Material Science and Engineering, Nanyang Technological University, Singapore, Singapore; 3Zernike Institute for Advanced Materials, University of Groningen, Nijenborgh, Netherlands.

Ruddlesden-Popper (RP) halide perovskites are promising optoelectronic materials due to their high-performance in PV applications and excellent ambient stability. Their ferroelectric properties provide an exciting opportunity to further improve PV performance based on the nature of their layered structure. Polar domains in ferroelectric materials play an important role in separating electrons and holes. However, the relation between structure and function which lead to the RP ferroelectrics remains unknown. Herein, we realize tunable ferroelectricity in 2-phenylethylammonium (PEA) and methylammonium (MA) RP halide perovskites (PEA)_x(MA)_yPbI_{3x+y}, by varying the number of inorganic layers and tuning the correlation length of the ferroelectric order. Firstly, the non-centrosymmetric nature of RP thin films is confirmed by nonlinear optics. Secondly, switchable polarity leading to ferroelectric properties is validated by piezo force microscopy and polarization-electric field measurements macroscopically and macroscopically. Then, the origin of ferroelectricity in the RP halide perovskites is investigated by MD simulations. Finally, dark current-voltage hysteresis phenomenon implies potential issues for light harvesting and light emitting applications. Importantly, our findings reveal an exciting approach to engineer tunable RP ferroelectrics, which could pave the way to new functionalities for perovskite optoelectronics.

11:45 AM ES17.01.07

In the world of growing energy demand, perovskite materials have emerged as a favorable alternative for next-generation solar cell devices owing to their high power conversion efficiency. The perovskite family is rich in multitudes, and the probability of discovering new and exciting photovoltaic materials are high. To date, most studies on this topic are focused around methyl and ethyl lead iodide structures. Recent advancement in the field of high throughput methodologies have paved a way towards the pursuit of new perovskite complexes beyond the conventional structures, facilitating an understanding of the basic physicochemical properties of these materials. Inverse Temperature Crystallization (ITC) methods were adapted to be compatible with robotic liquid-handler syntheses, resulting in the growth of large single crystals while maintain a high reaction throughput. Chemical spaces were mapped in several related systems and a large reaction dataset was generated for use with machine learning algorithms. A novel approach to prepare and characterize robot-ready perovskite crystals is described for lead halide perovskites.

SESSION ES17.02: High-Performance Light-Emitting Devices
Session Chairs: Barry Rand and Brandon Sutherland
Monday Afternoon, April 22, 2019
PCC North, 100 Level, Room 131 B

1:30 PM ES17.02.01
Highly Efficient Light-Emitting Diodes Based on Lead-Halide Perovskites Young-Hoon Kim1, Himchan Cho1, Min-Ho Park1, Su-Hun Park1, Soyeong Ahn2 and Taeg-Woo Lee2,1; 1Seoul National University, Seoul, Korea (the Republic of); 2Pohang University of Science and Technology, Pohang, Korea (the Republic of).

Lead halide perovskites have been used as emission layers in perovskite light-emitting diodes (PeLEDs), and have many advantages such as high charge-carrier mobility, solution processability, high color purity, color tunability and low material cost. However, low electroluminescence (EL) efficiency of PeLEDs at room temperature is a challenge that must be overcome. Here, we present high-efficiency PeLEDs by controlling the dimension and dimensionality (D) of perovskite grains/crystals to overcome the EL efficiency limitations. First, we kinetically control the grain size in 3D bulk polycrystalline films and achieve uniform methylammonium lead bromide (MAPbBr3) and CsPbBr3 films with...
Efficient and Stable of Perovskite Optoelectronic Devices

Jianpu Wang; Key Laboratory of Flexible Electronics (KLOFE) and Institute of Advanced Materials (IAM), Jiangsu National Synergetic Innovation Center for Advanced Materials (SICAM), Nanjing Tech University (NanjingTech), Nanjing, China.

Light-emitting diodes (LEDs), which convert electricity to light, are widely used in modern society—for example, in lighting, flat-panel displays, medical devices and many other situations. Generally, the efficiency of LEDs is limited by nonradiative recombination (whereby charge carriers recombine without releasing photons) and light trapping. In planar LEDs, such as organic LEDs, around 70% to 80% of the light generated from the emitters is trapped in the device, leaving considerable opportunity for improvements in efficiency. Many methods, including the use of diffraction gratings, low-index grids and buckling patterns, have been used to extract the light trapped in LEDs. However, these methods usually involve complicated fabrication processes, and can distort the light-output spectrum and directionality. Here we demonstrate efficient and high-brightness electroluminescence from solution-processed perovskites that spontaneously form submicrometre-scale structures, which can efficiently extract light from the device and retain wavelength- and viewing-angle-independent electroluminescence. These perovskites are formed simply by introducing amino-acid additives into the perovskite precursor solutions. Moreover, the additives can effectively passivate perovskite surface defects and reduce nonradiative recombination. Perovskite LEDs with a peak external quantum efficiency of 20.7% (at a current density of 18 mA cm⁻²) and an energy-conversion efficiency of 12% (at a high current density of 100 mA cm⁻²) can be achieved—values that approach those of the best-performing organic LEDs.

Efficient and Stable of Perovskite Optoelectronic Devices

Junbi You; Chinese Academy of Sciences, Beijing, China.

Lead halide perovskites is a new type of semiconductor optoelectronic material, which owns large absorption coefficient, long diffusion length, and also it shows high emission efficiency. This advantages feature it a great potential in in solar cells and also in light-emitting diodes. Recently, there are great breakthrough in these two types of optoelectronic devices, the power conversion efficiency (PCE) and the electroluminescence external quantum efficiency (EQE) have been pushed to 23.3% and over than 20% for perovskite solar cells and light-emitting diodes, respectively. In this talk, I will talk about how we achieve high performance and stable of perovskite based optoelectronic devices according to perovskite film growth control, interface engineering and surface passivation [1-5].

References

Metal halide perovskite generates extremely sharp emission peak and high luminescence quantum yield, enabling it to be a promising candidate as the new generation of emitting materials for displays. However, the development of perovskite LEDs is impeded by their fast carriers diffusion and poor stability in air. Herein, quasi 2D CsPbBr$_3$, quantum wells homogeneously surrounded by inorganic crystalline Cs$_3$Pb$_m$Br$_{3m}$, of large bandgap are grown. The centralization of carriers in nanoregions facilitates radiative recombination and brings much enhanced luminescence quantum yield. The external quantum efficiency and luminescence intensity of the LEDs based on this nanocomposite are one order of magnitude higher than the conventional low dimensional perovskite. Meanwhile, the use of inorganic nanocomposite materials brings much improved device operation lifetime under constant electrical field.

By using bidentate 2,2'-iminodibenzonic acid as conductive ligand, we preprepared CsPbI$_3$ NCs based high efficiency red color light emitting diode. The passivated NCs enabled us to realize red light emitting diodes (LEDs) with 5.02% external quantum efficiency and 748 cd/m$^2$ luminance, which is the highest efficiency realized at that time.

**Designing Efficient Energy Funneling Kinetics in Ruddlesden-Popper Perovskites for High Performance Light Emitting Diodes**

**Natalia Yantara, Annalisa Bruno, Azhar Iqbal, Nur Fadilah Jamaludin, Cesare Soci, Subodh Mhaisalkar and Niranjan Mathews; Nanyang Technological University, Singapore, Singapore.**

Ruddlesden Popper (RP) perovskites are of great interest in light emitting diodes (LED), due to the efficient energy transfer (funneling) from high bandgap (donor) domains to low bandgap (acceptor) domains which lead to enhanced photoluminescence (PL) intensity, long PL lifetime, and high efficiency LED. However, the influence of reduced effective emitter centers in the active emissive film as well as the implications of electrical injection into the larger bandgap donor material have been not addressed in the context of an active device. We critically assess and modulate the electrical and optical signatures of the energy cascading mechanisms in a model Ruddlesden Popper perovskite series ((Cs$_x$H$_y$)$_3$Ni$_2$(CH$_3$NH$_2$)$_3$)$_{3m}$Pb$_{3m}$Br$_{3m+1}$). Optimised devices demonstrated a current efficiency of 22.9 cd A$^{-1}$ and 5% external quantum efficiency, more than 5 times higher than systems where funneling was absent. The signature of non-ideal funneling in RP perovskites is revealed by the appearance of donor electroluminescence from the device, followed by a reduction in the LED performance.

**Present Status and Next Important Challenge of Perovskite Photovoltaics Towards Industrialization**

**Tsutomu Miyasaka; Toim University of Yokohama, Yokohama, Japan.**

Power conversion efficiency (PCE) of lead halide perovskite solar cell (over 23%) has surpassed those of CIGS and CdTe, approaching the top value of crystalline Si cell. Our group has been able to achieve PCE over 21% by low cost ambient fabrication. However, high PCE of single-cell enabled by lead halide-based perovskite absorbers are now being saturated, taking the Shockley Queisser (SQ) limit of open-circuit voltage ($V_{OC}$ ca.1.32V) into account. Tandem cell making, which can further increases PCE up to 28% or more, leads to higher material and process cost and will raise a question if performance/cost ratio can be accepted in industry. Therefore, a smart way is to create a single cell which has high PCE comparable with that of GaAs (>28%) by reducing bandgap energy to <1.4 eV without accompaniment of increase in $V_{OC}$. This possibility will be in a family of metal halide perovskite out of those depending on use of lead. In addition to such efficiency issue, high performance of organo lead halide materials is not compatible with robust high stability required for practical use. Ensuring the intrinsic thermal stability (desirably >200°C) of the perovskites is a key issue before industrialization. In addition, toxicity of lead-based perovskites are going to become the most formidable challenges for real use (commercialization), in particular, for applications to IoT society, which is one of the most promising field of perovskite photovoltaic device in terms of high voltage output even under weak illumination. These thoughts urge us to concentrate our next research of perovskite photovoltaics (PV) more on development of non-lead high efficiency absorbers. Sn perovskite is still a strong candidate because Sn(II) has been found to be stabilized against ambient air by metal doping method (such as Ge). Regarding Bi-based perovskites, we found AgBiI$_3$ as a promising all-inorganic absorber having high thermal and moisture stability. Stability also highly depends on the property of charge transport materials (CTMs), especially, the kind of hole transporter. Spiro-OMeTAD does not work at high temperature while P3HT, for example, is thermally stable. In our collaboration with JAXA, P3HT-based perovskite devices showed robust stability by exposure to high (100°C) and low (<80°C) temperature and also to high energy particle radiations (Science, 2018, 2, 148). Selection of CTMs is another important key in combination with non-lead perovskite materials. In conclusion, next direction of perovskite PV should be to enhance PV performance of non-lead all-inorganic semiconductor materials by extended compositional engineering, in parallel with developing thermally stable CTMs. Our on-going studies on non-lead perovskite materials in our group will be introduced in the talk.

**11:00 AM ES17.03.02/ES15.01.02/ES16.03.02**

**Issues and Solutions in Perovskite Solar Cells**

**Nam-Gyu Park; Sungkyunkwan University, Suwon, Korea (the Republic of).**

Since the first report on the high efficiency, stable perovskite solar cell (PSC) in 2012 by our group, following two seed works on perovskite-sensitized liquid junction solar cells in 2009 and 2011, PSC demonstrated its power conversion efficiency (PCE) of 23.3% in 2018. According to Web of Science, publications on PSC increase exponentially since 2012 and total number of publications reaches already over 10,000 as of October 2018, which is indicative of a paradigm shift in photovoltaics. Although small area cell exhibited superb efficiency surpassing the performance of thin film technologies, scale-up technology is required toward commercialization. In addition, further higher efficiency toward Shockley–Queisser limit is required in parallel. In this talk, Large-area coating technology is introduced using perovskite cluster embedded coating solution, followed by brief introduction on history of perovskite solar cell. Bi-facial stamping method was developed for not only scale-up technique but also interface modification and low-temperature phase stabilization. For higher efficiency, managing recombination is critical. Methodology reducing recombination is developed via interface and bulk engineering. Current-voltage hysteresis is also discussed because hysteresis is related to the stability of perovskite solar cell. Ion migration is now visualized and confirmed to correlate with hysteresis.

**Hybrid Halide Perovskite Semiconductors—An Historical Perspective**

**David B. Mitzi; Duke University, Durham, North Carolina, United States.**

Organic-inorganic perovskites enable a combination of useful organic and inorganic properties within a single molecular-scale composite and have attracted substantial interest for use within organic-inorganic electronic devices [1], in part due to the high carrier mobilities, long minority carrier lifetimes, tunable band gaps and relatively benign defects and grain boundaries for systems based on Group 14 metals (e.g., Ge, Sn and Pb) [2]. Indeed, these materials have enabled unprecedented rapid improvement in perovskite photovoltaic performance to levels above 20% power conversion efficiency and with open circuit voltages above 1V for a single junction photovoltaic (PV) device [3]. This talk will provide an historical perspective on foundational work related to the organic-inorganic perovskite semiconductors, including discussion of crystal structure flexibility [4,5], semiconducting properties, film deposition approaches and electronic device applications of the three-dimensional and lower-dimensional perovskite structures. Recent trends in the field, as they relate to application in photovoltaics and related devices, will also be coupled into this discussion.
The contribution is concerned with the significance of ionic conduction for hybrid perovskites. It starts with outlining the analysis of the nature of the ionic charge carriers and the quantification of their contributions to the overall transport in methyl-ammonium lead iodide. Apart from NMR, tracer exchange and doping experiments, detailed electrochemical experiments form the basis of these investigations. The prevailing mobile carriers are iodine vacancies, holes and conduction electrons. The analysis also reveals the adjusting screws that can be used to tune the charge carrier chemistry – mostly component partial pressure (iodine activity) and doping content [1-3].

The consequence of the mixed conductivity is not only carrier and mass transport, as it is decisive for chemical kinetics (e.g. decomposition kinetics), but also the occurrence of a substantial chemical capacitance [1,4]. These phenomena are well understood for oxide perovskites the behavior of which is analogous to the situation in the hybrid perovskites under dark conditions. Of particular relevance is the occurrence of a distinct long-time polarization (also the hysteresis in CV experiments) which is not a dielectric or space charge polarization, but a true bulk phenomenon. This stoichiometric effect is known as Wagner-Hebb polarization and is one of the basic phenomena in Solid State Ions involved e.g. in resistance degradation or electro-coloration.

A special role is played by oxygen because depending on the time window, its influence leads either to a varied iodine potential, to a doping effect or to a global decomposition. The understanding of this complex behavior reflects our far-reaching defect-chemical understanding of methyl-ammonium lead iodide [5].

In addition to understanding and influencing ionic and electronic carrier concentrations by classic Solid State Ionics principles, we also applied strategies of Nanoionics (e.g. heterogogeneous doping) [6]. In addition to offering further degrees of freedom for charge carrier tuning, such research reveals new insight into the interface chemistry, such as ionically dominated space charge zones. Most recent results are presented [7].

Last but not least, the striking finding of an enormously light-enhanced ion conductivity will be addressed. This is – also from the viewpoint of Solid State Ions – completely unexpected. The reason for this phenomenon is presented and implications for photo-decomposition but also for the design of novel “opto-ionic” devices are discussed [8].

References

Organic-inorganic hybrid perovskites (OIHs) have attracted extensive interest for potential use in next-generation photovoltaic devices due to the demonstrated high power conversion efficiency, low materials cost, and low fabrication cost. For conventional inorganic perovskites, commercial applications mainly rely on the strong electromechanical coupling, including both piezoelectricity and electrostriction. OIHs materials possess a similar lattice structure as conventional inorganic perovskites, however, the electromechanical coupling of OIHs has barely been explored. Here, we report the electrostrictive response of the MAPbI3 hybrid perovskite crystals as large as 1% compressive strain under a field of 3.7 V/μm along the electric field direction with a corresponding to an electrostrictive coefficient of ~730 nm/V2 and mechanical energy density of 0.74 J/cm2. Superior to other electrostrictive materials, MAPbI3 demonstrates both large electrostrictive strain and large elastic energy densities under a small applied field. The electrostrictive strain is independent of the electric field polarity and has a quadratic dependence on the electric field. The electrostrictive response time is in the order of millisecond. The influences of piezoelectricity, thermal expansion, intrinsic electrostrictive effect, Maxwell stress, ferroelectricity, local polar fluctuation, and methylammonium cation ordering on this electromechanical response are excluded. We speculate, using density functional theory, that electrostriction of MAPbI3 likely originates from lattice deformation due to the formation of additional defects under applied bias. Since almost every electronic device either operates under applied electric field or experiences an internal built-in field which is close to the field of 3.7 V/μm inducing 1% strain, the discovery of electrostriction and its origin may also impact the design and performance of OIH-based electronic devices, including solar cells, LEDs, photodetectors, and radiation detectors. The discovery of large electrostriction in lead-iodide perovskites may lead to new potential applications in actuators, sonar, and micro-electromechanical systems, and aid the understanding of other field-dependent material properties.

Suppressed Phase Separation in Mixed-Halide Perovskites

Mixing different halogen ions provided a convenient means to tune the bandgaps of halide perovskites (e.g. CsPb(BrI)1-x). The so-called mixed-halide perovskites, however, suffered from severe phase separation under optical illumination. In this talk, we will present a facile approach to suppress such phase separation by making the mixed halide
perovskites into composites. The tuned bandgap remained remarkably stable even under optical illumination 440 W/cm²at 405-nm (The AM1.5 spectrum has an integrated power of 0.1 W/cm²). The mechanism responsible for the suppression of phase separation pointed to a model based on thermodynamic nucleation, which was further verified by the temperature dependent photoluminescence. The tuned and stabilized bandgap is expected to be essential for the development of perovskite-based optoelectronics, such as tandem or concentrated solar cells, full-color LED displays, or wavelength-specific photodetectors.

3:00 PM BREAK

3:30 PM *ES17.04.05

The perovskite crystal structure hosts a wealth of intriguing properties, and the renaissance of interest in halide (and hybrid organic-inorganic) perovskites (HOIPs) has further broadened the palette of exciting physical phenomena. HOIPs have recently received great attention as candidates for commercially viable and efficient conversion of solar energy. Breakthroughs in HOIP synthesis, characterization, and solar cell design have led to remarkable increases in reported photovoltaic efficiency. However, the observed long carrier lifetime and PV performance have eluded comprehensive physical justification, and the performance and stability of these materials is greatly affected by water and moisture in the environment.

In this talk, recent theoretical progress in understanding HOIPs will be reviewed and integrated with experimental findings, and we investigate the nature of water interactions in hybrid perovskite MAPbI₃. By varying water concentration over two orders of magnitude, we study the process of water infiltration and the surface and bulk chemistry that follows and leads to first reversible, and then irreversible changes to the material’s structure. We discuss, based on electronicstructure analyses, how water changes the optical properties of the material in different concentrations. In addition, the large amplitude motions of HOIPs will be highlighted, including ionic diffusion, anharmonic phonons, and dynamic incipient order on various length and time scales. The intricate relationships between correlated structural fluctuations, polar order, and excited charge carrier dynamics will also be discussed.

This understanding of the nature of water-HOIP interactions and ionic dynamics should lead to the design of better and more stable solar cells.

Impact of Bias-Induced Ion Migration in Perovskite-Based Light-Emitting Diodes Trung-Fang Guo¹,², Teng Lam Shen¹, Nan-Jay Chiou¹, Chun-Hua Shih¹, Jeng-Jun Chen¹, Ying-Chi Chen¹ and Loganathan Aswaghosh¹; ¹Department of Photonics, National Cheng Kung University, Tainan, Taiwan; ²Advanced Optoelectronic Technology Center, National Cheng Kung University, Tainan, Taiwan.

The electroluminescence (EL) intensity as well as the efficiency are usually low for perovskite-based light-emitting diodes (PeLEDs) biased at the low current density regime, but markedly raise to a maximal magnitude at the high voltage or current biasconditions. We observe a nonlinear EL intensity versus current density curve (L-I curve) of devices and attribute this observation to the bias-induced migration of ions in perovskite active layer (CH₃NH₃PbBr₃) to modulate the device performance. In this work, we utilize the ac impedance and photoluminescence (PL) spectroscopy to characterize the effect of ion migration in polycrystalline CH₃NH₃PbBr₃ layer. The passivation of ionic defects by the mobile ions as induced by the electric bias markedly enhances PL magnitude of the polycrystalline CH₃NH₃PbBr₃ layer in PeLEDs. Here, by adding a small amount of additives to the polycrystalline CH₃NH₃PbBr₃ layer possibly passivates the surface ionic defects and suppress the inter-grain ion migration. We find a decrease of ionic conductivity in perovskite active layer by the additives in impedance measurement. In addition, as characterized by SEM, XRD, and PL measurement, adding the additives reduces the average crystalline size, enhances PL intensity, and elongates the carrier lifetime, but did not change the basic crystal structure of CH₃NH₃PbBr₃ perovskite. We observe the linear correlations of L-J curve for devices biased at different current regimes and the markedly enhanced brightness and efficiency of PeLEDs at the low current regime to be the feature of a decent LED.

4:30 PM ES17.04.07
Roles of Solvate Complexes in the Kinetics and Reversibility of Light-Induced Phase Separation Rhiannon (Rhys) M. Kennard, Clayton J. Dahlman, Ryan A. DeCrescent, Jon Schuller, Ram Seshadri and Michael L. Chabinyc; University of California, Santa Barbara, Santa Barbara, California, United States.

Halo perovskite nanocrystals exhibit exceptional brightness in vivid colors and with narrow emission bandwidths, making these materials potential “game-changers” for display technologies and light-emitting devices more generally. Bandgap tunability over the entire visible spectrum can be easily accomplished via halide mixing, with mixed chloride-bromide perovskites emitting in the blue-green range and mixed bromide-iodide perovskites emitting in the green-red range. However, at sufficiently high excitation intensities or in larger-dimension mixed-halide perovskites, light exposure causes phase separation of bromide-iodide perovskites into Br-rich and I-rich regions, limiting the applicability of these materials. Because the I-rich regions formed have narrower bandgap than the Br-rich regions, charges become trapped in the I-rich regions, which limits carrier mobility and causes large anomalous red photoluminescence. Strategies to suppress this light-induced phase separation (LIPS) have involved reducing perovskite crystal size or filling halide vacancies. However, much still remains unknown regarding LIPS – in particular, the potential roles played by solvent complexes/ perovskite intermediates in enhancing or mitigating LIPS has not been explored. This talk will discuss the contributions of solvent complexes to the kinetics and reversibility of LIPS in methylammonium lead bromide-iodide thin films, and will illustrate LIPS mechanistic pathways that are not tied to solvates. The insights gained by this study are expected to aid future design of LIPS-free mixed-halide perovskite devices.

LIPS is characterized by an intense red photoluminescence signal near 1.7 eV that grows with time as the I-rich phase forms, combined with a reduction in emission from the original bandgap of the mixed-halide perovskite. The rate of red photoluminescence (red-PL) growth increased strongly when large amounts of solvent remained in the film, suggesting a dynamic process in which solvent complexes aid formation of I-rich phases under light exposure. Correspondingly, in harshly-annealed films, longer exposure times were needed to induce LIPS. LIPS occurred more slowly in Br-rich films than in I-rich films (all harshly-annealed), suggesting that defect accumulation near iodide is necessary to induce LIPS. In harshly-annealed films, LIPS red-emission spectra exhibited multiple previously-unreported emissive states, which was attributed to formation of intermediary I-rich and Br-rich phases before formation of the equilibrium I-rich and Br-rich phases. Finally, solvent complexes enhanced red-PL growth reversibility, as evidenced by greater reversibility in unannealed films. These results provide guidelines for synthesizing solvate-free mixed-halide perovskite films and potentially identify novel LIPS kinetic pathways. We anticipate that the insights gained by this study will aid in understanding LIPS and design of LIPS-free mixed-halide perovskite optoelectronic devices.

Insight into the Role of Ligands in Halide Perovskite Nanocrystal Synthesis and Tuning the Perovskite Structure, Shape and Size of the CsPbBr₃ Nanocrystal Youngtaek Yoo and Soo Young Kim; Chung-Ang University, Seoul, Korea (the Republic of).

Colloidal nanocrystals of inorganic cesium lead halide (CsPbX₃, X = Cl, Br, I, or combinations thereof) perovskites have attracted much attention for photonic and optoelectronic applications due to the high carrier mobility, easily tunable optical absorption range, manufacturing simplicity and low cost. The optical and electrical properties of the halide perovskites significantly depend on their crystal structure, shape and size. And there were many studies on the shape and size of perovskite nanocrystals related to reaction time,
reaction temperature, and ligand changes. However, the roles of the acid ligand and the amine ligand were not identified.

In this study, we are able to control the shape and size of CsPbBr$_2$ perovskite nanocrystals by using different kinds of the ligands and changing the concentration of the ligands. By observing these phenomena, we could understand the respective effects of acid ligand and amine ligand on the structure, shape and size of perovskite nanocrystals. The acid ligands influenced the structure and shape of the perovskite nanocrystals. With acetic acid ligand, the 2D perovskite structure CsPbBr$_2$ nanorods were synthesized through the facile ligand-mediated synthesis. The 3D perovskite structure CsPb$_{2}$Br$_5$ nanosheets were synthesized using other acid ligands. And small nanorods and nanospheres were mixed in some cases. The amine ligands had a large effect on the size of the perovskite nanocrystals. The size of the nanocrystals decreased as the amine ligand became longer, and the crystal size could be finely controlled by adjusting the amount of the amine ligand. We believe that our report helps to understand the synthesis of halide perovskite for the application in optoelectronic devices.

ES17.05.02
Unprecedented White-light Emission from the Deep Trap States of Two-Dimensional Perovskites ($\text{Cs}_x\text{CH}_3\text{NH}_3\text{PbBr}_3\text{Cl}_4$) for the Light-Emitting Diodes Mi Hee Jung; Department of Nanotechnology and Advanced Materials Engineering, Sejong University, Seoul, Korea (the Republic of).

Two-dimensional (2D) perovskite, which consists of inorganic layers bearing electronic functionality and organic layers that act as a template for the structure, has attracted a lot of attention due to their superior stable optoelectronic properties. Especially, one of the emerging applications for 2D perovskite is broadband white-light emission for solid state lighting. With the help of the facile one-step synthesis, the 2D perovskite structure CsPbBr$_2$ nanoparticles were synthesized using the mixture of different ligands. And small nanorods and nanospheres were mixed in some cases. The amine ligands had a large effect on the size of the perovskite nanocrystals. The size of the nanocrystals decreased as the amine ligand became longer, and the crystal size could be finely controlled by adjusting the amount of the amine ligand. We believe that our report helps to understand the synthesis of halide perovskite for the application in optoelectronic devices.

ES17.05.03
Synthesis of Core/Shell Perovskite Nanocrystal for Fabrication Wide-Color-Gamut LCDs Hyeongjin Lee, Hee Chang Yoon and Young Rag Do; Kookmin University, Seoul, Korea (the Republic of).

In this study, green (G) CsPbBr$_2$/CsPbBr$_3$ and red (R) CsPbBr$_{3.3}$-I$_{0.7}$/CsPbBr$_4$ core/shell perovskite nanocrystals (PeNCs) are synthesized and utilized for the development of highly efficient and wide-color-gamut PeNC-emissive liquid crystal displays (LCDs). The photoluminescence quantum yields (PLQYs) for G and R core/shell PeNCs reached 77.4% and ~78.9%, respectively. The improved photo-stability and water resistance of the GR PeNC films imply more opportunities to fabricate GR color-converting films with these materials to replace GR color filters (CFs) in conventional LCDs. The realization of color-by-blue PeNC emissive-LCDs can overcome technical challenges related to conventional CF-assisted LCDs through the realization of introducing improved device efficiency levels and an enlarged color gamut. The conversion efficiency rates of a color-by-blue core/shell PeNC-emissive LCD consisting of G and R PeNC films sandwiched in the form of a recycling bottom layer and a blue-filtering top dichroic filter are 42.0% and 44.3%, respectively. The color gamut was enlarged to 134% compared to the NTSC standard. The GR colloidal PeNCs and the fabricated PeNC-films were analyzed by TEM, XRD, and EDX in terms of their structural properties, and by PL and EL with an integrating sphere with regard to their optical properties. This color-by-blue PeNC-emissive LCD represents an excellent opportunity to create new emissive-LCD products to replace traditional RGB CF-assisted LCDs.

ES17.05.04
Development of Novel and Highly Stable Crystals of Lead-Free Double Perovskite Based-on Bismuth Tineh Ma and Chu Zhang; Kyushu Institute of Technology, Kitakyushu, China.

Recently, bismuth-based perovskites have aroused as a promising choice in replacing the lead-based perovskites due to its non-toxic and stable 6p-block structure properties. In addition, computational predictions suggest that Bi-based perovskite exhibits lower intrinsic trap densities and defect states, long carrier lifetime and its defect-tolerate properties which the lead-based perovskite nanocrystals (PeNCs) and lead-free double perovskite via one-step facile hydrothermal process. In this work, we provided an in-depth study on the CNBI crystal growth process under the influence of various acid concentrations and its plausible crystal growing mechanisms. We here present our work on the succession in synthesizing high crystallinity, stable, and novel Cs$_x$Na$_{3-x}$Bi$_2$I$_{6-x}$ lead-free double perovskite via one-step facile hydrothermal process. By using different kinds of the ligands and changing the concentration of the ligands. By observing these phenomena, we could understand the respective effects of acid ligand and amine ligand on the structure, shape and size of perovskite nanocrystals. The acid ligands influenced the structure and shape of the perovskite nanocrystals. With acetic acid ligand, the 2D perovskite structure CsPbBr$_2$ nanorods were synthesized through the facile ligand-mediated synthesis. The 3D perovskite structure CsPb$_2$Br$_5$ nanosheets were synthesized using other acid ligands. And small nanorods and nanospheres were mixed in some cases. The amine ligands had a large effect on the size of the perovskite nanocrystals. The size of the nanocrystals decreased as the amine ligand became longer, and the crystal size could be finely controlled by adjusting the amount of the amine ligand. We believe that our report helps to understand the synthesis of halide perovskite for the application in optoelectronic devices.

Blue-Emissive CsPbBr$_5$ Quantum Dots in a Gel Matrix Marta Valles-Pelarda, Carles Felip-León, César A. Angulo-Pachón, Juan F. Miravit, Francisco Galindo and Ivan Mora-Sero; University of Jaume I, Castellón, Spain.

Metal halide perovskite nanocrystals have been deeply studied in the last years due to their multiple properties and applications. These materials usually have a high photoluminescence quantum yield (PLQY), narrow emission bandwidth and their band-gap is tuned easily by changing the chemical composition of the nanocrystals or by varying their morphology from cubic structures to nanoplatelets. All these outstanding properties make them suitable for optoelectronic applications, sensors and lasers. For the entire visible range, emissive perovskite nanoplatelets have been achieved. However, high PLQY blue emissive nanoplatelets are still a challenge, with high chloride content having relatively low PLQY. Recently, 70% was reported for CsPb$_2$Br$_5$ nanoplatelets and in films 88%, obtained with a mixture of different perovskites. [1,2] In this work, a combination of CsPb$_5$Br$_9$ nanoplatelets and a gelator agent leads to a blue-emissive gel, with PLQY of ~70% which is a high value compared with the PLQY of the nanoplatelets themselves (~75%). Interestingly, depending on the structure of the gelator agent, different behaviors are observed, tuning the emission. In addition, they present a great stability in ambient conditions, after 4 months the PLQY decreased only 7%. The nanoplatelets and the gel with nanoplatelets were also characterized by TEM. [1] B. J. Bohn, Y. Tong, M. Gramlich, M. L. Lai, D. Doblinger, K. Wang, R. L. Z. Hoye, P. Muller-Buschbaum, S. D. Stranks, A. S. Urban, L. Polavarapu and J. Feldmann, Nano Letters, 2018, 18, 5231-5238.

ES17.05.06
Photoluminescence Properties of Ba(Mg$_{0.5}$Nd$_{0.5}$)$_2$O$_4$:Eu$^{3+}$ Red-Emitting Phosphor with High Color Purity Jie Shen, Zixing Wang, Jing Zhou and Wen Chen; Wuhan University of Technology, Wuhan, China.

Phosphor-based white light-emitting diodes (WLEDs) have become a kind of attractive solid light source due to their merits of being environmentally friendly and exhibiting energy savings, high brightness, high luminous efficiency and a long lifetime [1]. The white LEDs based on the near-UV (NUV) light chip and red/green/blue (RGB) primary phosphors have been widely studied for their tunable color rendering index and color temperature [2]. However, the red phosphors which can be excited by NUV light in the
range of 380-410 nm are facing challenges such as their low efficiency, instability and lack of red-color purity, resulting in low color rendering index and high color temperature of white light [3]. Therefore, it is of paramount importance to find a desirable red-emitting phosphor, with good thermal stability and strong luminescent intensity, which can be successfully excited by the NUV light.

In this work, Ba(Mg1/3Nb2/3)O3 was employed as a host of the phosphor with the considering of its low phonon energy [4] and good optical properties [5], and a new red phosphor, Eu3+ ions doped Ba(Mg1/3Nb2/3)O3 was prepared by wet chemical method. Structure characterization results show that all the BMN:Eu phosphors, with various doping contents, have long-range ordering hexagonal perovskite structures and Eu3+ ions replace Ba2+ ions occupying at 2d sites with C2v point symmetry in BMN. The phosphors exhibit the apparent absorption located at 395 nm which matches well with the emission of NUV LED chip, and show the bright red emission of D1s-F2 transitions under the excitation of 395 nm NUV light. The Commission Internationale de L’Eclairage (CIE) chromaticity coordinate (0.657,0.343) of BMN:5%Eu phosphor is close to the standard value (0.670, 0.330) of red phosphors, which indicates that BMN:Eu is a promising red-emitting phosphor for NUV-based WLEDs.

Yellow Emissive Near Ultraviolet Light-Emitting Diodes Using MAPbBr3 Perovskite as a Phosphor Seonghoon Jeong, Munisk Oh and Hyunsoo Kim; School of Semiconductor and Chemical Engineering, Chonbuk National University, Jeonju-si, Korea (the Republic of).

Recently, inorganic III-nitride compound semiconductors have been applied in various fields. In particular, light-emitting diodes (LEDs) are being used in a lot of lighting applications with long-term stability, high efficiency and the field of their use is expanding. The GaN-based LEDs has advantages of high efficiency and light emission of various wavelengths by the composition of In and Al. However, a high level of epitaxial growth technology is required, and it is difficult to form Ohmic electrodes according to the compositional change. To emit white light, a blue LEDs chip and encapsulated phosphors to emit yellow light and mixed with blue light. However, the emitted light reduces the conversion efficiency of 50–80% caused by Stokes loss.

Conventional inorganic white LEDs suffer not only loss of conversion efficiency but also heat generation and possible package deterioration. There have been many studies in many groups to overcome this problem. However, the efficiency of white LEDs using phosphor is not remarkable. Recently, optical device research using halide perovskites has been reported. Perovskite is a semiconductor material structure with cubic AMX3 (A, M cation, X anion) composed of metal and halogen elements. It can control the emission spectrum by changing the element. Metal halide perovskite has been extensively studied as an active layer of solar cells and optical devices. Perovskite has advantages such as high carrier mobility, wavelength change due to halogen element composition, simplicity of process and low cost, so that it is competitive as a photoelectric material. However, it has a drawback that it is very vulnerable to oxygen and moisture, and research is underway to improve it. Many studies have used the high absorbance of perovskite as an active layer. However, we did not use it as an active layer but as a phosphor to convert light emitted from UVLEDs.

In this study, we synthesized perovskite and studied the fabrication method of LEDs which emits yellow light by using synthesized perovskite with UVLEDs phosphor. The synthesized MAPbBr3 was confirmed to have a wavelength peak of 539 nm using the photoluminescence (PL). The Br-containing perovskite was coated under the substrate of the fabricated UVLEDs and the electroluminescence (EL) spectrum was analyzed using a probe-station system equipped. The wavelengths of typical UVLEDs were observed 365 nm main peak wavelength and deep-level wavelength in the range of 500-600 nm. In contrast, UVLEDs coated with perovskite exhibit a stronger light emission at 539 nm with a wavelength of 365 nm and a distinct difference is observed through the emission image. The wavelength of the emitted UV region emitted from the UVLEDs emitted light at 539 nm due to absorption in the coated perovskite. Since the emission spectrum of perovskite is easily adjustable, our novel method will be a new avenue for white LEDs using perovskite instead of conventional phosphors.

ES17.05.08
New Cross-Linkable Hole Transporting Materials for Perovskite LEDs Seokwoo Kang1, Seonwoo Park1, Tae Wan Kim2 and Jongwook Park1; 1Chemical Engineering, Kyung Hee University, Suwon, Korea (the Republic of); 2Physics, Hongik University, Seoul, Korea (the Republic of).

In conventional organic light emitting diode (OLED) as well as perovskite light emitting diode (pLED) device, polyvinyl carbazole (PVK) and Poly-TPD have been widely used as a hole transporting layer (HTL) in the past. However, PVK and Poly-TPD have disadvantage in terms of soluble property limitation during stacked-soluble process device preparation. Therefore, we synthesized new cross-linkable HTL polymer, SMFP-DNBp for pLED device. It has non-soluble property to general solvent after thermal treatment and curing process. It includes phenyl naphthyl group, spirofluorene, and vinyl group. The device configuration is ITO/PEDOT:PSS-PSS:Na/ SMPF-DNPB or others/2D perovskite/TOPO/TBb/LiF/Al. When new HTL materials were used, it showed high luminance efficiency of more than 10 Cd/A in green pLED device.

ES17.05.09
Low Temperature Photoluminescence Mapping of Solar Cells Andrew J. Baker1, 2, Steve Johnston2 and Dana Sulas2; 1Clairmont University, Freedom, Pennsylvania, United States; 2National Renewable Energy Laboratory, Golden, Colorado, United States.

Photoluminescence mapping provides spatial information about a semiconductor’s (photovoltaic’s) defects, efficiency, bandgap, uniformity, and other important properties. Near liquid helium temperatures, photoluminescence peaks in the spectra become sharper than those observed at higher temperatures, and transitions not resolved at room temperature become observable. An automation system was designed to collect low temperature photoluminescence maps of solar cells to exploit the extra information obtained from cooling the sample being mapped. The photoluminescence spectra were collected from the sample at different temperatures by inserting the sample in a helium-based closed-cycle cryostat.

Automation was developed in which a LabView application controls the low temperature PL mapping process. This involved controlling the following mapping components: motion stages to scan the incoming light source and optics, the temperature of the cryostat, and the PL data collection via a spectrometer/camera combination. The result of combining these components was a system that generates PL maps at temperatures as low as ~8 K. A spatial filter was added to the system to remove signal generated from anywhere other than the point of interest. This addition helped the system approach the theoretical resolution achievable. The completed prototype will be used to study degradation of perovskite solar cells among other types of solar cells.

ES17.05.10
Functionalized Grain Boundaries in Halide Perovskite Materials and Devices Yuanyuan Zhou; Brown University, Providence, Rhode Island, United States.

Grain boundaries (GBs) are the most prominent microstructural features that play significant roles in determining the chemical and physical properties of halide perovskite (HP) thin films. Herein, we demonstrate the concept of ‘GB functionalization’ to manipulate the GB structures in a rational way. The detailed microstructures of functionalized GBs are carefully characterized, which are co-related to the enhanced properties and optoelectronic performance. In addition, the formation mechanisms of these functionalized GBs in HPIs are elucidated.

Efficient and Stable Ti- and Sn-Based Lead-Free Perovskite Solar Cells Min Chen1, Minggang Ju2, Xiao C. Zeng2, Yuanyuan Zhou1 and Nitin P. Padture1; 1Brown University, Providence, Rhode Island, United States; 2University of Nebraska–Lincoln, Lincoln, Nebraska, United States.

The state-of-the-art high efficiency perovskite solar cells (PSCs) contain lead and organic cations in the perovskite light-absorber. However, the toxicity associated with the lead and the volatility of the organic cations are hurdles in the path towards the future commercialization of PSCs. While there has been effort towards replacing lead cation with less toxic cations, typical lead-free PSCs still suffer from the low power-conversion efficiency (PCE) and poor stability. Herein, we were firstly inspired by calculation results from Ti-
Based robust double perovskite materials and then realized the PCE (> 3%) on such materials. Meanwhile, we utilized an alloying strategy in all-inorganic Sn-based perovskite materials and realized those PSCs with a promising PCE (> 7%). Furthermore, the formation native-oxide layer passivation effect resulted in superior air-stability for these perovskite materials. Thus, this work provides a new avenue for the design and development of high performance and stable Lead-free PSCs.

ES17.05.12
Extra-Large Grain Formation in Formamidinium Lead Iodide Perovskite Thin Films and Observation of Special Sub-Grain Boundaries Srinivas K. Yadavalli, Wenhai Li, Yuanyuan Zhou, Rashid Zia and Nitin P. Padture; Brown University, Providence, India.

Formamidinium Lead Iodide (FAPI) based perovskites have achieved a great deal of interest as solar cell absorbers due to their superior thermal stability and more suitable band gap compared to methylammonium based perovskites. Here, we report a new phenomenon, where fine-grained (~175 nm)-FAPII thin films transform rapidly to phase-pure n-FAPII. OHII thin films with ultra large grain size exceeding an unprecedented ∼5μm. The large grain nature of the films is confirmed using appropriate materials characterization. 

The improved kinetics of transformation is explained by studying the phase and morphological evolutions during film-solvent interaction. The nature of phase nucleation and growth is studied through in-situ microscopy techniques. In-situ X-ray diffraction and solvent polarity effect on the transformation rate also are studied to corroborate the proposed mechanism. Photoluminescence microscopy was carried out to probe into carrier diffusion within grains and grain boundaries. Eventually, the entire grain gives identical EBSD signal, it was observed that there exist sub-grain boundaries which obstruct carrier diffusion within the grains and likely limit the electronic properties. The passivation or tampering of sub-grain boundaries can become critical in improving the optoelectronic properties and hence need to be investigated further.

ES17.05.13
Magnetic Ordering of a Perovskite-Like La-, Nd-, and Gd-Doped Bismuth Ferrite Valery Sobol1, Barys Korzun2, Olga Mazurenko1, Temirkhan Bzhigistov4 and Sabit Tomaev4, Belarusian State Pedagogical University, Minsk, Belarus; 1The City University of New York, BMCC, New York, New York, United States; 2Belarusian Republican Foundation for Fundamental Research, Minsk, Belarus; 3Taraz State Pedagogical University, Taraz, Kazakhstan.

Bismuth ferrite (BiFeO3) is promising as magneto-electric material because both ferroelectric and antiferromagnetic orders coexist in this material at room temperature. Doping of BiFeO3 or the substitution of bismuth by other chemical elements can modify its magnetic properties. The goal of this paper is to determine the influence of bismuth substitution by rare earth elements La, Nd, and Gd on magnetic ordering in bismuth ferrite.

Substitutional alloys of BiFeO3 of the types Bi1-xLaxFeO3, Bi1-xNdxFeO3, and Bi1-xGdxFeO3 were synthesized by solid-state reaction method using powders of Bi2O3, Nd2O3, Gd2O3, La2O3, and Fe2O3 oxides of pure grade quality. The X-ray diffraction method was applied using the diffractometer Dron-3 on Cu Kα radiation to control crystal structure. Experimental data were collected during scanning, which was repeated ten times in the 2θ range from 20° to 90° at the scanning speed of 10°/6 min. The magnetization was measured using an automated vibrating sample magnetometer (VSM, Oxford instruments) in magnetic fields up to 1 T. Temperature measurements were carried out using Physical Property Measurement System equipped with a 9 T superconducting magnet (PPMS: Model 6000, Quantum design).

It was found that undoped samples of bismuth ferrite BiFeO3 show typical temperature dependence of magnetization, namely the jump of magnetization at 640 K and a lowering of ferromagnetic ordering—below this temperature. Total substitution of 0.10 - 0.15 atomic part of Bi by La, Nd, and Gd leads to the paramagnetic behavior of the doped bismuth ferrite at low temperatures in a wide range of magnetic field. Strong nonlinear dependence of magnetization on the magnetic field at low temperatures was detected. A ferromagnetic-like dependence of magnetization was observed for small magnetic fields. It can be explained by the exchange interaction between doping magnetic ions, as well as by the exchange interaction of these ions with ions of iron. It can be concluded that it is possible to change the initial magnetic ordering of bismuth ferrite by its doping by rare earth elements for the concentrations smaller than 0.10 atomic part of the doping element.

ES17.05.14
Low-Dimensional Lead-Free Halide Perovskites with Functional Organic Spacers Minggang Ju and Xiao C. Zeng; Department of Chemistry, University of Nebraska-Lincoln, Lincoln, Nebraska, United States.

Low-dimensional organic-inorganic halide perovskites (OIHs) have been hot topic lately for solar-cell applications, largely owing to their markedly high chemical stability. However, most low-dimensional OIHs show much lower device performance than their 3D counterparts, due mainly to the strong quantum-confinement and dielectric effects. Both properties are highly dependent on the “inorganic” component of 2D OIHs, while the “organic” component only improves the stability of 2D OIHs. We come up with an idea that functionalization on the “organic” component could open a door for designing new materials with much improved properties. We find that by introducing organic n-conjugate molecules, we can design a series of 2D OIHs with type II band alignment with two parallel high speed channels for hole and electron transfer, respectively. Remarkably, these 2D OIHs possess not only optimal bandgap, but also desirable optical absorption spectrum as well as high carrier mobility. Most importantly, we can modify the optoelectronic properties of these 2D OIHs by either changing halogen atoms, π-conjugate diaminoniums and/or layers of “inorganic” component for specific applications. These findings point out a new materials-design strategy for overcoming the charge-trap issue with the low-dimensional OIHs. We expect this work will draw broad attention from both organic and inorganic chemistry communities and materials science community.

SESSION ES17.06: New Physics in Halide Perovskites

8:30 AM *ES17.06.01
Exciton Spin Coherence in Hybrid Organic-Inorganic Perovskites Van Li; University of Utah, Salt Lake City, Utah, United States.

The hybrid organic-inorganic perovskites are an emerging class of semiconductors that have excellent optoelectronic properties, even being solution processed. These compounds also hold great promise for the field of spintronics due to their large and tunable spin-orbit coupling, spin-dependent optical selection rules, and predicted electrically tunable Rashba spin splittings. We demonstrate the optical orientation of spin-polarized excitons and spin coherence in polycrystalline films of MAPbI3 using time-resolved Faraday rotation measurement. The exciton spin coherence is manifested as oscillations of spin polarization in a transverse magnetic field, with a life time exceeding 1 ns at 4 K. The nanosecond spin coherence is quite surprising given that Pb and I exhibit large spin-orbit couplings. There are two frequencies in the oscillations show linear relationship with the transverse magnetic field, and the slopes give two g-factors which we assign to electrons and holes as g_e = 2.63, and g_h = 0.33. The energy dependence of the Faraday rotation follows the exciton absorption band at low temperatures, confirming its excitonic origin. However, exchange couplings of the excitons are very small (< 1 micro eV) in comparison to traditional semiconductors. We will discuss the possible spin relaxation mechanisms and unusual exciton spin physics.

9:00 AM *ES17.06.02
Spin-Orbital Coupling Effects in Perovskite Photovoltaic and Light-Emitting Devices Ranging from 3D to 2D Design Bin Hu; Materials Science and Engineer, The University of Tennessee, Knoxville, Knoxville, Tennessee, United States.

Organic-inorganic semiconductor perovskites have demonstrated very attractive room-temperature magneto-optical response, remarkable photovoltaic actions, high light-emitting properties, and low-threshold lasing actions, to become emerging multifunctional materials. On the other hand, organic-inorganic semiconductor perovskites possess a strong spin-orbital coupling within electrically polarizable semiconductor framework consisting of organic and inorganic components in ABX3 structure. In general, spin-orbital coupling can generate three major outcomes: (i) Rashba effect, (ii) spin mixing between different states, and (iii) electric-magnetic coupling in such hybrid perovskites. It should be pointed out that organic-inorganic semiconductor perovskites show significant orbital momentum to form a strong spin-orbital coupling with spin momentum. Therefore, using
orbital momentum presents a unique mechanism to tune the optoelectronic properties in such hybrid perovskites. We found that changing from 3D to 2D perovskites changes the internal interaction from short-range spin-spin interaction to long-distance orbital-orbital interaction, leading to distinct SOC effects on the populations on dark and bright states towards developing photovoltaic and light-emitting actions. On the other hand, we observed that the spin-orbital coupling can be changed by grain boundary polarization, leading to a convenient method to tune the spin-orbital coupling through doping and mechanical stress. Moreover, using the spin-orbital coupling presents a practical approach to remove the light-emitting loss from dark states in perovskite LEDs. In summary, this presentation will discuss the spin-orbital coupling effects involved in photovoltaic and light-emitting devices from 3D to 2D perovskites.

9:30 AM ES17.06.03 Computational Study of Polaron Emission in CsPbBr Nanocrystal Aaron Forde and Dmitri S. Klin; North Dakota State University, Fargo, North Dakota, United States.

Inorganic CsPbX₃ (X=Br,Cl) lead halide perovskites are of interest for photovoltaic and light-emitting applications due to long charge carrier diffusion lengths and tunability of the bandgap to generate photoluminescence (PL) with efficient quantum yields (QY). In the bulk morphology, the long charge carrier diffusion lengths are attributed to large polaron formation due to a ‘soft’ crystal lattice, which is inferred from infrared (IR) absorption. Polaron formation significantly reduces PL in films of CsPbX₃ NCs due to localization of photo-excited electrons and holes. A way to enhance IR polaron emission would be to confine the polaron which would significantly increase the spatial overlap of electron and hole states. CsPbX₃ nanocrystals (NCs) provide an excellent framework to explore the possibility of efficient IR polaron emission. Using a fully-passivated CsPbBr₃ NC atomic model, we compute spinor Kohn-Sham orbitals (SKSOs) with spin-orbit coupling (SOC) interaction as a basis to calculate efficiency of polaron emission. Efficiency of emission is determined from non-radiative recombination (kₚ) and radiative recombination (kᵣ) as kᵣ/(kᵣ + kₚ). Implications of this work provide framework for utilizing CsPbX₃ NCs as IR sensors.

9:45 AM ES17.06.04 Spin-Selectivie Light-Matter Interaction in Lead Halide Perovskites David Giovanni¹, Nirpan Mathews², ³, Subodh Mhasalkar², ³ and Tze Chien Sum¹; ¹School of Physical and Mathematical Sciences, Department of Physics and Applied Physics, Nanyang Technological University, Singapore, Singapore; ²School of Materials Science and Engineering, Nanyang Technological University, Singapore, Singapore; ³Energy Research Institute @ NTU (ERI@N), Nanyang Technological University, Singapore, Singapore.

Optical control of electron’s spin in a material system will lead to novel technological branch called as opto-spintronics. Conventional inorganic semiconductors (e.g. III-V and II-VI systems) face major challenges such as of lattice-matching and arduous fabrication processes. Moreover, optical spin control in most of these systems also requires cryogenic cooling. Herein, we propose lead halide perovskites as robust alternatives, where their band structures allows resonant excitation of 100% spin-polarized carriers/excitations. Few of their robustness to be highlighted: (i) ultra-large photoinduced Faraday rotation up to 10²°/μm in 3D perovskites, which is the largest reported up to our knowledge; and (ii) room-temperature tunable spin-selective optical Stark effect in 2D perovskites, which is a few times stronger than in the inorganic. Time-resolved studies on the spin-populations show that the spin-coherence live for a few ps in the 3D and few hundreds of fs in the 2D, due to Elliot-Yafet scattering and exciton exchange-interaction, respectively. Importantly, these works demonstrate robust optical control over spin-states, our result suggests the potential of perovskites for opto-spintronics applications.

10:00 AM BREAK

10:30 AM ES17.06.05 Epitaxy of Halide Perovskite Thin Films and Nanostructures Jian Shi; Rensselaer Polytechnic Institute, Troy, New York, United States.

Vapor-based epitaxial synthesis of halide perovskites remains rather limited. In this work, we present our recent progress in synthesizing epitaxial halide perovskite via a couple of epitaxy mechanisms. By van der Waals epitaxy, centimeter-scale in-plane interconnecting networks of CsPbBr₃ microwires and CsPb (Br₁, I₃₋ₓ) heterojunctions have been synthesized. By ionic epitaxy, single-crystalline CsPbBr₃ and CsSnI₃ films were grown on water-soluble NaCl substrates, which provides solutions for free-standing wafer-scale 3D-perovskite single-crystalline films. It is also shown that the concept of van der Waals epitaxy could be applied to the growth of Ruddlesden-Popper phase halide perovskite films. The epitaxial halide perovskites show unprecedented optoelectronic properties and phase transition behaviors.

11:00 AM ES17.06.06 Tuning Physical Properties of Halide Perovskites Using Composite Structures Hanwei Gao; Florida State University, Tallahassee, Florida, United States.

Halide Perovskites have shown potential for developing high-performance cost-effective optoelectronics. Previous work in this field was primarily focused on pristine perovskites. We discovered that perovskites in form of composites can exhibit more desirable physical properties with improved material stability. In this talk, I will discuss the correlation between material morphology and physical properties in composite halide perovskites, and their performance as light emitters.

11:30 AM ES17.06.07 Femtosecond Time-Resolved Excited State Dynamics at Interfaces and in the Bulk of MAPbI₃-xClₓ Clemens Burda; Chemistry, Case Western Reserve University, Cleveland, Ohio, United States.

The synthesis and excitonic properties of methylammonium lead halide perovskites and their mixed halides are presented with a focus on time-resolved photoluminescence and transient absorption spectroscopy. The substitution of a fraction of iodide with chloride anions leads to a distorted unit cell due to the smaller radius of the chloride anion relative to the iodide ion and thus to decreased symmetry and an increased band gap. Femtosecond laser induced transient absorption and photoluminescence measurements show that interface defects contribute to the relaxation processes in photoexcited perovskites. Under two-photon excitation, longer excited state lifetimes could be assigned to the lowest exciton with surprisingly different characteristics compared to the one-photon created states. Origins and implications of these materials properties will be discussed.

11:45 AM ES17.07.08 Tailoring Properties of Hybrid Perovskites by Domain-Width Engineering with Charged Walls Yurong Yang¹, ², Lan Chen³, Charles Paillard², Hong Jian Zhao¹, Jorge Iñiguez³ and Laurent Bellaiche³; ¹Nanjing University, Nanjing, China; ²University of Arkansas–Fayetteville, Fayetteville, Arkansas, United States; ³Luxembourg Institute of Science and Technology, Alzette, Luxembourg.

Charged ferroelectric domain walls are fascinating electrical topological defects that can exhibit unusual properties. Here, in the search for novel phenomena, we perform and analyze first-principles calculations to investigate the electrical domain width on properties of domains with charged walls in the photovoltaic material consisting of methylammonium lead iodide hybrid perovskite. We report that such domains are stable and have rather low domain wall energy for any investigated width (that is, up to 13 lattice constants). Increasing the domain width first linearly decreases the electronic band gap from about 1.4 eV to about zero (which therefore provides an efficient band-gap engineering), before the system undergoes an insulator-to-metal transition and then remains metallic (with both the tail-to-tail and head-to-head domain walls being conductive) for the largest widths. All these results can be understood in terms of (i) components of polarization along the normal of the domain walls being small in magnitude; (ii) an internal electric field that is basically independent of the domain width; and (iii) rather negligibly charge transfer between walls. These findings deepen the knowledge of charged ferroelectric domain walls and can further broaden their potential for applications, particularly in the context of halide perovskites for photovoltaics.
The remarkable solar performance of lead halide perovskites can be attributed to their excellent physical properties that present many mysteries, challenges, as well as opportunities. Better control over the crystal growth of these fascinating materials and better understanding of their complex solid state chemistry would further enhance their applications. Here I will first report new insights on the crystal growth of perovskite materials and the solution growth of single crystal nanowires and nanoparticles of methylammonium (MA), formamidinium (FA), and all-inorganic cesium (Cs) lead halides perovskites (APbX₃) via a dissolution-recrystallization pathway. We also developed the epitaxial growth of perovskite materials and 2D heterostructures with controlled phases. Moreover, chemical strategies to stabilize the metastable perovskite phases, such as FAPbI₃ and CsPbI₂Br were developed by using surface ligands to manipulate the delicate thermodynamic and kinetic balance between 3D and 2D layered perovskites. We demonstrated high performance room temperature lasing with broadband tunability of emission with these single-crystal perovskite nanowires. The excellent properties of these single-crystal perovskite nanostructures of diverse families of perovskite materials with different cations, anions, and dimensionality make them ideal for fundamental physical studies of carrier transport and decay mechanisms, and for enabling high performance lasers, LEDs, and other optoelectronic applications.

Semiconductor quantum wells and superlattices, which are usually fabricated through metal-organic chemical vapor deposition or molecular beam epitaxy, are key building blocks in modern optoelectronics. The ability to simultaneously realize defect-free epitaxial growth and to individually fine-tune the chemical composition and band structure of each layer is essential for achieving the desired performance. Such structures are challenging to realize using organic or hybrid materials because of the difficulty of controlling the materials growth. In this talk, I will present a molecular approach to the synthesis of high-quality organic-inorganic hybrid perovskite quantum wells through incorporating widely tunable organic semiconductor building blocks. By introducing sterically tailored groups into the molecular motif, the strong self-aggregation of the conjugated organic molecules can be suppressed, and single crystalline organic-perovskite hybrid quantum wells (down to one mono-layer thick) and superlattices can be easily obtained via one-step solution-processing. Energy transfer and charge transfer between adjacent organic and inorganic layers are extremely fast and efficient, owing to the atomically-flat interface and ultra-small interlayer distance. The 2D hybrid perovskite superlattices are surprisingly stable, due to the protection of the bulky hydrophobic organic groups. The molecularly engineered 2D semiconductors are promising candidates for use in next-generation nanoelectronics, optoelectronics, and photonics.

Our study centered on perovskite core-shell structure and excitonic oscillator strength of perovskite nanocrystals. The optical response was studied to shed light on why the very poor light emitter CsPbBr₂ becomes a high-efficiency fast emitter when imbedded as nanocrystals in the wider gap host CsPbBr₃. Kinetics at a high carrier density of pure (extended) CsPbBr₂ and the nano-inclusion composite were measured and analyzed, indicating second order kinetics in extended and mainly first-order kinetics in the confined CsPbBr₂, respectively. Analysis of absorption strength of this perovskite imbedded nanocrystal composite relative to pure CsPbBr₂ indicated enhanced oscillator strength. We successfully implanted the CsPbBr₂-CsPbBr₃ core-shell structure into the application of light emitting diode. The type I heterojunction between CsPbBr₂ and CsPbBr₃ indicated multi-quantum wells structure which efficiently collected the carriers into the CsPbBr₂ nanocrystals for the high yield radiative recombination. We also demonstrated the CsPbBr₂ nanocrystals could be greatly stabilized by CsPbBr₃ solid matrix dramatically improving the device reliability. On the other hand, our study addressed the potential scintillator application of the perovskite core-shell single crystal.

Crystal instability has been a major drawback hindering the commercialization of perovskite based devices. In this work, we demonstrate enhanced crystal stability and phase arrest at low temperatures in perovskite quantum dots, surface functionalized with 3-aminopropyl triethoxysilane. We studied temperature dependent crystal phase transitions in CH$_3$NH$_3$PbBr$_3$, Perovskite quantum dots (PQDs) ligated with octylamine bromide (P-OABr) and 3-aminopropyl triethoxysilane (P-APTES), using a framework of static and dynamic spectroscopy. P-OABr undergoes the expected structural phase transition from tetragonal to orthorhombic phase at ~140 K, established by the emergence of a higher energy band at 2.64 eV in the photoluminescence (PL) spectrum, while no phase transition was observed in the case of P-APTES. Such phase stabilization is a result of variation in their respective surface energies, an important contributing factor to the Gibbs free energy for nanomaterials. On further investigating the consequences of this altered crystal phase diagram using time-resolved PL, excitation power dependent PL and Raman microscopy over a range of 300 – 20 K, we observe significant differences in recombination rates and charge carrier types between P-APTES and P-OABr. Our findings highlight how aspects of PQD phase stabilization are linked to nanoscale morphology and the surface energy manipulation of the crystal phase diagram, providing critical insights into the synthesis of stable perovskite crystals for device implementation.

Low Band Gap Lead Iodide Perovskite Nanocrystals and Their Application in LED Raihana Begum; Nanyang Technological University, Singapore, Singapore.

Perovskite nanocrystals of lead halide with an efficient absorption of UV-Visible and near-infrared light as well as their remarkable performance in optoelectronics devices have recently emerged as an extremely important class of semiconductor materials in both solar and optoelectronic communities. Despite the substantial developments in the synthesis and characterization of these nanocrystals, the low band gap nanocrystals, are not much explored perhaps due to their instability issues related to phase degradation. We have developed synthesis methods that yields high stability in terms of colloidal and phase stability for CsPbI$_3$ and FAPbI$_3$ nanocrystals, further we will also present our latest research on red LED and near infrared LED. In addition, we have recently demonstrated multiple exciton generation (MEG) from internally confined FAPbI$_3$ nanocrystals. So far, MEG from this material could not be achieved due to weak confinement. However, our nanocrystals (band gap <1.7 eV, emission >750 nm) are size-confined. The smallest of the FAPbI$_3$ NCs (7.5 nm) are found to be most efficient in MEG. The nanocrystals have small band gap with suitable confinement needed for MEG. For this, we have optimised the phase stabilization condition in order to achieve phase stability without any extrinsic doping. More importantly, by centrifugation at three different speed, we have been able to achieve homogeneous size distribution that overcome degradation by Ostwald ripening of NCs.

Manipulating the Excited State of CsPbBr$_3$ Nanoplatelets for Superior Optical Properties Thomas Morgenstern; Matthew Jurow; Carissa N. Eisler; Jun Kang; Paul Alivisatos; Yi Liu; Wolfgang Brütting; Manual Engelward. 1University of Augsburg, Augsburg, Germany; 2Chemistry Department, University of California, Berkeley, California, United States; 3Molecular Foundary, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 4MATERIALS Science Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Lead halide perovskite (LHP) nanocrystals (NCs) and their light emitting properties have recently moved into the focus of optoelectronic applications. Due to their narrow emission linewidths and high quantum yields, LHP NCs are promising materials for display and lighting technology. Especially within the blue emission regime, they could even outperform their organic counterparts. However many properties of emissive LHP nanoparticles remain to be investigated for a complete understanding of their optoelectronic properties.

One of the core concepts for efficient organic light-emitting diodes (OLEDs) is the preferential alignment of the emissive transition dipole moments within the emitting layer of the device. Using this effect the external quantum efficiency of purely organic devices can easily exceed 30%. However, within the context of LHP NCs this effect is rarely investigated. Recently the orientation of the emissive transition dipole of LHP nanocrystals could be determined to be vertical with respect to the film surface, hampering the maximum achievable quantum efficiency of LED applications.

To overcome this limitation we investigated the orientation of the emissive transition dipole moment of CsPbBr$_3$ nanoplatelets. Compared to their cubic counterpart, which do not show any form of quantum confinement, these NCs exhibit weak quantum confinement within the dimensions of the plates. This feature leads to huge differences in the optical properties of the excited state. As a first consequence the energy of the emission peak shifts to shorter wavelengths, resulting in an emission peak at 460nm for the investigated nanoplatelets. Further the orientation of the transition dipole moments is confined in space and therefore aligns within the plane of the substrate. Combined with the high refractive index of the perovskite material, the NCs have the potential to outperform existing solutions for blue emitting devices within display and lighting applications.

Continuous Flow Synthesis and Anion Exchange of Colloidal Perovskite Quantum Dots Milad Abolhasani; NC State University, Raleigh, North Carolina, United States.

Since the discovery of colloidal metal halide perovskite quantum dots (QDs) three years ago,[1] they have rapidly grown to become one of the most promising classes of nanomaterials for applications in low-cost and highly efficient optoelectronic devices. Anion exchange reactions of the highly luminescent perovskite QDs provide a facile post-synthetic route for tuning of the absorption/emission bandgap of these exciting nanocrystals. The post-synthetic anion exchange reactions allow precise bandgap tuning of perovskite QDs tailored for the desired application. Synthesis, screening, and optimization of colloidal QDs are conventionally conducted using the time- and material-intensive flask-based approaches. Process optimization is therefore limited by the sampling rate, off-line analysis time, and batch reactor/reaction process control. Batch reactors suffer from crystal instability has been a major drawback hindering the commercialization of Perovskite based devices. In this work, we demonstrate enhanced crystal stability and phase arrest at low temperatures in perovskite quantum dots, surface functionalized with 3-aminopropyl triethoxysilane. We studied temperature dependent crystal phase transitions in CH$_3$NH$_3$PbBr$_3$, Perovskite quantum dots (PQDs) ligated with octylamine bromide (P-OABr) and 3-aminopropyl triethoxysilane (P-APTES), using a framework of static and dynamic spectroscopy. P-OABr undergoes the expected structural phase transition from tetragonal to orthorhombic phase at ~140 K, established by the emergence of a higher energy band at 2.64 eV in the photoluminescence (PL) spectrum, while no phase transition was observed in the case of P-APTES. Such phase stabilization is a result of variation in their respective surface energies, an important contributing factor to the Gibbs free energy for nanomaterials. On further investigating the consequences of this altered crystal phase diagram using time-resolved PL, excitation power dependent PL and Raman microscopy over a range of 300 – 20 K, we observe significant differences in recombination rates and charge carrier types between P-APTES and P-OABr. Our findings highlight how aspects of PQD phase stabilization are linked to nanoscale morphology and the surface energy manipulation of the crystal phase diagram, providing critical insights into the synthesis of stable perovskite crystals for device implementation.

2. Epps et al., Lab Chip 17, 4040–4047 (2017).
At the broadest level, the photoluminescence (PL) spectra of these materials show a massive Stokes shift compared to the corresponding absorption onset. Broadband emission is attributed to the formation of self-trapped excitons (STEs) due to the strong electron-phonon coupling. Interestingly, it has been observed in only certain three-dimensional and low-dimensional metal halide perovskites. In this talk, we will show how density-functional theory calculation that multiple STE structures exist in each perovskite exhibiting broadband emission. However, only the STE with Jahn-Teller like octahedral distortion is mainly responsible for the observed broadband emission, though it may not be the lowest energy structure. Our results provide important insights for designing perovskite materials for broadband emissions with preferred chromaticity coordinate or color temperature.

Prospects of widespread perovskite optoelectronics are contingent on the ability to exploit the unique photophysics of such class of materials for device functionality [1]. Photocarbonizing devices, like solar cells, as well as light-emitting ones, like LEDs and lasers, work best when non-radiative recombination is reduced, either by passivating traps and defects or by boosting radiative recombination rates. Concerning solar cells, the optimal Shockley-Queisser photoconversion efficiency is achieved precisely in the radiative limit, when the only carrier loss is optical emission. We demonstrate a technique, based on the absolute photoluminescence quantum yield as a function of the excitation intensity, to measure the photoconversion open circuit voltage (the free energy) and the ideality factor without any current flowing through the film [2]. A picture emerges of selective traps creating unbalanced free electron and hole populations, universally shared by perovskite materials with various compositions and fabrication routes. We identify interfaces or materials that are the limiting the solar cell photocathedral efficiencies and highlight a rational method to optimize solar cells.

The very nature of the optical emission process in perovskites, whether it comes from a direct or indirect bandgap, is actively debated, as recent studies have proposed that the Rashba spin orbit coupling gives rise to an indirect gap, few tenths of meV lower in energy than the direct one. The instantaneous intensity of photoluminescence under pulsed excitation provides measurements for the radiative recombination rates in halide perovskites and shows that radiative recombination becomes faster with decreasing temperature, as in all direct bandgap materials and contrary to what expected for 3D Rashba semiconductors [3]. As for strategies to boost light emission at low excitation levels, carrier confinement enhances local concentration of photoexcitations either in mixed 2D-3D materials or quantum-dot-in-a-matrix architectures, where a low concentration of localized excited states can be filled efficiently even by photoexcitation even in the low excitation regime [4], leading to efficient LEDs or low-threshold lasers.

Given the major progress achieved in perovskite devices by understanding their photophysics, deployment of optical spectroscopy tools will provide crucial guidance for the understanding of the ultrafast dynamics and sub-picosecond processes observed in photoexcited perovskites.

Element-Specific Contributions to the Electronic Structures of Inorganic Cesium Lead Halide Perovskites Revealed by Resonant X-Ray Photoelectron Spectroscopy
Xuechen Jiao, 1, 2, 3, 4
1 University of Melbourne, Melbourne, Victoria, Australia; 2 Australian Synchrotron, Australian National University and Technology Organisation, Melbourne, Victoria, Australia.

Inorganic cesium lead halide perovskites (such as CsPbBr$_3$) constitute an emerging class of high performance semiconducting materials, delivering promising device performances in solar cells and light emitting devices. Despite the rapid development of device optimisation, many fundamental issues remain open. One of the questions attracting huge attention is: do the constituent elements contribute equally to the electronic structures of perovskites? To address this, synchrotron-based resonant photoelectron spectroscopy (resPES) was employed to resolve the low binding energy region from -5 eV to 100 eV (valence band and shallow core levels) of a model inorganic perovskite material – CsPbBr$_3$, which delivers high air stability and satisfactory solar cell performance. Taking advantage of the energy tunability provided by synchrotron, the incident X-ray energy was tuned around the absorption edges of the component elements, including Cs, Pb, Br, and I. With the high-resolution photoelectron spectroscopy at the low binding energy
region from -5 eV to 100 eV, it was found that the photomission cross-sections at the shallow core levels of the constituent elements and valence band region follow different trends when the incident X-ray energy was tuned toward the absorption edges of different elements. Intriguingly, additional photoemission bands emerged around the valence band region when Cs²⁺ was selectively excited, while the X-ray excitations around other constituent elements do not show such extra photoelectron bands. With the aid of resPES, direct experimental evidence was obtained to support that different constituent elements contribute, in a dissimilar way, to the electronic structure of inorganic cesium lead halide perovskites. This exciting work is believed to be able to experimentally verify or disapprove the proposed electronic structure models of high performance perovskite materials.

Photophysical Properties of Perovskite Thin Films, Microcrystals and Nanocrystals Hernán Míguez, Andrea Rubino, Mauricio Calvo, David Tiede and Juan Galisteo; Consejo Superior de Investigaciones Científicas, Instituto de Ciencia de Materiales de Sevilla, Seville, Spain.

A description of the photophysical properties of perovskite thin films, microcrystals and nanocrystals, and their dependence with the chemical and optical environment, will be provided. The exposure of thin films and microcrystals to different atmospheres has a strong effect on their photoemission, which reveals relevant information about the mechanism behind ion migration, one of the most intriguing observations reported for these semiconductors [1,2,3] A detailed analysis of the processes triggered by photoexcitation that lead to activation and latter deactivation of luminescence will be presented. Also, it will be shown that precise control of the spectral features of the luminescence, along with enhanced stability, can be achieved from perovskite microcrystals synthesized in different types of nanoporous matrices [4,5] Interestingly, under these conditions, increase of the photoluminescence quantum yield results from the improved optical environment they are exposed to [6] All this opens the door to the development of novel color converting coatings of application in LED technology, as it will be demonstrated in this talk.

Transport Properties of All-Inorganic Perovskite CsPbX₃ Nanocubes—Developed by a Facile Room Temperature Surfactant-Mediated Emulsion Approach Sayantani Das; Department of Physics, Jadavpur University, Kolkata, India.

Inorganic-organometallic halides with perovskite structures (ABX₃) have emerged as novel materials because of their unique properties of high absorption coefficients, balanced electron/hole mobility, possible low temperature processing, small exciton binding energies and long exciton diffusion lengths [1, 2]. Here we have developed uniform sized, nano-cube shaped, inorganic perovskite nanocrystals via a facile room temperature surfactant-mediated emulsion approach which may lead to opportunity for different applications like lasing, light-emitting diodes, solar cells, photo detectors etc. The samples we have prepared are all inorganic perovskite nanocubes of CsPbX₃ where the cation A is Cs⁺, B is a bivalent metal cation Pb²⁺ and X is a halide, usually CI⁻; Br⁻ and/or I⁻. Surface morphology and crystallinity of the synthesized samples are examined by field emission scanning electron microscope (FESEM). X-ray diffraction (XRD) analysis gives the confirmation of the phase structure of the samples. To attain further crystallinity confirmation we have carried out high resolution transmission electron microscope (TEM) analysis. UV-visible spectra are recorded in reflectance mode and band gap (Eg) is estimated for the samples. The optical properties (band gap and photoluminescence behaviour) of CsPbX₃ are enhanced significantly in nano cube sample as compared to the bulk CsPbX₃ samples. Elemental composition of the sample is investigated via EDX analysis. These single crystalline nanocubes crystallize in orthorhombic phase and exhibit strong photoluminescence emission too.

Impact of Monovalent Cation in Metal Halide Perovskites on Monomolecular and Bimolecular Charge Recombination Benjamin Foley¹, Katelyn Dagnall¹, Ying-Zhong Ma² and Joshua Choi³; ¹University of Virginia, Charlottesville, Virginia, United States; ²Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Monomolecular and bimolecular recombination constants in metal halide perovskite thin films of various monovalent cations with consistent morphology and charge trap density were studied. Our results reveal that the monovalent cation plays different roles in monomolecular and bimolecular recombination, indicating that the remarkably customizable metal halide perovskites may be more tunable than previously thought.

SESSION ES17.09: Compositions and Structures of Halide Perovskites
Session Chairs: Steve Cranford and Michael Saliba
Thursday Afternoon, April 25, 2019
PCC North, 100 Level, Room 131 B

1:30 PM *ES17.09.01
The Versatility of Polyelemental Perovskite Compositions Michael Saliba; Adolphe Merkle Institute, Fribourg, Switzerland.

Perovskites have emerged as low-cost, high efficiency photovoltaics with certified efficiencies of 22.1% approaching already established technologies. The perovskites used for solar cells have an ABX₃ structure where the cation A is methylammonium (MA), formamidinium (FA), or cesium (Cs); the metal B is Pb or Sn; and the halide X is Cl, Br or I. Unfortunately, single-cation perovskites often suffer from phase, temperature or humidity instabilities. This is particularly noteworthy for CsPbX₃ and FAPbX₃, which are stable at room temperature as a photoinactive “yellow phase” instead of the more desired photovoltaic “black phase” that is only stable at higher temperatures. Moreover, apart from phase stability, operating perovskite solar cells (PSCs) at elevated temperatures (of 85 °C) is required for passing industrial norms. Recently, double-cation perovskites (using MA, FA or Cs, FA) were shown to have a stable “black phase” at room temperature. These perovskites also exhibit unexpected, novel properties. For example, Cs/FA mixtures suppress halide segregation enabling band gaps for perovskite/silicon or perovskite/perovskite tandems. In general, adding more components increases entropy that can stabilize unstable materials (such as the “yellow phase” of FAPbI₃) that can be avoided using the also unstable CsPbI₃. Here, we take the mixing approach further to investigate triple cation (with Cs, MA, FA) perovskites resulting in significantly improved reproducibility and stability.
engineering as a strategy to integrate the seemingly too small rubidium (Rb) (that never shows a black phase as a single-cation perovskite) to study novel multication perovskites. (5)

One composition containing Rb, Cs, MA and FA resulted in a stabilized efficiency of 21.6% and an electroluminescence of 3.8%. The Voc of 1.24 V at a band gap of 1.63 eV leads to a very small loss-in-potential of 0.39 V, one of the lowest measured on any PV material indicating the almost recombination-free nature of the novel compound. Polymer-coated cells maintained 95% of their initial performance at 85°C for 500 hours under full illumination and maximum power point tracking. This is a crucial step towards industrialisation of perovskite solar cells.

Lastly, to explore the theme of multicomponent perovskites further, molecular cations were revaluated using a globularity factor. With this, we calculated that ethylammonium (EA) has been missclassified as too large. Using the multication strategy, we studied an EA-containing compound that yielded an open-circuit voltage of 1.59 V, one of the highest to date. Moreover, using EA, we demonstrate a continuous fine-tuning for perovskites in the “green gap” which is highly relevant for lasers and display technology. The last part elaborates on a roadmap on how to extend the multication to multicomponent engineering providing a series of new compounds that are highly relevant candidates for the coming years. (6)

Atomic Scale Analysis of Perovskite MAPbI\textsubscript{3} for Light Emitting Applications
Afshan Jamshaid, Robin Ohmann, Jeremy Hieulle, Collin Stecker, Luis K. Ono and Yabing Qi; EMSSU, Okinawa Institute of Science & Technology, Onna, Japan.

In recent years, the organic-inorganic hybrid perovskite has gained an increasing research interest in academia for applications in highly efficient thin film solar cells and LEDs, due to the low-cost fabrication process, low non-radiative recombination, tunable bandgap \( [\text{1}] \), and material availability \( [\text{2}] \). For highly efficient LEDs, the highly uniform ultra-flat films with nanometer-sized grains are required. Among the hybrid perovskites, MAPbI\textsubscript{3} (CH\textsubscript{3}NH\textsubscript{3}PbI\textsubscript{3}) based LEDs has shown high efficiency but with several obstacles such as instability of un-encapsulated LEDs, and hysteresis loss. Therefore, commercialization of these LEDs is still a challenge. Understanding and resolving these issues necessitates the investigation of the perovskite thin films at the atomic scale to determine the underlying fundamental processes. Here, we present the growth and experimental characterization of thin MAPbI\textsubscript{3} films on Au \((111)\) under ultra-high vacuum conditions. The thin films were prepared by vacuum evaporation of the precursor molecules MAI and PbI\textsubscript{2}, with a thickness of a few monolayers (approx. 4 nm). We characterize the sample with scanning tunneling microscopy (STM), and X-ray photoelectron spectroscopy (XPS), obtaining information about the atomic structure, and chemical composition. For the electronic properties analysis, we used Ultraviolet photoemission spectroscopy (UPS), and Inverse Photoemission spectroscopy (IPES). Our study will provide the basis for further exploration of mixed perovskite materials for the future highly efficient LED applications.

Lead-Halide Perovskite Surface Defects and Their Implications for Device Interface Engineering
Collin Stecker\textsuperscript{1}, Kexi Liu\textsuperscript{1}, Jeremy Hieulle\textsuperscript{1}, Zhengyu Liu\textsuperscript{2}, Robin Ohmann\textsuperscript{1}, Luis K. Ono\textsuperscript{1}, Guofeng Wang\textsuperscript{3} and Yabing Qi\textsuperscript{1}; Okinawa Institute of Science and Technology, Okinawa, Japan; \textsuperscript{2}Swanson School of Engineering, University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

Lead-halide perovskites are an exciting new class of low-cost semiconductors with optoelectronic properties suitable for LED applications. MAPbI\textsubscript{3} has been utilized to create LEDs with an external quantum efficiency of 9.3\% (Xiao et al., 2017) However, defects in perovskite films can affect device performance. It has been hypothesized that vacancy defects are MABr vacancies and that vacancy defects at the surface of the film change the local work function, which has important implications for energy level alignment between layers in an LED device.

Pressure-Induced Dramatic Changes in Structures and Optoelectronic Properties of Halide Perovskites
XuJie Li; Center for High Pressure Science and Technology Advanced Research, Beijing, China.

Metal halide perovskites have emerged as a promising family of functional materials for advanced optoelectronic applications with high performance and low costs. Various chemical methods and processing approaches have been employed to modify the compositions, structures, morphologies, and electronic properties of hybrid perovskites, great progress has been achieved. Whereas, challenges still remain such as the low stability, the use of environmentally unfriendly chemicals, and the lack of an insightful understanding of the structure-property relationships. In this talk, we will present our efforts in using an alternative means, pressure, to tune the structures and physical properties of halide perovskites. Using state-of-the-art high-pressure techniques coupled with \textit{in situ} synchrotron-based and in-laboratory property measurements, we characterized the changes in their structural, electrical, and optical properties. Pressure-sensitive enhanced properties such as higher electron transport and stronger light absorption, as well as pressure-induced novel phenomena, were observed. Our findings reveal that high pressure can potentially be able to realize enhanced and/or emergent properties of halide perovskites, and further our understanding of the structure-property relationships.

Borisevich\textsuperscript{1}, Juan C. Idrobo\textsuperscript{3} and Rohan Mishra\textsuperscript{2, 1}; \textsuperscript{1}Institute of Materials Science & Engineering, Washington University in St. Louis, St. Louis, Missouri, United States; \textsuperscript{2}Department of Mechanical Engineering & Materials Science, Washington University in St. Louis, St. Louis, Missouri, United States; \textsuperscript{3}Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; \textsuperscript{4}Department of Chemical Engineering, University of Missouri, Columbia, Missouri, United States.

Lead-halide perovskites have emerged as a promising class of highly efficient and affordable semiconductors with applications in solar cells and optoelectronic devices. One of the...
key features of these lead-halide perovskites is their ability to retain their performance even in the presence of a large concentration of defects that are generated from their fast solution-based synthesis. Point defects in lead-halide perovskites either lead to shallow defects levels or resonant levels within the valence or conduction bands, which allow efficient carrier transport. In addition to point defects, the solution-deposited polycrystalline perovskites also have a large concentration of planar defects, such as grain boundaries. These defects are critical to the charge transport and electron-hole recombination characteristics of a semiconductor, and therefore, to the overall device performance. Nevertheless, there are diverging reports on the electrical activity of grain boundaries in lead-halide perovskites. While some reports have suggested them to be benign or even beneficial for charge separation and transport, others have suggested them to be detrimental. A major reason of this controversy lies in the fact that, till date, there have been no experimental reports on the atomic structure and composition of planar defects in these materials.

We have combined aberration-corrected scanning transmission electron microscopy (STEM) and first-principles density-functional theory (DFT) calculations to image grain boundaries and other planar faults in CsPbBr3 nanocrystals and elucidate their impact on the electronic properties. We have employed a novel post-synthesis process to trigger the formation of as-synthesized nanocrystals that leads to the formation of planar faults. Using atomic resolution STEM we observe that the fusion process is accompanied by the formation of predominantly two types of planar faults: previously unreported Br-rich $\Sigma_3$ grain boundaries and Ruddlesden-Popper (RP) planar faults. Generally, in conventional semiconductors planar defects — such as grain boundaries — can be detrimental to their performance as they can introduce mid-gap states, which act as nonradiative recombination centers. However, using DFT calculations we find that neither of the planar faults observed in CsPbBr3 induce deep defect levels, but their Br-deficient counterparts do. We find that the $\Sigma_3$ grain boundaries repel electrons and attract holes, similar to an n-p-n junction, while the RP planar defects repel both electrons and holes, similar to a semiconductor-insulator-semiconductor junction. We will discuss the implications of these findings along with strategies to improve the performance of lead-halide perovskites by tailoring the planar faults, in fact, to achieve stable photoluminescence.

Acknowledgments: This work was supported by NSF grant DMR-1806147. This work used computational resources of the Extreme Science and Engineering Discovery Environment, which is supported by the NSF grant number ACI-1053575. A portion of the STEM experiments was conducted at the Center for Nanophase Materials Sciences at Oak Ridge National Laboratory (ORNL), which is a Department of Energy (DOE) Office of Science User Facility, through a user project (J.A.H. and J.C.I.).

3:00 PM BREAK

3:30 PM +ES17.09.06 Photophysical Properties of Materials Composition Tunable and Doped Colloidal Perovskite Nanocrystals Joseph Luther1, Abhibit Hazarika1, Ashley Gaulding1, Qian Zhao1, 2, Mokshin Suri3, 2 and Taylor Moot1; 1National Renewable Energy Laboratory, Lakewood, Colorado, United States; 2College of Chemistry, Nankai University, Tianjin, China; 3University of Texas, Austin, Austin, Texas, United States.

Colloidal Perovskite Quantum Dots (QDs) have some outstanding optoelectronic properties. Here we present results on such properties of perovskite QDs in solution and in films measured through a variety of optical and electrical techniques. Such Perovskite QD solar cells show high $V_{OC}$ of 90% of their maximum in the radiative limit, but also show promise in non-PV applications such as light emitters for LED, lasing, displays, or sensing such as photoFETs, which will be the focus of this talk. Perovskite QDs possess unique properties that are not accessible in their bulk or thin-film counterparts. For example, inorganic perovskite materials of CsPbI3 are unstable in ambient condition in bulk or thin-films, but they are phase stable in their quantum confined form. Another interesting advantage of these QD materials is that their compositions can be tuned without changing the crystal framework either by direct synthesis or by post-synthetic ion exchanges. Particularly, X-site ion exchange in the perovskite QDs with general formula ABX3 (where A= Cs, Cs–methanimmonium–MA, formamidinium–FA etc., B= Pb or Sn; X= Cl, Br, I) has shown to be very facile. On the other hand, A-site composition tunability is very limited in these materials, or even in very thin films. For example, high FA concentration Cs8,FA,Pb3 has not previously been demonstrated in either QDs and thin films, and it has been shown that only compositions with (1-x)<0.4 can be realized in the pure usable perovskite phase. This is due to thermal instability of FAPbI3 at temperatures required to crystallize CsPbI3 (above 300 °C). However, we present a simple post synthetic cross-cation exchange reaction between colloidal solutions of CsPbI3 and FA-Pb nanocrystals just by mixing them at temperatures slightly above the room temperature that enables us to achieve compositions in the whole range of 0<x<1. This helps us to realize compositions that were not known previously. The photoluminescence (PL) kinetics studies reveal that the activation energy required to inter-exchange the Cs+ and FA+ ions is around 0.65 eV, higher than that for X-site exchange in lead halide perovskites. We have studied a wide range of perovskite QD compositions with time resolved photoluminescence and microwave conductivity as well as studied the application toward photosensing FETs.

4:00 PM ES17.09.07 On the Chemical Origins of Crystalline Orientations in Hybrid Perovskite Thin Films—Microstructures Revisited Shambhu Pratap1, 2, Johannes Schlipf1, Lorenz Bielmann1 and Peter Müller-Buschbaum1; 1Technische Universität München, München, Germany; 2Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Technische Universität München, Heinz-Maier-Leibniz Zentrum (MLZ), München, Germany.

Mixed perovskites towards high efficiency photovoltaics have been pioneered in the photovoltaic community and extensive efforts have been made in order to enable the technology. The impact however, of chemical mixing of such dynamic systems on the morphological structures is largely understudied. Within our study we show that not only does chemical engineering of perovskites affect electronic structure within the material, but the colloidal precursor of the material behaves in strongly dynamic ways and leads to the emergence of intense hierarchical structures within thin films. The phenomenon is similar to those within vivid natural and material systems. Unlike other studies which emphasize on refining film morphologies, we explain the science behind the emergence of natural microstructures, with the aim of elucidating the inherent behaviour of perovskite precursors, which would assist in better understanding and treatment of the material and its properties. We utilize simple and highly intuitive measurements (microscopy and scattering) which strongly support the natural and can be easily understood by a broad range of scientists and engineers- spanning from those interested in photovoltaic material processing, colloidal and soft materials, fluid dynamics, pattern formation, crystallography, to name a few. We explain the emergence of different length scales of film microstructure from different perspectives and how they all are intertwined and dependant on the lowest common multiple of all systems- thermodynamics and energetics, during non-equilibrium conditions.

4:15 PM ES17.09.08 Revealing Cations Locations and Their Impact on the Properties of Mixed MAxCs1−xPbBr3 Perovskite for Light Emitting Diode Application Jeremy G. Hieule1, Shulin Luo2, Afshan Jamshaid2, Collin Stecker1, Robin Ohmann1, Luis K. Ono3, Lijun Zhang4 and Yabing Qi4; 1Okinawa Institute of Science and Technology Graduate University (OIST), Onna, Japan; 2Key Laboratory of Automobile Materials of MOE and College of Materials Science and Engineering, Jilin University, Changchun, China.

Metal halide perovskites are an emerging class of semiconductor with a great potential for use in optoelectronic devices. Recent work, reported the formation of a perovskite based light-emitting diode with external quantum efficiency (EQE) exceeding 20% [1]. This record EQE for perovskite based technology was achieved by managing the compositional distribution in a CsPbBr3/MABr system, to provide high luminance and balanced charge injection. The MABr species is suggested to passivate defects and grain boundaries in the perovskite film. However, the exact location of the methylammonium species and its interplay with the perovskite lattice is still unclear. Therefore, the determination of the diffusion and the control of the perovskite morphology [2] as well as the locations of the cations in the material are of prime importance for developing perovskite-based LED with high EQE.

In this work, combining scanning tunneling microscopy (STM) and density functional theory (DFT), we reveal the exact location of MA (CH3NH3) and Cs cations in MAx,Cs1−xPbBr3 mixed perovskite lattice at the atomic scale. Additionally, using UV/X-ray photoelectron spectroscopy (UPS/XPS), we demonstrate the impact of cations mixing on the material electronic properties. The understanding of the structure/property relationship in mixed MAx,Cs1−xPbBr3 cations perovskite provide new tools for the precise design of light emitting devices.
HALIDE PEROVSKITES (HPs) are a large family of fascinating semiconductor materials that have revolutionized the field of optoelectronics. While the bandgap of HPs is highly tunable, the HPs that are mostly studied have bandgaps over 1.4 eV in general. It is highly demanded to develop HPs with bandgaps below 1.4 eV for certain optoelectronic applications such as infrared-light-emitting devices and photodetectors. Here, we have provided rational materials-design approaches for achieving halide perovskites that not only exhibit low-bandgaps (<1.4 eV), but also have high stability for potential device applications. The formation mechanisms of these materials are discussed in details.

SESSION ES17.10: Nanocrystals and Single-Crystals of Halide Perovskites

Session Chair: Zhijun Ning
Friday Morning, April 26, 2019
PCC North, 100 Level, Room 131 B
An intriguing reversible band gap narrowing behavior of the lead-free hybrid perovskite single crystal DMASnI (DMA = CH3NHCH3) from yellow to black is observed without oxidation and phase transformation. We discuss the transformation mechanism in detail. More interestingly, the transformed samples in black can rapidly self-heal into yellow ones when exposed to deionized water (DI water). Contrary to other hybrid perovskites, DMASnI crystals exhibit excellent water phase stability. For example, DMASnI was immersed in DI water for 16 h and no decomposition was observed. Inspired by its excellent water phase stability, we demonstrate a potential eco-friendly application of DMASnI in photo-catalysis for H2 evolution in DI water. We present the first H2 evolution rate of 0.64 μmol h−1 with good recycling properties for pure DMASnI crystals. After the narrowing process, the optical band gap of DMASnI can be lowered from 2.48 eV to 1.32 eV. Systematical characterizations are applied to investigate their structural and optoelectronic properties. The reversible band gap narrowing behavior and outstanding electrical properties, such as higher carrier mobility and longer carrier lifetime show that DMASnI has a great potential for optoelectronic applications.

10:00 AM BREAK

10:30 AM ES17.10.05

Inorganic Halide Perovskite Single Crystal—Growth Mechanism, Structural and Optical Properties Sovesh Mohapatra, Naveen K. Tailor and Soumitra Satapathi; Indian Institute of Technology, Roorkee, India.

Lead halide semiconductors with a perovskite crystal structure and APbX3 stoichiometry (A = Cs+, Rb+, or K+, X = Cl, Br, or I) are well known for their potential use in optoelectronic devices. In this work, we demonstrate the growth of inorganic lead halide perovskite single crystals (NCs) via a conventional ion-exchange method using parent compounds of CsPbX3. The single crystal XRD, UV-Vis, PL, and TSPC results show the high quality of the synthesized single crystals. The band gap energies of these nanocrystals were tuned from 2.02 eV to 3.00 eV, which is the highest band gap of lead halide perovskite single crystals. The PLQYs of these nanocrystals were over 90%, which is the highest value for lead halide perovskite single crystals. The tunability of the band gap and the high PLQYs make these single crystals potential candidates for optoelectronic applications.

Lead-based inorganic metal halide perovskite materials have the general chemical formula of CsPbX3, where X is Cl, Br, or I. The electronic and optical properties of metal halide perovskites (MHP), such as narrow emission wavelengths, readily adjustable emission wavelengths, and high photoluminescence quantum yields (PLQYs) are advantageous for a number of different optoelectronic devices, including photovoltaics, lasers, and light emitting diodes. Though synthesis and anion-exchange of MHPs are relatively facile, synthesized MHP nanocrystals (NCs) via typical ion-exchange methods show instability in air and moisture, and PLQYs of MHPNCs decrease over time due to a continuous loss of labile parent surface ligands. To enable the further development and application of MHPNCs, the stability must be increased while maintaining or improving high PLQYs. Herein, we report a fast and simple anion-exchange reaction for MHPNCs using allylchlororosilane (RSLCl) at room temperature (20°C-22°C), with motivation stemming from the ability of the allylchlororosilane to both provide the chloride for the anion exchange while also forming a protective stabilizing siloxane shells around the exchanged NCs. In this study, we show that colloidal host CsPbBr3 NCs transform into colloidal CsPbCl3 NCs upon exposure to RSLCl due to the anion-exchange reaction between Br of CsPbBr3 and Cl of RSLCl. Both colloidal and solid thin films of CsPbCl3 NCs produced with allylchlororosilane show good moisture stability and relatively high PLQYs of ~13%, whereas colloidal CsPbBr3 NCs produced via typical methods show low PLQYs (1-10%) and degrade rapidly upon exposure to moisture or ambient air.

11:00 AM ES17.10.07

Properties of 2D/3D Halide Perovskites with Organic Conjugated Cations Ivan Mora-Serio; Universität Jaume I, Castelló de la Plana, Spain.

Two-dimensional (2D) hybrid perovskites (HPVKs) are structures alternating organic and inorganic layers, arising from inclusion of a large organic cation providing Goldschmidt’s tolerance factor higher than 1. This fact generates separation of a determined number of inorganic layers (n), which can range from 1 to ∞, which corresponds to a 3D arrangement. A variation of this pure organic—inorganic structure can be obtained by addition of a small organic cation, MA (CH3NH3+) in most cases, providing a cavity is supported by single-crystal XRD and structural determination of select compounds. The facile ligand assisted reprecipitation method to synthesize colloidal nanoplatelets of Ruddlesden-Popper lead halide perovskites is characterized by high PLQYs and stability. In this study, we demonstrate the successful tunability of dielectric confinement by the inclusion of a conjugated molecule, anilinium cation, as a bulky cation, in the fabrication of the 2D/3D PVK material (C6H5NH3)2(CH3NH3)n-1PbnI3n+1, where n=3-5.

11:15 AM ES17.10.08

Colloidal Nanoplatelets of Ruddlesden-Popper Lead Halide Perovskites Containing Various A-site Cations Matthew P. Hautzinger; Alexis Peggs; Dongceu Pan; John Wright; and Song Jin; Chemistry, University of Wisconsin—Madison, Madison, Wisconsin, United States; 2Dillard University, New Orleans, Louisiana, United States.

The structure of organic-inorganic lead halide perovskites (APbI3) has been limited by geometric considerations to what cation can occupy the A-site cavity. Here we have continued to expand beyond this A-site limit by synthesizing colloidal nanoplatelets of the structurally labile Ruddlesden-Popper perovskites (\(A\:A\'_n \text{Pb}_n \text{I}_{3n+1}\)) containing a series of new large A-site cations, such as ethylammonium (EA), as well as the commonly observed methylammonium (MA), formamidinium (FA) and cesium. The flexible lattice of the Ruddlesden-Popper’s structure allows the introduction of large A-site cations into the perovskite A-site cavity. The occupancy of these large A-cations in the perovskite A-site cavity is supported by single-crystal XRD and structural determination of select compounds. The facile ligand assisted reprecipitation method to synthesize colloidal nanoplatelets of (EA)n(A)PbI3 with varying A-cations was utilized as a convenient pathway to explore more exotic cations. The nanoplatelets are 100-200 nm in lateral dimension and exhibit clear quantum confinement structure. Optic characterization demonstrates strong photoluminescence as well as a strong excitonic feature in the absorbance spectra. The A-site cation is shown to have an impact on the absorbance onset position, PL peak position, QY, and lifetimes. This work highlights a pathway to synthesizing model systems as a way to systematically compare the impact of the A-site cations role in the optoelectronic properties of lead halide perovskites.
Solution-processable perovskites have recently emerged as extraordinary semiconductor materials for light-emitting diodes (LEDs). So far most of the high efficiency LEDs have been demonstrated on small area and by employing difficult-to-control anti-solvent engineering techniques, whereby the required processes do not permit uniform coating over a large area, hindering the potential commercialization of the technology in large area lightings and display devices. Here we report a scalable method to deposit large-area and uniform nanostructured perovskite thin film for active layer in LEDs. The large area deposition is enabled by the pre-synthesized colloidal nanocrystal inks, which allows the formation of unique self-assembled perovskite nanostructure featuring 3D formamidinium lead bromide (FAPbBr3) nanocrystals of graded size coupled with microplatelets of octylammonium lead bromide perovskites. The nanostructure thin film, formed by a simple spincoating deposition of colloidal inks, exhibits photoluminescence quantum yields of over 80%, enabled by the energy cascading effect that significantly improve bimolecular recombination properties at lower charge injection density. Our small area (3 mm2) LEDs reach high external quantum efficiency exceeding 13% and brightness above 50k cd m−2. Moreover we also demonstrate large area LED (≤5 cm2) with a uniform emission and high brightness (>20k cd m−2). These results demonstrate the benefits of the pre-synthesized colloidal inks for fabrication of large area LEDs.

Chemical Vapor Transport Deposition of Stable Cubic CsPbI3 Optical Films on Porous Alumina Substrate Cong Zhao1, Shichao Zhao2, Yuanfang Zhao1, Fang He1, Jingzhou Li1, Shixi Zhao1, Feiyi Kang1, and Guodan Wu1; 1Tsinghua-Berkeley Shenzhen Institute, Tsinghua University, Shenzhen, China; 2College of Materials & Environmental Engineering, Hangzhou Dianzi University, Shenzhen, China; 3Graduate School at Shenzhen, Tsinghua University, Shenzhen, China.

Cesium lead iodide perovskite (CsPbI3) with excellent optical and electrical properties have attracted numerous academic attentions. Specifically, the black cubic phase CsPbI3 with a direct band gap of 1.74 eV has been most appropriate materials for various optoelectronic applications, especially for photovoltaic (PV), Light-Emitting Diodes (LED) and photodetector applications. However, the preferred cubic phase of bulk CsPbI3 (α-CsPbI3) is usually only stable at high temperatures and it will undergo an immediate phase transformation to orthorhombic phase (δ-CsPbI3) after fabrication at room temperature. Attempts to stabilize the cubic phase in ambient temperature have been focused on complicated procedures such as quantum dot-induced films, poly-vinylpyrrolidone (PVP)-induced surface passivation engineering and chemical composition tuning. In the meantime, most of current efforts have been focused on solution process. Up to now, it has been still a challenge to synthesize the CsPbI3 through chemical vapor deposition (CVD) method. In this work, we have discovered a convenient CVD method to investigate the growth behavior of the cubic α-CsPbI3 film on the porous alumina substrate. The lead iodide and cesium iodide were used as the precursors for the deposition of CsPbI3. The effect of CsPbI3 with high surface area and large pore volume was used as growth substrate. It was shown that the porous alumina promoted the growth of CsPbI3 film by absorbing the precursor and increasing the nucleation density. The prepared CsPbI3 film emitted strong and stable red light (ca. 1.9 eV) under ultraviolet light excitation and room temperature ambient atmosphere. The lead iodide was absorbed on the surface of the porous alumina firstly then reacted with cesium iodide to form the CsPbI3. The successful preparation of the CsPbI3 by the CVD method paves the way for its large scale growth and application in optoelectronic devices.

SESSION ES17.11: Frontier Phenomena of Halide Perovskites

PN Junction of a Thin-Film Perovskite Daniel Ramirez and Dmitri S. Kilin; Chemistry & Biochemistry, North Dakota State University, Fargo, North Dakota, United States.

Lead-halide perovskites exhibit favorable properties when compared to conventional optoelectronic materials. The single-crystalline hybrid perovskites have important photovoltaic properties for solar semiconductor devices, such as cells and light emitting diodes. Here we implement a first principle study to identify and analyze dependence of optoelectronic properties of Cesium Lead Bromide perovskite, CsPbBr3, on composition, quantum confinement, and surface morphology. The calculations include combination of ground state modeling by DFT and dynamics modeling of excited state. The dynamic of excited states is modeled via Redfield equation of motion for electronic degrees of freedom, parameterized by nonadiabatic couplings, i.e. response of electronic states to thermal dynamics of nuclei. Specifically, we model how dynamics of photoinduced electronic state at the surface of 2D quantum confined films of perovskite depends on presence or absence of different adsortbates and symmetry of exposed crystallographic surface. By analyzing dynamics of charge redistribution between inner area of thin film of the perovskite and surface defects we can identify the winner in the competition between radiative and nonradiative recombination pathways, and, thus, quantum yield of photoluminescence. The obtained results allow for theory-guided design of optimal morphology of 2D perovskite films for light emitting applications.

The Correlation of Ferroelasticity and Chemistry in CH3NH3PbI3 Twin Domains Yongtuo Liu1,2, Anton V. Ievlev1, Lian Collins1, Songkil Kim1, Benjamin Dougherty1, Malshid Ahmadi2, Stephen Jesse1, Scott T. Retterer1, Alex Belianinov1, Kai Xiao1, Bobby G. Sumpter1, Sergei V. Kalinin1, Bin Hu2 and Olga S. Ovchinnikova1; 1Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Department of Materials Science and Engineering, The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 3Chemical Sciences Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Hybrid organic-inorganic perovskites (HOIPs) have drawn significant attention due to their extraordinary optoelectronic performance. Recently, two-dimensional structure was demonstrated that the films exhibit enhanced thermal/moisture tolerance under compressive strain and lower tolerance under tensile strain by physically bending the substrates. Here, we follow the evolution of stresses and highlight the thermal effects and structural changes in the film. For doing so, we also propose a processing method to achieve flat films with different stress states on transparent-conducting flexible substrates. The effect of residual stress on the optoelectronic properties and thermal and environmental stability of the films is studied. The observed changes in the film properties are correlated with the nature of the defects generated/annihilated as the film passes through a bending cycle. Understanding the fundamental role of stresses on film properties would help in discovering ways to mitigate its detrimental effects and achieve a more robust technology.
precise engineering and systematic characterization of the functional heterostructure in all-inorganic halide perovskite nanowires. On one work, we show that the n-p junctions can be readily induced through a localized thermal-driven phase transition in a single-crystalline halide perovskite CsSnI₃ nanowire. This phenomenon undergoes a phase transition from a double chain yellow phase to an orthorhombic black phase. The formation energies of the cation and anion vacancies in these two phases are significantly different, which leads to n- and p-type electrical characteristics for yellow and black phases respectively. Interface formation between these two phases and directional interface propagation within a single NW are directly observed under cathodoluminescence microscopy. Further, we demonstrate the current rectifying behavior of the resulting n-p heterostructure originating from the distinctly different charge transport properties of these two phases. On the other hand, taking advantage of the soft and reconfigurable ionic lattice characteristics in halide perovskite materials, we design a CsPbBr₂CsPbCl₃ heterostructure nanowire that bridges the pre-patterned parallel Au electrodes, via a precisely controlled anion exchange approach. Quantitative correlation between halide ion ratios and photoluminescence emission wavelengths in halide perovskites allows us to visualize the halide ion migration across the heterostructure interface under electric fields. More interestingly, we show that the halide ion migration is heavily dependent on the bias polarity across the nanowire, leading to the field-induced halide ion migration rectification in this solid-state material. The present approaches to heterostructure formation could inspire the precise control over the design of functional heterostructures using halide perovskites as building blocks.

Discovery of Halide Perovskites—Crystal Chemistry, Photoluminescence and Their Optoelectronic Applications

Zhiguo Xia; School of Materials Science and Engineering, University of Science and Technology Beijing (USTB), Beijing, China.

Recently, the appearance of halide perovskites has catalyzed an unprecedented revolution in the field of (opto)electronics with tunability in the crystal-structure dimensionality and chemical composition. Our group has previously proposed a unifying methodology for the discovery of new earth phosphors for LED applications by mineral-inspired prototype evolution and new phase construction via cosubstitution strategy, and many useful phosphors have been reported. Since it is a challenge to discover the counterparts for rare earth phosphor, our group firstly conducted the investigations on perovskite quantum dots represented by CsPbX₃ to target the improved quantum efficiency and enhanced stability, and they also demonstrated potential for liquid crystal display backlight application. Secondly, in the search of stable lead-free perovskites, hybrid perovskites or perovskites double have been utilized. This development has yielded heterovariant substitution or chemical unit cosubstitution proposed by our group in the phosphor studies. Our pioneer work on Cs₂AgInCl₅ crystals, as an example, focused on the structural design, crystal structure, and morphology related with solution-based crystal growth habit, band structure, optical properties, and the stability. This compound has now become the “star” materials in the luminescent perovskites. Finally, our recent work on the crystal chemistry and photoluminescence behavior of the new zero-dimensional (0D) or two-dimensional (2D) structures will be mainly addressed in this talk, moreover the Mn²⁺ or other ions doped perovskites, as well as the photoluminescence and optoelectronic applications will also be discussed.

3:15 PM ES17.11.06
Thin-Film Processing for Large-Scale Optoelectronic Applications

Luis K. Ono, Longhui Qiu, Zonghao Liu, Yan Jiang, Matthew R. Leyden, Sonia R. Raga, Mikas Remeika, Emilio J. Juarez-Perez, Zhiguo Xia, Hongshao Wang and Yating Bi; Energy Materials and Surface Sciences Unit (EMSS), Okinawa Institute of Science and Technology, Okinawa, Japan.

Lab scale (<0.1 cm²) metal halide perovskite solar cells were fabricated to achieve power conversion efficiencies (PCEs) comparable to several other photovoltaic technologies. However, development of up-scaling processes (>10 cm²) with high PCE and stability is important for moving forward this technology towards commercialization [1,2]. At OIST, a team of researchers in the Energy Materials and Surface Sciences Unit has been making concerted efforts to develop processes aiming at high PCE, high-throughput, and minimum batch-to-batch variation, and compatible with large-area perovskite solar cells and modules. In this talk, we will present our recent progress to use chemical vapor deposition CVD [3-6] to fabricate perovskite solar cells and light-emitting diodes [7]. Also, we will introduce a novel methylamine (CH₃NH₂) gas induced crystallization process [8-10], which provides valuable insight into the formation of perovskite films.

In the past few years, the hybrid lead perovskite materials are the megastar in photovoltaics research field and has grab enormous attention due to its excellent absorption coefficient, charge-transport properties and long carrier life time. This thus has enabled a wide range of optoelectronic applications, notably in high efficiency photovoltaics with power conversion efficiency exceeding 23%; and bright light-emitting diodes (LEDs), sensitive photo-detector. Very recently, perovskites have been recognized as promising semiconductor for solid-state radiation detectors due to their high radiation absorption cross-section enhanced by the presence of heavy ions, such as lead, cesium and halide etc. State-of-the-art solid-state X-ray detector utilize germanium and silicon that exhibits an excellent detectivity. However, such performance is only achievable under bulk volume of materials due to its low z number, whereas operation suffers from charge diffusion and drifting that is detrimental to the detector sensitivity. Therefore, perovskite-based semiconductor with high mobility-lifetime product, low defect density would be a novel candidate for X-ray detector.

Here, for the first time we demonstrate a thin film X-ray detector using a P-I-N diode fabricated with highly crystalline Ruddles-Popper layered Perovskites thin films. It features with ultra-low dark current and high X-ray induced photocurrent signal, greater than state-of-the-art silicon diode. Most impressively, using merely 200 nm active layer, we could detect high energy hard X-ray above 10 keV with on/off ratio over 10^3. We attribute such performance to be the superior crystallinity in layered perovskite that suppressed recombination induced dark current that thus enhance the X-ray detection sensitivity. Our demonstration holds promise for efficient high energy radiation detection such as X-ray and low energy Gamma-Ray, using thin film PIN junction configuration. Our findings also inform a new generation of highly efficient and low-cost X-ray detectors based on Ruddles-Popper Layered Perovskites thin film.

Enhancement of MAPbBr3 Nanoparticles on Stability and Photocatalysis with a Polynorepinephrine Shell

Yidi Wang and Bin Fei; The Hong Kong Polytechnic University, Hong Kong, Hong Kong.

Organic-inorganic hybrid methylammonium lead halide perovskite (MAPbX3, X= Cl, Br, I) is an emerging candidate of diverse fields, including the light emitting diode, solar cell, photodetector, and photocatalysis. Due to their low formation energy, MAPbX3 materials are sensitive to many factors, including polar solvents, moisture, light, and high temperature. To address this issue, a straightforward method, encapsulating MAPbX3 nanoparticles (NPs) with stable polymer-like shells is commonly reported. Meanwhile, the previously reported encapsulated MAPbX3 were limited to the macroscale, which makes it difficult to develop the applications requiring monodisperse particles with high uniformity. In this work, monodisperse MAPbBr3@poly(norepinephrine) (PNE) NPs were successfully prepared by reverse micelle method and in-situ polymerization. In the polymerization process, the MAPbBr3 NPs were encapsulated with the stable and thin layer of PNE homogeneously, maintaining the intrinsic crystalline structure and monodisperse morphology. Meanwhile, PNE shell bearing alkyl hydroxyl groups resulted in activated MAPbBr3 NPs with remarkable features in photocatalysis tests even after treatment with water. Our work not only proposes a novel approach to produce core-shell perovskite NPs on the single particle level but also enhances the stability and photocatalytic efficiency of pristine perovskite.

Excitons and Exciton Confinement in Organic Heterojunctions

Stephen Forrest, Xiao Liu, Kan Ding and Yongxi Li; EECS and Physics, University of Michigan, ANN ARBOR, Michigan, United States.

Excitons play a central role in photogeneration in organic detectors and solar cells. The efficiency of the exciton dissociation process is directly related to molecular structure of the donor and acceptor molecules and the film morphology. In our work, we have focused on understanding the microscopic nature of these interactions in both fullerene and nonfullerene based junctions. We have developed quantum mechanical models coupled with molecular dynamics simulations to understand the role that morphology plays on the energy of the charge transfer state – i.e. the intermediate between exciton and free polaron – and ultimately its ability to generate free charge at a low expense of energy. We find that quantum confinement of the exciton by crystalline domains in dilute donor-acceptor blends can result in substantial energy shifts in the state, thereby impacting its binding energy. [1, 2] Further, we have developed models that quantitatively relate the energy loss in nonfullerene acceptors to the molecular structure itself. Ultimately, this understanding of exciton and CT state energetics has led to very high efficiency (>15%) organic solar cells, with prospects of reaching 20% in the not distant future.[3, 4] The models, experiments and implications of these findings will be discussed in my presentation. Finally, if there remains time, I will discuss confinement effects in novel quantum well structures comprising a combination of organic and inorganic semiconductors, including 2D solids.[5]

---

In this contribution, we report on analysis of non-radiative losses of representative solution-processed bulk-heterojunction OSCs based on NFAs with some of them achieving a remarkably low non-radiative $V_{OC}$ loss of 0.20 V, which is beginning to align with the state-of-the-art solar technologies based on silicon, CIGS and perovskite solar cells.[4-7] Analysis on the non-radiative recombination losses with its relation to intrinsic material's photo-physical properties, e.g., absorption coefficient, stokes shift, the energy-levels, photoluminescence efficiency, as well as extrinsic thin film properties, e.g., energetic and structural disorders, will be presented.

Efficient NIR Organic Bulk Heterojunction Solar Cells Using Nonfullerene Acceptors

Thuc-Quyen Nguyen; University of California, Santa Barbara, Santa Barbara, California, United States.

The field of non-fullerene organic solar cells (OSC) has experienced rapid development during the past few years, mainly driven by the development of novel non-fullerene acceptors and matching donor semiconductors with device efficiencies approaching 15%. However, organic solar cell material development has progressed via a trial-and-error approach with limited understanding of the materials’ structure–property relationships and the underlying device physics of non-fullerene devices. In addition, the availability of hundreds of donor and acceptor semiconductors creates a large pool of possible donor–acceptor combinations, which poses a daunting challenge for rationally screening material combinations. Resonant soft X-ray scattering (RSoXS) has proven to be a powerful technique to measure domain purity in OSC active layer blends. In polymer-fullerene systems, RSoXS has shown that higher average domain purity is generally correlated to device performance. A simple interpretation of RSoXS purity measurements is complicated by the consideration that real morphologies may be composed of three or more phases, with mixed amorphous regions in addition to relatively pure, aggregated donor and acceptor domains. Whilst charges are understood to migrate to the aggregated domains due to a favorable electronic landscape, these charges might be effectively trapped in aggregates if there is insufficient number of percolating pathways in the amorphous mixed regions. Conversely, if the mixed regions have a composition much beyond the percolation threshold or if the volume faction of the mixed regions is large, then recombination is enhanced. Therefore, understanding the role of domain purity over different length scales and controlling the mixed amorphous phase for maximum charge creation and minimum recombination remains a principal challenge for non-fullerene OSCs.

We will summarize several of our RSoXS studies that compare non-fullerene acceptor based organic solar cells having different primary chemical structures of the constituents and with significant processing variations. Our analysis suggests that mixed regions are often detrimental to good performance in these systems, typically having a pronounced negative impact on FF. Optimizing performance continues to be a delicate balance of competing factors and the volume fraction of the ideal morphology remains to be determined. However, the miscibility of blend components, which might be probed using near-edge X-ray absorption spectroscopy as a screening tool, can guide expectations of achievable phase purity and ultimately the achievable performance of the active layer.

References
recombination rates.[1] Recent work has produced the liquid crystalleld bisphenol-a-thiophene-phenol (BTR).[2] When blended with PC71BM, BQR-based devices can achieve a power conversion efficiency over 9%, a high fill factor (FF) of 0.7, and also maintain good performance with a thick active layer. To further understand the structure-property relationships that yield high performance in this blend, we compare detailed morphological characterization from X-ray scattering [3] and transmission electron microscopy with a rigorous electrical model to predict the performance of donor and acceptor materials. However, the performance of BQR-based devices has not been determined to produce reliable measurements of donor and acceptor material properties and to demonstrate any improvements in the active layer of the donor and acceptor materials, in particular, for the device structure, the morphology of the active layer plays a crucial role in determining the power conversion efficiency (PCE) of the device. Considerable research has demonstrated that the donor and acceptor phase-separated the active layer to achieve efficient exciton separation, carrier transport and collection. However, non-fullerene molecules have two-dimensional structure, its strong electronic coupling is only expected for molecules oriented with their π systems parallel to each other, leading to a weak driving force for nucleation. Moreover, non-fullerene molecules have large molecular volume, inhibiting the process of molecular diffusion, which is not benefit for the crystal growth process. As a result, the crystallization of non-fullerene molecules was suppressed, inhibiting the formation of interpenetrating networks. Herein, we regulated the crystallization dynamics to enhance the crystallinity of non-fullerene molecules, i.e., regulating the crystallization process of donor and acceptor to reduce the molecular volume and enhance molecular diffusion capability. Take P3HT-O-IDTBR blends for an example, due to the film-forming process the crystallization of donor and acceptor tend to occur simultaneously. It would reduce the π-π interaction between like molecules, thus lead to a high nucleation barrier, which is not benefit for obtaining a film with high crystallinity. Here, TCB is selected as cosolvent to modify the film-forming kinetics due to its selective solubility and high boiling point. As a result, the crystallization process of P3HT and O-IDTBR was separated, which increase the chance of π-π electronic coupling among donors and acceptors, resulting in high crystallinity for both P3HT and O-IDTBR. Another factor to influence the formation of interpenetrating networks is the molecular diffusion capability. For example, for PDBD-T-TITC blends, due to the competition between crystallization and phase separation, the polymer is prone to crystallize first, which inhibits the molecular diffusion of ITIC, resulting in weak crystallinity of ITIC. We proposed to change the crystallization sequence of donor and acceptor, i.e., ITIC crystallized first, then the polymer crystallized. Thus, molecular diffusion of ITIC could be improved without the confinement of polymer, leading to an enhanced crystallinity. The enhanced crystallinity of non-fullerene molecules is beneficial to the formation of interpenetrating network, which facilitates the electron transport and suppresses the bimolecular recombination. This work demonstrates that manipulation of crystallization sequence of donor and acceptor may be a key to further optimize the morphology of NF-OSCs.

Organic solar cells (OSC) have drawn much interest due to their apparent advantages including lightweight, low-cost production, semitransparency, flexibility and large-area manufacturing. In addition to the synthesis of donor and acceptor materials, interface engineering and device structure, the morphology of the active layer plays a crucial role in determining the power conversion efficiency (PCE) of the device. Considerable research has demonstrated that the donor and acceptor phase-separated the active layer to achieve efficient exciton separation, carrier transport and collection. However, non-fullerene molecules have two-dimensional structure, its strong electronic coupling is only expected for molecules oriented with their π systems parallel to each other, leading to a weak driving force for nucleation. Moreover, non-fullerene molecules have large molecular volume, inhibiting the process of molecular diffusion, which is not benefit for the crystal growth process. As a result, the crystallization of non-fullerene molecules was suppressed, inhibiting the formation of interpenetrating networks. Herein, we regulated the crystallization dynamics to enhance the crystallinity of non-fullerene molecules, i.e., regulating the crystallization process of donor and acceptor to reduce the molecular volume and enhance molecular diffusion capability. Take P3HT-O-IDTBR blends for an example, due to the film-forming process the crystallization of donor and acceptor tend to occur simultaneously. It would reduce the π-π interaction between like molecules, thus lead to a high nucleation barrier, which is not benefit for obtaining a film with high crystallinity. Here, TCB is selected as cosolvent to modify the film-forming kinetics due to its selective solubility and high boiling point. As a result, the crystallization process of P3HT and O-IDTBR was separated, which increase the chance of π-π electronic coupling among donors and acceptors, resulting in high crystallinity for both P3HT and O-IDTBR. Another factor to influence the formation of interpenetrating networks is the molecular diffusion capability. For example, for PDBD-T-TITC blends, due to the competition between crystallization and phase separation, the polymer is prone to crystallize first, which inhibits the molecular diffusion of ITIC, resulting in weak crystallinity of ITIC. We proposed to change the crystallization sequence of donor and acceptor, i.e., ITIC crystallized first, then the polymer crystallized. Thus, molecular diffusion of ITIC could be improved without the confinement of polymer, leading to an enhanced crystallinity. The enhanced crystallinity of non-fullerene molecules is beneficial to the formation of interpenetrating network, which facilitates the electron transport and suppresses the bimolecular recombination. This work demonstrates that manipulation of crystallization sequence of donor and acceptor may be a key to further optimize the morphology of NF-OSCs.

4:00 PM ES18.02.06 Novel 4D-STEM Characterization of Nanoscale Morphology and Molecular Ordering in Organic Photovoltaics Gabriel Calderon1, Letian Dou2 and Jinwoo Hwang1; 1Department of Materials Science and Engineering, The Ohio State University, Columbus, Ohio, United States; 2Chemical Engineering, Purdue University, West Lafayette, Indiana, United States.

We present the novel characterization of the morphology and molecular ordering at the nanoscale structure of organic photovoltaics (OPVs) using 4-dimensional scanning transmission electron microscopy (4D-STEM). 4D-STEM utilizes the new-generation fast pixelated STEM detector that enables fast acquisition of electron nanodiffraction patterns from the entire area of the OPV with oversampling. The fast acquisition rate of the new detector is the key to minimize the radiation damage and carbon contamination on the sample when combined with low electron dose and in situ annealing. Real space reconstruction of the nanodiffraction data based on the intensity fluctuation analysis can reveal the detailed spatial and orientation maps of the structure with unprecedented resolution and precision. The new information we can gain from this new approach includes (i) the size, orientation and volume fraction of each type of ordered domains, (ii) how different domains (e.g. donor and acceptor domains) are correlated in terms of their structure and orientation at the interface, and (iii) how processing conditions or doping affects the molecular ordering and morphology in detail. We will demonstrate the results acquired from polymer OPV systems, blended with fullerene or non-fullerene acceptors, and also from more recent high-performance ternary systems, and show how their nanoscale structure and morphology relate to the charge transport, photovoltaic properties, and mechanical stability of the films.

Miscibility and Mixed Domains in OPVs—Is the Ever-Evolving Story of the Role of Mixed Domains Converging to a Stable Structure-Function Paradigm? Harald Ade; North Carolina State University, Raleigh, North Carolina, United States.

Polymer solar cells (PSCs) are lead-free and can now be processed from relatively benign solvents with high efficiency of >14%. For many years, progress has relied mostly on intuition and trial-and-error approaches. For example, it was commonly known that fundamental molecular interactions must control the achievable PSC morphology, quantifying these interactions and predicting important transient and final device morphology parameter such as the composition of the mixed domains and their relation to performance remained unattainable for a long time. This presentation will review the history of this winding road, the lost tracks, the parallel paths, and some of the blind alley of the field to understand “miscibility” and the phase behavior of PSC blends. Recent progress indicates that we might converge on a coherent understanding of structure-function relationships and that computer simulations might help to screen materials combinations for their suitability of high performance system. In some cases, the amorphous-amorphous phase behavior of a range of fullerene- and NFA-based systems has been determined and the metastable miscibility gap (the phase boundary) could be parameterized and thus quantified by the temperature-dependent Flory-Huggins interaction parameter χ(T). This has allowed to clearly show that there are two regimes: i) low χ systems with shallow quenches, where the best performance is achieved when the mixed domains reach the miscibility limit, and ii) high χ systems with deep quenches/low miscibility were the mixed domains have to be quenched into a composition that is close to the percolation threshold for electron transport. The deep quenched systems are intrinsically unstable and further purification of the mixed domains often leads to burn-in degradation, although some highly vitrified systems have been discovered. We will review these developments and arguments and present some preliminary data that also hints that there might be a relationship between χ and the propensity for a system to vitrify and thus be stabilized.
Design and Synthesis of Small Molecule Electron Acceptors for High Performance Organic Solar Cells

Hongzheng Chen; Zhejiang Univ, Hangzhou, China.

Fullerene derivatives are dominantly used electron acceptors in organic solar cells (OSCs) for decades owing to their high electron mobility and fine phase separation. However, the drawbacks of fullerene derivatives, such as high cost, poor absorption, limited energy levels tunability and morphological instability, provide an opportunity for the development of non-fullerene electron acceptors. So far, numerous non-fullerene electron acceptors, especially small molecule electron acceptors, are designed and synthesized with outstanding performances recently. Among them, fused-ring electron acceptors are the most famous ones with good structural planarity and rigidity, which successfully boost the PCEs of OSCs over 14%. In this presentation, I will introduce couple of small electron acceptors with unfused ring cores. PCEs over 12% can be obtained for polymer solar cells based on the electron acceptors with unfused ring cores. A high PCE over 14% is delivered for tandem polymer solar cells based on the newly designed NIR photoresponsive fullerene-free acceptor.

Development of Non-Fullerene Electron Acceptors for Organic Solar Cells

Jain McCulloch1,2; KAUST Solar Center (KSC), King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 2Imperial College London, London, United Kingdom.

Development of non-fullerene electron acceptors for organic solar cells

The power conversion efficiency (PCE) of single junction organic solar cells has increased significantly during the last decade and now approaching the threshold considered necessary for commercialisation. During this period, the structural diversity of semiconducting donor polymers for solar cells has increased dramatically, enabling accelerated development of bulk heterojunction (BHJ) organic solar cells based on polymer donor materials and molecular fullerene derivatives. However, both the fullerene, and the low bandgap polymers typically suffer from low absorption coefficients due to weak oscillator strength. Our approach is to use P3HT as a p-type hole acceptor, and design highly absorbing, low-bandgap n-type small molecules to replace fullerenes. These fullerene acceptors not only have weak absorption, but also poor tunability of absorption over the longer wavelengths of the solar spectrum; morphological instability in thin film blends over time; high synthetic costs and limited scope for synthetic control over electronic and structural properties. For these reasons, we have developed new, synthetically simple electron acceptor materials, based on rhodanine end groups, which have much larger absorption coefficients than fullerenes, coupled with high lying LUMO energy levels, to maximize cell voltages. In BHJ devices with P3HT donor polymer, the rhodanine molecules were demonstrated to outperform fullerenes. The highest performing P3HT devices have power conversion efficiencies approaching 8%, based on a ternary blend of two rhodanine acceptors. We also demonstrate performances of over 12% with one non-fullerene acceptor in combination with lower bandgap polymers, deposited from non-chlorinated solvents.

Photo-Stability of Organic Solar Cells—Fullerene vs Non-Fullerene Polymer Solar Cells

Nutifafa Y. Doumon1, Mikhail V. Dryzhov1, Felix V. Houard1, Jingjin Dong2, Panagiotsi Christodoulis3, Azadeh R. Chatri1, Vincent Le Corre1, Giuseppe Portale4 and Lambert Jan Anton Koster2; 1Photophysics and OptoElectronics, Zernike Institute for Advanced Materials, University of Groningen, Groningen, Netherlands; 2Molecular Chemistry and New Polymeric Materials, Zernike Institute for Advanced Materials, University of Groningen, Groningen, Netherlands.

Tapping energy from sunlight can be a sustainable way to meet the increasing world energy demand. Organic photovoltaics (OPVs) are a viable technology in this direction. For the technology to be marketable, issues of low efficiency, high instability and the short lifetime of organic solar cells (OSCs) must be addressed. Recently, the advent of non-fullerene acceptors (NFA) made it possible for OSCs to break the 10% efficiency barrier hardly attained by fullerene acceptors (FA). This is because of the interesting possibilities offered by this new class of acceptors which the FAs are bereft of, namely, the broad/strong absorption, the facile synthesis, the ease of tuning their properties and the apparent enhanced stability.[1] Thus, in the past five years more than hundreds of NFA with applications in the OPV field were synthesized, thus, allowing for a notable current record efficiency of above 14%[2-3] in single junction solar cells and 17.3%[4] in a multijunction solar cells. Hence, there is an impressive shift in interest towards the NFAs. However, there has been little work on the stability of this new type of materials and devices. More importantly, there is very little to no comparative work on the photo-stability of FA vs. NFA solar cells, to really ascertain the pros and cons of the two systems.

In this work, we show the photo-stability of solar cells based on two workhorse acceptors, in both conventional and inverted structure, namely ITIC (as NFA) and [70]PCBM (as FA) blended with either PBDB-T or PTB7-Th polymer. We find that either irrespective of the polymer, the cell structure, or the initial efficiency, the [70]PCBM devices are more photo-stable than the ITIC ones. This observation, however, opposes the generally assumed claim that NFA solar cells are more stable. Finally, we propose ternary blend (D:A:A) made of the PBDB-T polymer and the two acceptors as a path to making the solar cell devices more stable. These findings suggest that there is still work left to be done for OSCs to achieve an acceptable level of stability.

Designing Highly Efficient Non-Fullerene Acceptors via Tuning the Intramolecular Charge Transfer Effect

Huileng Yao and Jianhui Hou; Institute of Chemistry, Chinese Academy of Sciences, Beijing, China.

Over the last few years, the development of fullerenefree organic photovoltaic (OPV) cells have achieved great attention, and the power conversion efficiencies (PCEs) of small molecular acceptor-based OPV devices have surpassed 14% recently. The non-fullerene small molecules have the advantage of easily tuned absorption spectra and molecular energy levels, contributing greatly to the rapid increasing PCEs of the resulting OPV devices. Among the varied kinds of non-fullerene acceptors, the ones with acceptor-donor-acceptor structures like ITIC show the outstanding performance. In our work, we tuned the intramolecular charge transfer (ICT) effect in this kind of molecules and designed a series of highly efficient materials.

First, we weakened the ICT effect of ITIC by replacing its benzene terminal groups with thiophene units to synthesize the ITCC. Then, we further added methyl groups on thiophene rings to decrease the ICT effect to prepare the ITCC-m.[1] As thiophene rings and methyl groups have relatively electron-donating properties than benzene rings, the ICT effect in ITIC is weakened gradually in ITCC and ITCC-m. When compared to ITIC, the ITCC and ITCC-m show upshifted the lowest unoccupied molecular orbital (LUMO) levels and blue-shifted absorption spectra. In the OPV cells fabricated with a polymer PBDB-T as the donor material, the ITCC- and ITCC-m yielded much higher open-circuit voltages.

Then, we adopted the contrary molecular design strategy to enhance the ICT effect in the small molecular acceptors. Taking IEIC as an example, we introducing the electron-donating alkoxy groups and electron-withdrawing fluorine atoms on the donor and acceptor parts of IEIC, respectively, to synthesize the IEICO and IEICO-4F.[2-3] Both of the acceptors show much-redshifted absorption spectra and thus obtained considerable enhancement of short-circuit current densities in the resulting OPV cells. Recently, we used the chlorination to replace the fluorination to further enhance the ICT effect and synthesized the IEICO-4Cl, which has very weak absorption in the visible range.[4] When blending different donors, the colors of the blend films were changed accordingly. We selected three polymer donor with varied colors and fabricated the semi-transparent OPV devices, to really ascertain the pros and cons of the two systems.
devices, which showed very good photovoltaic performance. We also integrating the advantages of the wide bandgap and narrow bandgap acceptors to fabricate the double-junction OPV cells. For example, we used the ITCC-m and IEICO to fabricate the front and rear devices in the tandem cells, respectively, a high PCE of 13.8% was recorded. After that, we replaced the IEICO with IEICO-4F with broader absorption spectrum, the PCE approached to 15%.

In our recent work, in order to understand the efficient charge transfer mechanism in these non-fullerene-systems, we studied the distributions of the molecular electrostatic potential (ESP) of these molecules. As there is much difference in electronegativity on the different part of the non-fullerene molecules, the theoretical calculations suggest that most parts of this kind of acceptor have positive ESP values. By contrast, the polymer donors usually have negative ESP on the backbones. Therefore, we think the ESP difference will induce an intermolecular filed to assist the charge transfer between the donors and acceptors in the active layers.

Fused-Ring Electron Acceptors for Organic Photovoltaics
Xiaowei Zhan; Peking University, Beijing, China.

We proposed a new concept termed “fused-ring electron acceptor (FREA)”, invented the star molecule ITIC, created a class of high-performance nonfullerene acceptors, and built up an ITIC kingdom. The ITIC family presents some advantages: 1) Their chemical structures are facile to tailor and synthesis is easy to scale up; 2) Their absorption and energy levels can be tuned and thus match with various high-performance electron donors; 3) Their crystallinity and film morphology can be tuned; 4) They exhibit strong and broad absorption, especially in the 700–1000 nm range, and can match with wide-bandgap donor materials to achieve complementary absorption; 5) They have high electron mobilities similar to those of fullerenes. Single-junction binary-blend organic solar cells (OSC) based on these FREAs exhibit power conversion efficiencies of >14%. Moreover, the FREAs-based OSCs exhibit good morphology stability and long device lifetime. Now FREAs invented by Zhan group are commercial available. Around 130 research groups have already utilized these FREAs to fabricate high-efficiency OSCs, which surpass fullerene acceptor counterparts.

Materials and Device Structures for Efficient Organic Solar Cells and Photodetectors
Karl Leo; Natalia Sergeeva, Tianyi Li, Jonas Kublitski and Andreas Hofacker; IAPP, TU Dresden, Dresden, Germany.

Organic materials and devices offer the possibility for a novel electronics realized by low-cost processing on flexible substrates. Despite their limited mobilities, organic materials excellent optoelectronic properties which allow devices with excellent performance in photovoltaic and photodetector applications. Also, devices based on organic materials can display surprisingly high stability if well encapsulated from water vapor and oxygen.

In this talk, we will first present studies about the influence of defect states. We investigate defects in a system composed of the small-molecule oligothiophene derivative DCVST-Me blended with C-60, having power conversion efficiencies above 8% when used in a solar cell. Impedance spectroscopy shows a Gaussian distribution of trap states below the electron transport level. Comparison with drift-diffusion simulations show that the trap states mainly lead to a decrease of fill factor. Further, we discuss some new materials for solar cells and photodetectors based on bulky and merocyanine dyes. In particular the former class allows excellent devices absorbing in the infrared spectral range with high stability.

11:00 AM ES18.04.02
Nature of Photogenerated Defects in Bulk Heterojunction OPVs
Joshua Wolanyk, Raghunandan B-Iyer, Ruth Shinar and Joseph Shinar; Iowa State University, Ames, Iowa, United States.

Intrinsic photodegradation of organic solar cells, particularly bulk heterojunction (BHJ), remains a key commercialization barrier. Two types of photogenerated defects in BHJ films and related systems have recently been explored via electron paramagnetic resonance (EPR): (a) deeply trapped holes and electrons in polyelectrolyte-fullerene assemblies [1] and (b) carbon dangling bonds (C DBs) [2]; the latter were involved in support of simulations [3,4]. In both cases, the generated EPR defect signature observed in
photodegraded films weakens over several days. This talk will present new results of broadly examined various donor/acceptor structures, including of BHJ blend films with a non-fullerene acceptor, to obtain a comprehensive understanding of photodegradation. Evidence for C DBs vs deeply trapped holes and electrons will be discussed, given that the defects are generated largely by blue/UV irradiation rather than longer wavelengths. This observation clearly supports C DB formation over deeply trapped charges. The role of “hot” polarons in donor/acceptor interface C DB formation will also be discussed.

11:15 AM ESI18.04.03 Voltage Loss in Polymer Solar Cells and Perovskite Solar Cells Hyungdo Kim and Hideo Ohkita; Department of Polymer Chemistry, Kyoto Univ., Kyoto, Japan.

Solution-processed polymer solar cells and perovskite solar cells are a promising class of photovoltaic devices because of noticeable progress in the device performance with their many advantages such as flexibility and easy fabrication with low cost. The power conversion efficiency (PCE) has gradually increased over the last few decades and recently exceeded 14% for polymer solar cells. On the other hand, it has been steeply improved up to 23% for perovskite solar cells. In other words, the PCE of polymer solar cells still lag far behind that of perovskite counterparts. This is mainly ascribed to the difference in voltage loss (photon energy loss, \(E_{\text{loss}} = \mathcal{E}_p - qV_{\text{OC}}\)) between the two devices. The \(E_{\text{loss}}\) is typically in the range of about 0.7–1.1 eV for polymer solar cells while it is reported to be about 0.4–0.5 eV for perovskite solar cells. This indicates that such a voltage loss is dependent upon different mechanisms. In this research, we therefore studied the origin of \(E_{\text{loss}}\) in both polymer solar cells and perovskite solar cells. By measuring the temperature dependence of \(V_{\text{OC}}\), we discussed the difference in \(E_{\text{loss}}\) between the two devices. As a result, we found that there are temperature-independent and -dependent voltage losses in polymer solar cells whereas there is only a temperature-dependent voltage loss in perovskite solar cells. This discrepancy results from different charge generation and recombination mechanisms between them. On the basis of these experimental data, we further discuss the potential strategies for further improvement in \(V_{\text{OC}}\) for both devices.

11:30 AM ESI18.04.04 Quantifying Tie-Chain Fraction and Its Impact on Charge Transport in Model Conjugated Polymers Yueh-Lin (Lynn) Loo; Andlinger Center for Energy and the Environment, Department of Chemical and Biological Engineering, Princeton University, Princeton, New Jersey, United States.

The presence of tie chains that connect between crystallites can critically impact the electrical properties of conjugated polymers. Yet, the community has not yet been able to directly visualize them, let alone quantify their content in conjugated polymers. We applied the Huang-Brown model, a framework commonly used to elucidate the structural origins of mechanical properties in polyolefins, to quantify the tie-chain contribution to charge transport in a series of model poly(3-hexylthiophene), PSHT, and its blends. Plotting field-effect mobility as a function of tie-chain content, as extracted from the Huang-Brown model, collapses the data on a single curve not previously seen when the charge transport property is plotted against molar mass. We find a threshold tie-chain fraction of 10\(^{-6}\), below which intercrystallite connectivity limits macroscopic charge transport. X-ray paracrystallinity analysis of these PSHT films suggests intracrystallite disorder to be the bottleneck that limits charge transport when crystallitles are connected. Our study affirms the importance of connectivity between crystalline domains, with the Huang-Brown model implicating long polymer chains with rigid backbone to facilitate macroscopic charge transport.

1:30 PM ESI18.05.01 Molecular Design, Morphological Control and Device Characterization of Non-Fullerene Solar Cells with Significantly Reduced Photovoltage Loss and Enhanced Power Conversion Efficiency Alex Jen 1,2, 3; 1Department of Materials Science and Engineering, University of Washington, Seattle, Washington, United States; 2Engineering, City University of Hong Kong, Hong Kong, Hong Kong.

Minimizing energy loss is a key aspect to transcend the current limitations on the performance of organic photovoltaics (OPV). However, an inherent limit has set for both devices.

2:00 PM ESI18.05.02 B—NContaining N-Type Conjugated Polymers and Polyarenes Chundong Dou, Jun Liu and Lixiang Wang; Changchun Institute of Applied Chemistry, CAS, Changchun, China.

Conjugated polymers and molecules are very important for their applications as semiconducting materials in organic electronics. In comparison to many p-type semiconductors, n-type semiconductors are very rare. Most of molecular designs of n-type semiconductors are based on the amide units. It is important but challenging to develop new design concept of n-type semiconductors. Based on organoboron chemistry,1,2 we now use boron-nitrogen coordination bond (B←N) as a powerful strategy to develop n-type semiconductors.3,4 We have proposed two approaches to design n-type conjugated polymers using B—N unit. The one is to replace a C−C unit by a B←N unit in conjugated polymers to transform a p-type polymer to a n-type polymer.4 The other approach is to construct novel electron-deficient building block based on B—N unit for n-type polymer.5 Following these two approaches, polymer electron acceptors containing B—N unit have been developed for all-polymer solar cells with power conversion efficiency of exceeding 8%.6 Moreover, we use B—N unit to design n-type polyarenes. A series of polyarenes containing B—N unit have been developed. They exhibit low-lying LUMO energy levels and high electron affinity. They have been used as electron-transporting semiconductors for solution-processed organic thin-film transistors. The electron mobility has reached 0.21 cm\(^2\) V\(^{-1}\) s\(^{-1}\). These results indicate that organoboron chemistry is a new toolbox to develop organic and polymer semiconductors.

The ability to control the translation of molecular properties to bulk properties remains crucial in our development of high performance materials for organic electronics. We investigate the effect of differing core substituents on the benzodithiophene-based high-performing organic photovoltaic (OPV) material BTR. Through sidechain engineering four novel p-type small-molecule semiconducting materials based on the BTR molecular structure are designed and synthesized to carry out this study, with one of our analogues possessing an excellent PCE of over 9% in simple device architectures. Through grazing incidence wide-angle X-ray scattering (GIWAXS) depth-dependent studies we find that this efficiency is realized through an optimal active-layer morphology comprised of a spectrum of crystallite orientations. We go on to establish that high solubility in the spin-coating solution during OPV active layer formation significantly improves the formation of this beneficial crystallite orientation. These results further our understanding of these high-performing class of materials and demonstrate the vital importance of solubility considerations to OPV morphology.

Non-Adiabatic Molecular Dynamics Study on Charge Transfer Dynamics at the Boron Subphthalocyanine Chloride/C60 Interface

Kosuke Satō, Ekadashi Pradhan, Kosuke Sato, Ekadashi Pradhan, Kosuke Sato, Senku Tanaka, Takuya Yoshitomi and Masaki Tsuka; Kindai University, Higashiosaka, Osaka, Japan.

We fabricated a semi-transparent organic photovoltaic (OPV) using a carbon nanotube (CNT) sheet as the top transparent electrode and an indium tin oxide (ITO) as the bottom electrode. A bulk heterojunction layer of poly(3-hexylthiophene-2,5-diyl) (P3HT) and [6,6]-Phenyl C61 butyric acid methyl ester (PCBM) was used as the photovoltaic layer. We investigated the illumination direction dependence on the photovoltaic properties of OPVs. It was found that the power conversion efficiency under the CNT side illumination showed the lower value than that under the ITO side illumination. Especially, the short-circuit current density (JSC) was decreased significantly.

A simple reason for the asymmetric photovoltaic properties was considered as the difference between the transparency of the two electrodes. The transparency of the ITO electrode (including the glass substrate) was higher than that of the CNT-sheet electrode. However, the decrease ratio of the JSC was much larger than the difference of the transparencies. In addition, the external quantum efficiency (EQE) spectrum of the CNT side illumination showed a decrease of EQE in the absorption region of PCBM. These results inferred that there were other reasons for the asymmetry.

To investigate the origin of the asymmetry, we fabricated semi-transparent OPVs with a wide range of thickness of the photovoltaic layer (50 ~ 5000 nm) and investigated the illumination direction dependence of the photovoltaic properties. It was found that the discrepancy of the JSC between the ITO side and the CNT side was increased with the increase of thickness. In the present OPV, electrons and holes were extracted from the ITO electrode and the CNT electrode, respectively. Hence, the difference of the illumination direction results in the difference of the transfer distance of electrons and holes.

We considered that a difference between electron and hole for an annihilation probability during the transfer through the bulk heterojunction layer was the main reason for the asymmetric JSC. We estimated an effective extraction length (EEL) of each carrier from the thickness dependence of the asymmetric ratio of JSC. Our results indicated that the EEL of electron was shorter than that of hole. It should be noted that, in many reports, the electron mobility in the P3HT:PCBM blend film is higher than the hole mobility: the trend of mobility does not explain our results. We consider that the EEL is another useful index for the understanding of the photovoltaic mechanism in the bulk heterojunction layer.

ES18.07.02
Doping ZnO Electron Transport Layers with MoS2 Nanosheets Enhances the Efficiency of Polymer Solar Cells

Renee Lee, Yi-Jiun Huang, Ben Chang and Kung-Hwa Wei; Materials Science And Engineering, National Chiao Tung University, Hsinchu, Taiwan.

In this study, we incorporated molybdenum disulfide (MoS2) nanosheets into solid-gel-processed zinc oxide (ZnO) to form ZnO:MoS2 composites for use as electron transport layers (ETLs) in inverted polymer solar cells featuring a binary blend active layer. We could effectively tune the energy band of the ZnO:MoS2 composite film from 4.45 to 4.22 eV by varying the content of MoS2 up to 0.5 wt%, such that the composite was suitable for use in bulk heterojunction photovoltaic devices based on poly[6,6]-phenyl C61 butyric acid methyl ester (PCBM). In particular, the power conversion efficiency (PCE) of the PTB7-Th:PCBM (1:1.5, w/w) device incorporating the ZnO:MoS2 (0.5 wt%) composite layer as the ETL was 10.1%, up from 8.8% for the corresponding device featuring ZnO alone as the ETL—a relative increase of 15%. Incorporating a small amount of MoS2 nanosheets into the ETL flattened the morphology of the ETL and resulted in enhanced fill factors and PCEs. We used ultraviolet photoelectron spectroscopy, synchrotron grazing-incidence wide-/small-angle X-ray scattering, atomic force microscopy, and transmission electron microscopy to characterize the energy band structures, internal structures, surface roughnesses, and morphologies, respectively, of the ZnO:MoS2 composite films.
Structural Isomerism as a Tool to Tune Properties in BODIPY Copolymers for Fullerene-Free Solar Cell

Gourav Tarafdar, Sanchita Sengupta, Upendra K. Pandey and Praveen C. Ramamurthy

1Interdisciplinary Center for Energy Research, Indian Institute of Science, Bangalore, India; 2Materials Engineering, Indian Institute of Science, Bangalore, India; 3Chemical Sciences, Indian Institute of Science Education and Research, Mohali, India.

Substituting fullerenes in organic bulk heterojunction (BHJ) solar cells with organic small molecules or polymers as electron acceptor can improve performances in solar cells. A lot of research is therefore being designed to test novel organic acceptors. Copolymers of 4,4-Difluoro-4-bora-3a,4a-diaza-s-indacene or BODIPY have been reported for photovoltaic applications. However, to our best knowledge in most of these reports the BODIPY copolymers have been used as the donor material in BHJ and the application of this class of materials as electron acceptor in organic BHJ solar cells have not been explored.

In this work we have synthesized four (two pairs) donor-acceptor copolymers of BODIPY with Benzodithiophene (P1 and P2) and Fluorene (P3 and P4). Each pair of polymers exhibit structural isomerism of the polymer backbone due to the difference in the point of attachment on the BODIPY (α or β) to the donor moiety (Benzodithiophene or fluorene).

The polymers are synthesized using Stille and Suzuki coupling reactions. The α connected polymers (P1 and P3) have a coiled backbone as compared to the β connected polymers (P2 and P4). The backbone isomerism is seen to alter the HOMO and LUMO energy levels of the polymer. While all the polymers have low lying HOMO (~ –5.2 eV) and hence good ambient stability, the energy of the HOMO in the aconnected polymers is than that in their bconnected counterparts. The polymers show narrow band gap (~ 1.5 eV) and absorption ranging from 700 nm to 900 nm which is influenced by the structural isomerism. The thermal stability of the a connected polymers (P1 and P3) is better than the β connected ones (P2 and P4). Space charge limited current (SCLC) measurements were performed to obtain the charge carrier mobility values in the polymers. Interestingly, the isomerism of the polymer backbone has no significant effect on the charge transport property of the polymers. All of the polymers exhibit ambipolar charge transport property with mobility values of the order of 10^-6 cm^2/Vs for the BODIPY-Benzodithiophene polymers and 10^-5 cm^2/Vs for the BODIPY Fluorene polymers. Photoluminescence quenching experiments on blend of these polymers with P3HT provide evidence of photoinduced charge transport from P3HT to these polymers. However, it was observed from Time resolved photoluminescence (TRPL) studies that charge transport is more efficient in the case of the α connected polymers than their β connected counterparts. This observation is supported by results from Density functional theory calculations which show greater degree of delocalization of the LUMO orbitals in the α connected polymers, whereas in case of the β connected polymers are the LUMO orbitals are mostly localized on the BODIPY units.

The better electron acceptor property of the aconnected polymers translates into better photovoltaic properties of the all polymer solar cells fabricated using P3HT: αP3αs as compared to P3HT: αP2P4. The best efficiency of these polymer solar cells is ~ 0.3 %. The low photovoltaic conversion efficiencies can be attributed to the low charge carrier mobility and hence low Voc. Modifying the alkyl side chain on the backbone of the polymer might be instrumental in improving the charge carrier mobility. Nevertheless, this study provides a crucial insight into the effect of LUMO delocalization on the ability of a material to perform as an electron acceptor. These results could be used as roadmap to the design of BODIPY based novel electron acceptor for fullerene free solar cells.

A DOE to Determine Significant Process Design Parameters in OPVs (Iain Tracton, Soumya Gupta, Zhila Hooshang, Jordan McNaughton, Jeremy Cody and Chris Collison)

The polymers are synthesized using Stille and Suzuki coupling reactions. The α connected polymers (P1 and P2) have a coiled backbone as compared to the β connected polymers (P4). The backbone isomerism is seen to alter the HOMO and LUMO energy levels of the polymer. While all the polymers have low lying HOMO (~ –5.2 eV) and hence good ambient stability, the energy of the HOMO in the aconnected polymers is than that in their bconnected counterparts. The polymers show narrow band gap (~ 1.5 eV) and absorption ranging from 700 nm to 900 nm which is influenced by the structural isomerism. The thermal stability of the a connected polymers (P1 and P3) is better than the β connected ones (P2 and P4). Space charge limited current (SCLC) measurements were performed to obtain the charge carrier mobility values in the polymers. Interestingly, the isomerism of the polymer backbone has no significant effect on the charge transport property of the polymers. All of the polymers exhibit ambipolar charge transport property with mobility values of the order of 10^-6 cm^2/Vs for the BODIPY-Benzodithiophene polymers and 10^-5 cm^2/Vs for the BODIPY Fluorene polymers. Photoluminescence quenching experiments on blend of these polymers with P3HT provide evidence of photoinduced charge transport from P3HT to these polymers. However, it was observed from Time resolved photoluminescence (TRPL) studies that charge transport is more efficient in the case of the α connected polymers than their β connected counterparts. This observation is supported by results from Density functional theory calculations which show greater degree of delocalization of the LUMO orbitals in the α connected polymers, whereas in case of the β connected polymers are the LUMO orbitals are mostly localized on the BODIPY units.

The better electron acceptor property of the aconnected polymers translates into better photovoltaic properties of the all polymer solar cells fabricated using P3HT: αP3αs as compared to P3HT: αP2P4. The best efficiency of these polymer solar cells is ~ 0.3 %. The low photovoltaic conversion efficiencies can be attributed to the low charge carrier mobility and hence low Voc. Modifying the alkyl side chain on the backbone of the polymer might be instrumental in improving the charge carrier mobility. Nevertheless, this study provides a crucial insight into the effect of LUMO delocalization on the ability of a material to perform as an electron acceptor. These results could be used as roadmap to the design of BODIPY based novel electron acceptor for fullerene free solar cells.

A Study on Mechanical Properties of Semicrystalline N-Type Polymers via Controlling the Molecular Weight—The Importance of Critical Molecular Weight for Stretchable Organic Electronics (Joohyeong Choi, Wansun Kim, Taek-Soo Kim and Bumjoon Kim)

The polymers are synthesized using Stille and Suzuki coupling reactions. The α connected polymers (P1 and P2) have a coiled backbone as compared to the β connected polymers (P4). The backbone isomerism is seen to alter the HOMO and LUMO energy levels of the polymer. While all the polymers have low lying HOMO (~ –5.2 eV) and hence good ambient stability, the energy of the HOMO in the aconnected polymers is than that in their bconnected counterparts. The polymers show narrow band gap (~ 1.5 eV) and absorption ranging from 700 nm to 900 nm which is influenced by the structural isomerism. The thermal stability of the a connected polymers (P1 and P3) is better than the β connected ones (P2 and P4). Space charge limited current (SCLC) measurements were performed to obtain the charge carrier mobility values in the polymers. Interestingly, the isomerism of the polymer backbone has no significant effect on the charge transport property of the polymers. All of the polymers exhibit ambipolar charge transport property with mobility values of the order of 10^-6 cm^2/Vs for the BODIPY-Benzodithiophene polymers and 10^-5 cm^2/Vs for the BODIPY Fluorene polymers. Photoluminescence quenching experiments on blend of these polymers with P3HT provide evidence of photoinduced charge transport from P3HT to these polymers. The best efficiency of these polymer solar cells is ~ 0.3 %. The low photovoltaic conversion efficiencies can be attributed to the low charge carrier mobility and hence low Voc. Modifying the alkyl side chain on the backbone of the polymer might be instrumental in improving the charge carrier mobility. Nevertheless, this study provides a crucial insight into the effect of LUMO delocalization on the ability of a material to perform as an electron acceptor. These results could be used as roadmap to the design of BODIPY based novel electron acceptor for fullerene free solar cells.

Impact of Molecular Planarity of Acceptor–Donor–Acceptor-Type Small Molecules on Molecular Packing and Photovoltaic Properties (Sang Woo Kim, Joohyeong Choi, Yu Jeong Lee, Young Woong Lee, Chang Woo Koh, Yeran Lee, Min Je Kim, Kin Liao, Jeong Ho Cho, Bumjoon Kim and Han Young Woo)

In this work, we have investigated the intrinsic mechanical properties of naphthalene diimide (NDI) based n-type conjugated polymer, P(NDI2OD-T2) via controlling the number-average molecular weight (Mn), varying from low to very high Mn = 15, 20, 48, 103 and 163 kg mol^-1. While we observed the general increasing trend of tensile properties as a function of Mn, a sharp transition in the strain at fracture and toughness values was observed between 48 and 103 kg mol^-1 with an increase by a factor of 26 and 160, respectively. The critical molecular weight at which the fracture toughness is minimal is attributed to the presence of large fraction of amorphous regions including tie molecules and interchain entanglements, which can effectively dissipate a substantial strain energy. The molecular weight dependence of mechanical behavior coincide well with thermal, viscoelastic and microstructural and thin film morphological properties. Therefore, our work suggests design rule for n-type conjugated polymer having good compromise between mechanical reliability and electrical performance for producing highly flexible and stretchable electronics.

High Temperature Semiconducting Polymer Blends (Aristide Gummesson, Purdue University, West Lafayette, Indiana, United States.)

In this study, we designed and synthesized a new A-D-A type SMs with thiophene-phenylene based central donor unit (P3T4) and different acceptor terminal groups of dicyanovinylene (VCN) and dicyanoindenedione (INCN). The P3T4 central donor unit is designed to allow intramolecular non-covalent Coulomb interaction, which has the feature that the torsional angle is minimized to improve planarity. We investigated the influence of terminal end-groups on intramolecular packing and the resulting electrical and photovoltaic characteristics. A small change in the end-group structure of the SMs induces a significant variation in the torsional structures, molecular packing, and pristine/blend film morphology. P3T4-VCN displayed a highly planar conformation and strongly crystalline morphology even in the post treatments and did not exhibit noticeable morphological changes. Our results demonstrate the importance of the terminal end-group for the design of A-D-A type SMs and their sensitivity toward the post-processing treatments in optimizing their performance.
Although high temperature operation (i.e., beyond 150 Celsius) is of great interest for many electronics applications, it is fundamentally challenging to achieve stable carrier mobilities for organic semiconductors at elevated temperatures. We report a general strategy to make thermally-stable high-temperature semiconducting polymer blends, composed of interpenetrating semicrystalline conjugated polymers and high glass-transition temperature insulating matrices. When properly engineered, such polymer blends display a temperature-insensitive charge transport behavior with hole mobility exceeding 2.0 cm²/Vs across a wide temperature range from room temperature up to 220 Celsius in thin-film transistors.

Relating Molecular Morphology to Charge Transport Through Efficient Multi-Scale Techniques
Matthew L. Jones1, Alexander L. Ayzer2, Lei Fang3 and Eric Jankowski1; 1Mieron School of Materials Science and Engineering, Boise State University, Boise, Idaho, United States; 2Department of Chemistry and Biochemistry, University of California, Santa Cruz, Santa Cruz, California, United States; 3Department of Chemistry, Texas A&M University, College Station, Texas, United States.

Solution-processed organic semiconductors are a promising class of materials, as they have the potential to be more economically viable than conventional inorganic photovoltaic devices, where fast return-on-investment and scalable, inexpensive manufacturing are a priority. The self-assembled molecular morphology strongly affects device performance and unlimited candidate molecules and processing protocols make it challenging to identify which combinations lead to nanostructures that result in the most efficient devices. Efficiently elucidating the links between morphology and final device performance is therefore a critical prerequisite for the large-scale adoption of these materials.

We demonstrate an open-source, multi-scale computational pipeline, MorphCT, that seamlessly combines molecular dynamics, quantum chemical calculations, machine learning, and kinetic Monte Carlo simulations. MorphCT encompasses length-scales from angstroms to microns and time-scales from femtoseconds to microseconds, linking molecular morphologies to device properties with excellent experimental agreement. We evaluate both donor and acceptor molecules across several classes of semiconductor (perylenes, fullerences, ladder molecules, polymers, and block-copolymers) for computer-aided device simulations, while identifying optimal processing conditions for device performance. This information is expected to be useful to device manufacturers to help focus further research efforts and identify a set of design rules for producing the most efficient devices.

Photonicallly Manipulated Polymer Solar Cells to Enhance Their Performance by Spectral Upconversion Systems
Ha-Eun Cho1, Na-Kyung Lee1, Young Jin Song1, Seok-Ho Cho2 and Sung-Min Lee1; 1Kookmin University, Seoul, Korea (the Republic of); 2Chonnam National University, Chonnam, Korea (the Republic of).

Despite many alluring advantages of polymer solar cells (PSCs) including low-cost fabrication process and device flexibility, comparatively low efficiency of PSCs has been a main hurdle for their full commercialization. There have been huge impressive efforts to overcome this drawback by developing active materials with high internal quantum efficiency, designing layer arrangement for high open-circuit voltage, and applying optical nanostructures that can enhance the photon absorption. Recently, novel approach of employing the spectral upconversion medium underneath cells has been arising to enable additional absorption for the solar photons for energy below the bandgap of active materials. While successful demonstrations of photovoltaics with the upconversion systems have been made for silicon or III-V solar cells, attaining meaningful enhancement of the performance of polymer-based thin film solar cells by such upconversion system is still challenging, because a reflective metallic electrode that can substantially increase the optical path length inhibits the penetration of the below-bandgap photons for excitation of the upconversion medium behind the cells, as well as of consequently upconverted above-bandgap photons. Herein we report an alternative design of PSCs to achieve the maximum benefits from the upconversion process without compromising pre-existing absorption of the incident solar photons. An opaque thick (~100 nm) silver (Ag) cathode typically used in PSCs is replaced by a multilayer electrode consisting of Ag (20 nm)/NPB (220 nm)/Ag (20 nm)/MoO3 (100 nm) that can selectively transmit the photons with wavelengths corresponding to the excitation (~980 nm) or emission (~540 nm) of NaYF4:Er3+ upconversion luminophors, thereby provoking the upconversion process and retrieving the resulting upconverted photons. To incorporate the highly effective upconversion system, a separately prepared upconversion medium deposited on a plastically nanostructured plate is attached to the damaged PSCs by using a polymeric adhesive without physical or chemical damages. The optimally designed PSCs with the plastically enhanced upconversion medium present a boosted level of the short-circuit current, even compared to the typical PSCs.

ES18.07.11

Semi-Transparent Quaternary Organic Photovoltaics Using NIR-Sensitive 4-Terminal Tandem System
Joo-Han Kang, Minwoo Nam and Doo-Hyun Ko; Applied Chemistry, Kyung Hee University, Yongin, Korea (the Republic of).

Organic photovoltaics are attracting much attention because they have many advantages such as low cost production, simple manufacturing process, and being able to fabricate on a flexible substrate which can be applied to modern technology. Here we exhibit highly-efficient and transparent quaternary organic photovoltaics (Q-OPVs) in a 4-terminal (4-T) tandem system. This system shows wide-range absorption spectra and high efficiency enough to assist other PV modules. This feature is meaningful that it can be used as additional tool for enhancing currently installed solar panels so that it can open up for possibility of diverse commercial applications.

ES18.07.12

The Importance of Molecular Weight in Optimizing the Mechanical and Electrical Performance of All-Polymer Solar Cells
Nup Balar1, Jeremy Rech2, Reece Henry3, Long Ye3, Harald Ade3, Wei You2 and Brendan T. O’Connor1; 1Mechanical and Aerospace Engineering, North Carolina State University, Raleigh, North Carolina, United States; 2Chemistry, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States; 3Physics, North Carolina State University, Raleigh, North Carolina, United States.

As organic photovoltaic (OPV) devices reach efficiencies that make them attractive for commercial implementation, it is becoming increasingly important to understand the thermo-mechanical behavior of the active layers to ensure reliable operation. This is particularly important to exploit intrinsic mechanical advantages of polymers to make physically robust flexible solar cells. Currently, high efficiency OPV devices are typically processed by blending a donor polymer with a small-molecule acceptor. These polymer-small molecule films, however, often demonstrate poor mechanical behavior and are prone to fail due to the detrimental effect of the small molecules. All-polymer solar cells (all-PSCs) provide a promising alternative that can be thermally and mechanically robust. However, the mechanical behavior of all-polymer films is dependent upon a number of factors of the individual polymers and interactions between the polymers. Here, we present the mechanical behavior of two high performing all-PSCs consisting of PDTT-TS1:PPDIODT and PBNDT-FTAZ:PDND2OD-T2. We focus on the fracture energy, crack onset strain, and storage and loss moduli of the films, and explore how the film morphology, polymer ratios, and polymer molecular weights impact both mechanical behavior and device performance. We also compare these results to their polymer:fullerene counterparts. We show that the all-PSC active layers can have a number of mechanical advantages over polymer:fullerene films including greater ductility and toughness and discuss the key molecular and morphological features that govern thermo-mechanical behavior. For example, we show that for the PBNDT-FTAZ:PDND2OD-T2 system, increasing the molecular weight of each polymer leads to both improved power conversion efficiency and cohesive fracture energy resulting in high performance mechanically robust flexible solar cells.

ES18.07.13

Balancing Crystal Size in Small Molecule Non-Fullerene Solar Cells Through Fine-Tuning the Film-Forming Kinetics to Fabricate Interpenetrating Network
Liu Jiampang and Yanchun Han; Changchun Institute of Applied Chemistry, Changchun, China.

All small molecule non-fullerene solar cells (AS-NFSCs), based on the binary blend of small molecule donors (SMDs) and non-fullerene small molecule acceptors (NFAs), are of emerging interest due to various virtues over conventional polymer/fullerene devices including easily tunable energy levels, well-defined chemical structure, high purity, and stable batch quality. In addition to the synthesis of donor and acceptor materials, interface engineering and device structure, the morphology of the active layer plays a crucial role in determining the power conversion efficiency (PCE) of device. Considerable research has demonstrated that the donor and acceptor should form an interpenetrating network, comprising a pure donor and acceptor crystals of 10-20 nm domain size with large interfacial mixed phase, to guarantee efficient exciton separation, carrier transport and carrier collection. However, in comparison with the case of polymer/fullerene or polymer/polymer based solar cells, achieving bicontinuous phase structure in AS-NFSCs is very challenging due to narrower processing windows, since small molecules are more sensitive to casting conditions. Furthermore, the variation trend of crystallinity for donor and acceptor are prone to follow the same trend, which inhibited to form similar crystal size between donor and acceptor.

Herein, we proposed the balanced crystal size between donor and acceptor is an important prerequisite to construct the interpenetrating network for AS-NFSCs. Additionally, the independent control of crystallinity for donor and acceptor was also realized by tuning the solution state and film-forming kinetics. Here, BDTT-S-TR (S-TR) was selected as...
donor and ITIC was chosen as acceptor. Due to the large difference in crystal size between S-TR and ITIC in blend system, i.e. the crystal size of S-TR ($L_d$) is 16 nm and the crystal size of ITIC ($L_a$) is 0, the phase separation was dominated by the crystallization of S-TR, thus formed grain-like phase separation structure. In order to balance the crystal size between S-TR and ITIC, an enlarged $L_d$ ($9.2$ nm) was achieved. The large crystal size between S-TR and ITIC-induced formation of interpenetrating network. The optimized morphology facilitates the dissociation of exciton and suppresses the recombination of charge transport process, leading to an improved device performance. Our work raised the principle for how to optimize the morphology of AS-NFSCs, and also provided method to individually control crystallinity for donor and acceptor, which could extend the ideal pair of SMDs and NFAs.

ES18.07.14 Preparation of Conjugated Polymers for Solar Cell Applications Using Direct Arylation Polymerization (DArp) Robert M. Pankow and Barry C. Thompson; University of Southern California, Los Angeles, California, United States.

Direct arylation polymerization (DArp) has emerged as a viable alternative to conventional polymerizations, such as Stille and Suzuki-Miyaura polymerizations, for conjugated polymer synthesis. DArP utilizes C-H activation, circumventing the need for the functionalization of monomers with a transmetalating reagent, reducing the overall number of synthetic steps and associated chemical waste. Through extensive study, conditions have been realized that allow for the polymer products with undetectable levels of undesired couplings (donor-donor, acceptor-acceptor, or branching defects). The incorporation of polymers prepared using DArP into electronic devices, such as organic photovoltaic applications has remained limited, however. We report the preparation of a series of perfectly-alternating conjugated polymers incorporating the acceptor thiieno[3,4-c]pyrroloindene and various donors and their incorporation into polymer bulk-heterojunction (BHJ) solar cells. The focus was to discover conjugated polymers that can be synthesized from simple building-blocks and their structure-property relationships unraveled. The ary groups incorporated into the TPD copolymers include thiophene (BT), thiienothiophene (TT), thiylenevinylene-thiophene (TVT), and ethylenedioxythiophene (EDOT). The BT based copolymer was shown to have the highest performance with a short-circuit current ($J_s$) of 10.54 mA cm$^{-2}$, an open-circuit voltage ($V_{oc}$) of 0.74 V, and a fill-factor (FF) of 0.61 affording a power conversion efficiency of 4.76% with PC$_{60}$BM as the acceptor and fabricated under ambient conditions. This methodology is then applied to the polymer, poly[(4,4'-bis(2-butyletheroxy)-[2,2'-bithiophene]-5,5'-diyl)-alt-(2,2'-bithiophene-5,5'-diyl)] (PDBCT), which is made of simple constructs and the structure can be easily modified through varying of various monomers to generate a library of polymer donors for BHJ solar cell applications using DArP.

ES18.07.16 Efficient Ternary Organic Solar Cells Near-IR Sensitized by Porphyrins Xiaobin Peng; South China University of Technology, Guangzhou, China.

Multi-components organic solar cells (OSCs) that use mixtures of light absorption materials have shown promising progress of elevating power conversion efficiency (PCE) of devices. Comparing to binary bulk heterojunction (BHJ) mixtures, ternary mixtures, the simplest system in multi-components systems, provide a larger parameter space to fine-tune light absorption, energy levels, and morphology, with the added benefits of forming cascading energy transfer ladders and providing multi-transporting channels for charge carriers. It is thus believed that ternary mixtures are ideal systems for single layer devices, which can also be implemented in tandem devices to further improve device performances. The most popular ternary blends use two donor materials and modified fullerene acceptor to address the technical challenges in light absorption, morphology, carrier mobility and energy level alignment. Extraordinary successes have been demonstrated in mid-band gap hosting polymer PBT7 and PBT7-Th based mixtures. However, the complimentary light absorption absorbing materials in these high-performance ternary BHJ ternary blends are wide band gap species, which can only serve the purpose of energetic and morphological improvement. Extending absorption to near-infrared (NIR) region is still challenging, leaving as a “bottleneck” in multi-components OSCs. It should also be noted that ternary blends have a much more complicated morphology comparing to binary counterparts, leaving this feature a key parameter to be optimized. It would be of high interest to develop new systems that have a stable morphology and can sustain compositional variations, which can thus be further implemented in large scaled manufacturing. We show herein efficient ternary mixtures that reaches PCE larger than 11%. A recent developed deep absorbing porphyrin small molecule (DPPEZnP-TEH) dopant plays a key role in near IR sensitization. PTB7 based polymers presents much higher ratio of NT unit, which can be integrated with a wide-bandgap electron-donating copolymer PBTA-BO to construct all-heterojunction ternary BHJ OSCs. Comparison to binary counterparts, this feature is a key parameter to be optimized. It would be of high importance to develop new systems that have a stable morphology and can sustain compositional variations, which can thus be further implemented in large scaled manufacturing. The composite film showed an absorption beyond 900 nm, making it a breakthrough in ternary OSC research.

ES18.07.17 Effect of Fluorine Substitution on Molecular Interaction and Performance in Organic Electronics In-Bok Kim1, Soo-Young Jang2, Yunseul Kim3, Dongseong Yang1, Yeonsu Cho1 and Dong-Yu Kim4;1 School of Materials Science and Engineering, Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of); 2Research Institute for Solar and Sustainable Energies, Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of).

Fluorine (F) substitution on conjugated polymers in polymer solar cells (PSCs) has a diverse influence of molecular properties and device performance. We synthesize a series of three D-A type conjugated polymers (PBT, PFBT and PDBFT) based on dithienothiophene and benzothiadiazole units with different numbers of F atoms to find the effect on F substitution by comparing the molecular interactions of the polymer in PSCs. In the UV-Vis absorption spectra, the pre-aggregation behavior of fluorinated polymers in o-DCB proves that polymers have strong intramolecular interactions even in solution state. Besides, more closely packed structures of F substitution polymers are observed in polymer:PC$_{60}$BM blends by GIXD which is beneficial for charge transport and ultimately, for current density (4.3, 13.0 and 14.5 mA cm$^{-2}$ for PBT, PFBT and PDBFT, respectively) and for the fill factor (0.41, 0.68 and 0.69 for PBT, PFBT and PDBFT, respectively) in PSCs. Consequently, the PCE of PSCs reached 7.3% without any additional treatment (annealing, solvent additive, etc) in the polymer containing di-fluorinated BT (PDBFT) which is much higher than non-fluorinated BT (PBT – 1%) and mono-fluorinated BT (PFBT – 6%).

ES18.07.18 Influence of Energy Level Offsets in Ternary Blend Organic Photovoltaics Sanket Samal, Pratyusha Das, Negan Kazerooni and Barry C. Thompson; University of Southern California, Los Angeles, California, United States.

Ternary solar cells have become an important architecture for organic solar cells in recent years. By adjusting the composition of the active layer, the open circuit voltage ($V_{oc}$) of the solar cell can be tuned across the composition range of the active layer. It was theoretically proposed that the maximum offset between HOMO/LUMO energies of synergistic donors/acceptors couldn't exceed 0.3 eV without pinning the $V_{oc}$. Recently it was demonstrated that, the ternary blend active layer containing poly[2,5-bis[3-tetradecylhexyl]thiophene]-2,5′-diyl] [poly(3,4-dihexylquinacridone)-alt-phenylenevinylene]-alt-[poly(3,4-dihexylquinacridone)] as donor and two fullerene based acceptors having an offset of 0.5 eV between their LUMO energies still result in solar cells exhibiting maximum energy offset ($V_{oc}$). Although this shows that 0.3 eV is not the limit, the maximum achievable energy offset is still unknown for $V_{oc}$. We tried to address the issue by using a pair of two random donors consisting of poly[3-(3-hexylthiophene)-co-3-hexylhexithiophene] (PH3T-co-3HET) and poly[3-(3-hexylthiophene)-co-3-hexyloxythiophene] (PH3T-co-3HOT). This specific system was used because previous studies showed that we can easily tune the HOMO levels of the respective polymers by varying the composition of the individual monomers and can achieve a maximum offset of 1.2 eV between HOMO levels of PH3T-co-3HET and PH3T-co-3HOT. We have studied the influence of polymer surface energy on polymer-polymer miscibility, and judiciously functionalized the polymers to ensure adequate mixing for alloy formation. The characterization of the ternary blends and solar cell performance will be discussed.

ES18.07.19 Overcoming Morphological and Efficiency Limit in All-Polymer Solar Cells by Designing Copolymers Containing naphto[1,2-c:5,6-c']bis[1,2,5]thiadiazole] moity Wei Yang; South China University of Technology, Guangzhou, China.

We designed and synthesized a series of narrow bandgap conjugated copolymers by combining two conjugated polymers with various molar ratios of naphthobis[1,2,5]thiadiazole (NT) unit. All-polymer solar cells (all-PSCs) based on the resulting ternary copolymers NT40 and N2200 exhibited an impressively high power conversion efficiency (PCE) over 8.0%, which obviously outperformed those of obtained from devices based on the N70/N7102/N2200 blended films. Detailed characterization of the morphology of the films revealed that the incorporation of the NT unit can improve n-p stacking and a degree of phase separation conducive to exciton diffusion and charge transport. It is interesting to note that the resulting copolymer NT95, which has much higher ratio of NT unit, can be integrated with a wide-bandgap electron-donating copolymer PBTB-BO to construct all
PSCs with N2200, which presents an impressively high PCE over 10%. The improved photovoltaic performance is attributable to the combined effects of the extended absorption profile, a favorable film morphology, and more efficient charge transfer. Of particular interest is that these ternary blend films were processed using a non-halogenated solvent, 2-methyltetrahydrofuran, which is promising for practical applications. These findings lend credence to the ternary approach as a facile and promising strategy for achieving high-performance all-PSCs.

**ES18.07.20**

New Fully Conjugated Block Copolymer Bearing Wide-Bandgap Donor and Narrow-Bandgap Acceptor Blocks — Application to Single Active Material Polymer Solar Cell Hyung J. Kim, Ji Hyung Lee, Chang Geun Park, Young Un Kim, Su Hong Park, Na Yeon Kwon, Min Ju Cho and Dong Hoon Choi; Korea University, Seoul, Korea (the Republic of).

All polymer solar cells (PSCs) have attracted a considerable attention owing to their advantages such as their film-forming properties and the mechanical stability of their active layers. However, the major disadvantages of polymer/polymer blend films include poor miscibility, difficulty in controlling crystallinity, nonuniform internal phase composition, and large-scale phase segregation, all of which adversely affect the performance of the final PSC device. To overcome these shortcomings, much effort is being expended to develop a single-component active layer in PSCs which exhibits several key advantages such as simplified devices, stable internal morphology, and efficient exciton diffusion, dissociation, charge transport rather than a binary blend active layer. To date, few studies on single active material polymer solar cell (SAMPSCs) have been reported and the development of SAM is needed for the realization of high-performance organic solar cells.

In this presentation, we introduced a very intriguing conjugated block copolymers (CBCs) containing a p-type oligomeric unit and an n-type oligomeric unit. CBC showed very broad complementary absorption owing to the wide band gap of the p-type block and the narrow band gap of the n-type block, and also showed complete PL quenching because of the formation of photoinduced inter- and intramolecular charge transfer states. A CBC-based SAMPSC exhibited an unusually high PCE of ~4.00 % and excellent shelf-life under ambient conditions compared with the PSC fabricated with the blend film composed of p/n-type blocks. This is the first study to report excellent shelf-life for a CBC-based SAMPSC under ambient conditions.

**ES18.07.21**

Novel Terpolymer with Broad Complementary Absorption and Robust Morphology for Highly Efficient All Polymer Solar Cells Young Un Kim, Aesun Kim, Su Hong Park, Hyung J. Kim, Choel Hun Jeong, Jiwon Yoon, Na Yeon Kwon, Min Ju Cho and Dong Hoon Choi; Korea University, Seoul, Korea (the Republic of).

Terpolymer is designed by introducing a third monomer into the binary D–A copolymer structure and has a various property such as the absorption wavelength range, molecular energy level, charge carrier mobility, and solubility can be precisely tailored, often leading to improvements in the carrier mobility and power conversion efficiency (PCE) via synergistic effects between the three monomers. In other words, the chemical structure and distinct properties of the conjugated polymers can be finely controlled by this strategy. In this presentation, terpolymer, Ter-3MTTPD was synthesized using 4,8-bis(5-(2-ethylhexyl)thiophen-2-yl)benzo[1,2-b:4,5-b0]dithiophene as a donor and methyl thiophene-3-carboxylate (3MT) and 5-(2-ethylhexyl)4-H-thieno[3,4-c]pyrrole-4,6(5H)-dione (TPD) as acceptor units to investigate its fundamental properties. The absorption spectrum of Ter-3MTTPD was intriguingly observed to the spectrum obtained by simply adding the absorption spectra of copolymers, Co-3MT and Co-TPD. This resulted in efficient complementary absorption properties after mixing NDl-Se as n-type polymer with Ter-3MTTPD. In terms of morphology, a blend film of Ter-3MTTPD:NDl-Se exhibited a relatively smooth surface and fine internal morphology, and the BHJ-type all-polymer solar cell (all-PSC) based on it provided a maximum efficiency of 7.7 %. This was further supported by the results of time-resolved photoluminescence (TRPL) in Ter-3MTTPD:NDl-Se blend film states and also showed the excellent shelf-life (~1000 h) of the all-PSC at ambient conditions compared to the other two copolymers.

**ES18.07.22**

Efficient Semi-Transparent Organic Photovoltaics Using Quaternary Blends Jisu Shin, Minwoo Nam and Doo-Hyun Ko; Kyung Hee University, Suwon, Korea (the Republic of).

Recently, organic photovoltaics (OPVs) have been studied through vigorous efforts, resulting in the rapid improvement of photovoltaic characteristics. This development has led to further research into the applicability as well as the performance of OPVs. Semi-transparent OPVs (ST OPVs) could be applied in many fields such as a window and roof of vehicle. We herein developed highly efficient ST OPVs based on quaternary blends involving additional donor and non-fullerene acceptor in polymer:fullerene binary OPVs. The ST Q-OPVs with experimentally optimized composition ratio exhibited high power conversion efficiency (PCE) under any illumination environments, this feature can open up the possibility of versatile commercial applications.

Multi-Layered Polymer Solar Cells Using Stamped Active Layers from Water Juyeong Lee; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

The device performance of bulk heterojunction (BHJ) polymer solar cells is very sensitive to the blend film nanomorphology including phase separation, molecular orientation, and crystalline nature, which depends significantly on the manufacturing process conditions such as temperature, humidity, and types of solvents and processing additives used. Especially in large-areas required for commercialization, these difficulties in controlling the nanoscale morphologies of both phases may degrade the reproducibility of the devices. Such sensitivity to processing conditions can be alleviated easily in multilayer heterojunction structures because individual layer properties including thickness and crystalline nature can be independently controlled, thereby simplifying morphology optimization and improving device performance. However, the multilayer heterojunction structures could be limited to certain materials and solvents combinations because the top layer should be sequentially deposited from a semi-orthogonal solvent with respect to the bottom.

Recently, we reported a novel technique that can form large-scale organic thin films while keeping high-quality nanomorphology in a very short time based on a Marangoni flow. The film formed from the process can be easily stamped and transferred on various substrates, suggesting the multilayer heterojunction structure can be effectively formed with high performing nanomorphology though the process. To obtain insight in the parameters controlling the formation of multilayer heterojunction structure, we study a bilayer structured device stamped poly[(2,5-bis(2-hexyldecyloxy)phenylene)-alt-(5,6-difluoro-4,7-di(thiophen-2-yl)benzo[c][1,2,5]-thiadiazole)] (PPD2FTB) donor film on top of poly[N,N'-bis(2-octyldodecyl)naphtalene-1,4,5,8-bis(dicarboximide)-2,6-diyl]-alt-5,5'-(2,2'-bithiophene) (PND2O2D-T2) acceptor film us the aforementioned technique. Morphology studies reveal that more ordered molecular packing with strong face-on stacking and partially penetrated PPD2FTB molecules into the pre-deposited PND2O2D-T2 layer upon the solvent vapor annealing (SVA) process. Lastly, we discuss factors that control orientations of polymer backbones, which have great impact on the performance of optoelectronic devices.

Evaluating Stability of Push-Pull Small Molecule Donors for Organic Photovoltaics Trung Nguyen1, Kristen Watts1, Bharati Neelamraju1, Michael Anderson1, Wade Braunecker2, Zbyaw Owczerczyk2, Bryon Larson2, Bertrand Tremolet de Villers2, Ross Larsen2, Jeanne Pemberton1 and Erin L. Ratcliff1; 1University of Arizona, Tucson, Arizona, United States; 2National Renewable Energy Laboratory, Golden, Colorado, United States.
High efficiency organic photovoltaic devices have relied on the development of new donor and acceptor materials to optimize opto-electronic properties and control charge-transfer rates. To date, the highest single-junction organic photovoltaic devices have demonstrated ~14% power conversion efficiencies using non-fullerene acceptor molecules and tandem devices with efficiencies ~17%. For both donors and acceptors, push-pull of the electron density between different parts of the molecule allows for facile tuning of the band gap for maximizing the absorption of the solar spectrum, while simultaneously altering the redox properties to control the open circuit voltage and maximizing the photo-generated excitons to free carrier dynamics for optimal short-circuit current. Of these, small molecule-based materials hold exceptional promise over polymeric systems, with reduced batch-to-batch variations, high open circuit voltages and higher hole mobilities. Yet small molecules have more confined electronic density, which could make the materials more susceptible to degradation effects.

This work focuses on the degradation chemistry of a class of small molecule donors inspired by benzodithiophene terthiophene cores (BDT-3T) with rhodanine end caps, which have demonstrated 9% efficiency in single junction devices and ~11% in ternary cells. Herein we show that the same opto-electronic properties can be achieved for three additional molecules by simply changing the end cap to benzoazolato-terthiophene, pyrrole, or barbituric acid functional groups. This allows us to evaluate the stability of the 3T-BDT core as well as the role of the stability of the different end groups, each of which has unique spectroscopic signatures. Time-dependent degradation is monitored using both UV-vis and FT-IR spectroscopies, with changes in transmission related to the CIE color coordinate system. Changes in frontier orbitals and electronic structure are monitored using a combination of laboratory and synchrotron-based photoelectron spectroscopies and correlated to density functional theory predictions of degradation products.

8:45 AM ES18.08.03

Strategy for Efficient Eco-Friendly Processable Polymer Solar Cells via Side Chain Engineering of Aqueous Soluble Fullerenes
Youngkown Kim, Junhyeong Choi, Changyeon Lee, Youngwoong Kim, Changkyun Kim, Thanh L. Nguyen, Bhjo Gautam, Kenan Gundogdu, Han Young Woo and Bumjoon Kim; KAIST, Daejeon, Korea (the Republic of); Korea University, Seoul, Korea (the Republic of); Fayetteville State University, Fayetteville, North Carolina, United States; North Carolina State University, Raleigh, North Carolina, United States.

We develop a new series of aqueous solvent-soluble fullerene derivatives and successfully fabricate polymer solar cells (PSCs) using only aqueous solvents, essential to adapt for industrial criteria. In order to optimize the processability of the fullerenes in aqueous solvents and the device performances, different fullerene mono-adducts were designed by introducing oligoethylene glycol (OEG) side-chains having different lengths and the number of branches. As the results, we achieve the power conversion efficiency (PCE) of 1.4% for the PSCs processed by aqueous solvent in air. Significantly, the new fullerene derivative showed the superior electron mobility (1.30 × 10⁻⁶ cm² V⁻¹ s⁻¹), which is three different order higher than that of the previously reported alcohol soluble fullerenes owing to our design of fullerene-adducts that produce efficient packing between the fullerenes while ensuring sufficient solubility in aqueous solvents. Femtosecond transient absorption spectroscopy revealed the acceptor side chain to markedly impact geminate and/or nongeminate charge recombination in the PSCs. In addition, optimizing side-chains of these fullerenes produced the well-intermixed blend morphology with aqueous solvent-soluble p-type polymers to provide hole and electron pathway. Our results provide important guidelines for the design of the electroactive materials for real human-benign fabrication of the PSCs and other organic-electronics.

9:00 AM ES18.08.04

Toward Solution-Processed High-Performance Large Area Polymer Solar Cells
Zhang Kai; State Key Laboratory of Luminous Materials and Devices, South China University of Technology, Guangzhou, China.

While the performance of laboratory-scale polymer solar cells (PSCs) continues to grow, there are still challenges on the way to realizing efficient module devices, such as the low compatibility of the thickness-sensitive interlayer and active layer with large area coating techniques, the tremendous power loss on enlarged electrode, the frequent need for toxic solvents and tedious optimization processes used during device fabrication.

To avoid some of these problems and achieve high-performance large area PSC modules, we carried out a series of studies. Firstly, we developed a simple and efficient approach for achieving a large area cathode interlayer with controlled thickness at the nanometer-scale using an electrostatic layer-by-layer self-assembly (eLbL) process. The eLbL films exhibited excellent cathode modification ability and can be integrated into the current large area device processing techniques. Then, we employed a newly developed strategy of creating conjugated polymer P3NF-2TNDI as the ETL and PEDOT:PSS as the HTL to construct the interconnection layer (ICL) for conventional tandem PSCs, in which the device short current density (Jsc) was largely suppressed to minimize the power loss on the electrode. And then, we developed a highly efficient thickness-insensitive PSCs based on PTB7-Th:PC70BM that processed with single-component green solvent 2-methylanilole, in which both junction thickness limitation and solvent toxicity issues are simultaneously addressed. 16 cm² and 93 cm² PSC with the doctor-blade coating with a state-of-the-art power conversion efficiency of 7.5% and 4.5% were obtained.

Lastly, we have developed highly efficient (12.9%) non-fullerene PSCs by using sequential bilayer deposition method from non-halogenated solvents. More importantly, bilayer structure devices show less dependence on the processing condition (e.g., D/A ratio, solvent, annealing and so on). Using this bilayer processing method, PSCs can be scaled up to a larger area (1 cm²) while maintaining a high performance of 11.4% using the doctor-blade coating technique. This method offers a truly compatible processing technique for printing large area PSC modules.

Reference
Polymer solar cells (PSC) boasting a range of advantages including low cost, light weight and superior mechanical properties represent an important family in the third-generation solar cells. In the past few years, a variety of non-fullerene small-molecule acceptors have been reported, which afforded outstanding solar cell performances and are proven competent for replacing fullerene derivatives as the acceptor materials. Compared to the small molecule-polymer blends, solar cells comprising all-polymer active layers presumably present more stable donor-acceptor phase separation morphology and thus potentially superior long-term stability. The bottleneck of further enhancing the power conversion efficiency (PCE) of all-PSCs currently lies with the performance of polymer acceptors. Thus far, the most extensively studied polymer acceptors are naphthalenediimide (NDI) polymers, and pertinent all-PSCs have achieved impressive PCEs up to over 10%. Another important type of polymer acceptors is perylenediimide (PDI) polymers. Compared to NDI polymers, more versatile synthetic methods and diverse chemical structures have been developed with PDI polymers, which allow for more convenient tuning of the electronic and morphology properties. Our group have endeavored to improve the performance of all-PSCs by designing new high-performance PDI polymer acceptors. Particularly, we reported the application of a PDI-vinylene polymer acceptor (PDI-V) in all-PSCs. With PTB7-Th as the donor, PCE of 7.57% was attained. More recently, we designed and synthesized a new polymer acceptor NDP-V, which was chemically modified from PDI-V and contained an enlarged polycyclic aromatic dicarboximide, namely naphthodiperylene diimide (NDP), as the main building block, and the PCE of all-PSC using this polymer acceptor was boosted to over 8.5%. More recently, as an effort to fine tune the phase separation morphology, the donor polymer structure was further modified by adding chlorine substituents in the backbone. Upon adding the new polymer as a co-c donor to form a ternary blend active layer, the best PCE of NDP-V based all-PSC was further improved to over 9%. Finally, since perylene and naphthalenedicarboximide polymers both bring about outstanding performance, we are currently trying to develop new acceptor polymers by further diversifying the composing aromatic dicarboximide units. A series of new polycyclic aromatic dicarboximide monomers have been designed and synthesized, which will be applied to preparing new polymer acceptors.

Ternary-Blend Solar Cell, a Leading Strategy in Development of OPV Technology
Takebeh Ameri; Physical Chemistry, University of Munich (LMU), Munich, Germany.

The unique selling points of organic photovoltaics (OPVs), such as excellent light harvesting capability, freedom of form, color and transparency, environmental friendliness, easy scalability and lower manufacturing costs based on roll-to-roll printing methods, position this technology for the mobile power market, and this most properly reflects the state of the art in commercialization. An important milestone towards OPV commercialization has been surpassed by reaching a power conversion efficiency (PCE) of over 15%. To boost the performance, ternary blend organic solar cells represent one of the most dominant strategies that have been explored in the last decade. The outstanding advantage of ternary blends consists of maintaining the simplicity of the processing conditions used for single active layer devices. Moreover, all the optimization strategies developed for binary cells can be also effectively applied for ternary solar cells. In this elegant configuration, all three photovoltaic parameters (V_{OC}, J_{SC}, FF) can be tackled simultaneously or individually by optimizing the ratio between the three materials used in the photoactive layer. Promisingly, the ternary-blend strategy, in single junction as well as multi-junction solar cells, has further closed the gap between the organic and perovskite photovoltaic technologies, where OPV technology has significant advantages in terms of large-area processability and environmentally-friendly nature. In this presentation, we will discuss our achieved results in details for various prototype organic ternary systems with a central focus on the fundamental complexity of microstructure and charge transport mechanisms. Importantly, we will explain the key issues that result in modified recombination mechanisms and consequently improved FF and V_{OC} in high-efficiency ternary solar cells.

11:00 AM ES18.09.02
Strategy for Designing Ternary Solar Cells from Interfacial Energetic View
Chuanfei Wang, Xianjie Liu and Mats Fahlman; Linköping University, Linköping, Sweden.

So called ternary device structure is being deployed to overcome the limitation of the binary solar cells for energy conversion. One of the most important tasks during design and fabrication of organic devices is to determine the energy levels of the organic materials and understand the energy level alignment at the interfaces involving semiconducting molecules and polymers. Introducing the third component in the ternary device structure means that there will be more interfaces in the devices. Therefore, it is urgent to find a general strategy to design efficient ternary solar cells from interfacial energetic view to improve the performance. A correlation between CV-derived oxidation potentials with UPS-derived IP is obtained for organic semiconductor films typically used in organic solar cells, enabling complementarily use of these two techniques [Sol. RRL 2018, 2, 1800122]. In organic devices, energy level alignment at interface can be described by integer charge transfer (ICT) model. Based on energy-level diagrams obtained with the ICT model, we design ternary solar cells by adding non-fullerene acceptor to binary blends, demonstrating an unprecedented increase in V_{oc} beyond the binary reference values and a significant improvement of PCE, J_{sc} and thermal stability simultaneously. [Nano Energy, 2017, 27, 24]. Ternary solar cells with minimum voltage loss were also developed by combining two donor materials featuring complementary optical absorption and the same ionization potential and positive ICT energy, matching the fullerene acceptor’s negative ICT energy. This design concept is shown to enhance dissociation of all polymer donor and fullerene acceptor excitons and to suppress bimolecular and trap assisted recombination [Adv. Energy Mater. 2017, 6, 1700390].

Correlating Morphological Characterization of the Active Layer of Ternary Organic Solar Cells with Their Photovoltaic Performance
Ismail A. Ayhan and Enrique D. Gomez; Chemical Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States.

Ternary organic solar cells (TOSCs), consisting of multiple donor or acceptor materials in one photoactive layer, recently have emerged as one of the most promising strategy for broadening the light absorption spectrum and enhancing the power conversion efficiency (PCE) of photovoltaic devices compared with traditional binary solar cells. To enable efficient separation, transport and collection of charges, the photoactive layer morphology plays a dominating role for high-performance OSCs because there are some critical challenging issues such as controlling the phase separation and domain size of the device components. We propose that differentiating all-three components from each other in the TOSCs by using advanced characterization techniques can lead to a better understanding on the phase behavior and improvement of the device performance. Here, we demonstrate high-efficiency OSCs by combining the organic semiconductor components complementing with each other, such as donors(D) (PFBT4T-2OD (C_{66}H_{4}F_{2}N_{2}S_{2}O), PTB7-Th (C_{47}H_{38}N_{6}S_{2}), PCDTBT (C_{47}H_{38}N_{6}S_{2}), ICBA (C_{60}), PC71BM (C_{60}H_{4}O_{2}), IDIC (C_{6}H_{14}N_{4}O_{3}S_{2}), O-IDTBR (C_{6}H_{14}N_{4}O_{3}S_{2}), and their photovoltaic properties and morphology modification were studied through optimizing processing parameters such as polymer concentration, D:A1:A2 ratio, and thermal annealing. The effect of these parameters on the structural, morphological, electrical and photovoltaic properties were systematically investigated by performing UV-Vis absorption, Grazing-Incidence Wide-Angle X-ray Scattering (GIWAXS) and Energy-Filtered Transmission Electron Microscopy (EFTEM). This work shows ternary systems composed of morphologically compatible acceptors at their comparable loadings can achieve fibril-like nanostructure features resulting in improving phase separation, a remarkable high PCE (>10%), significant enhancement of short-circuit current due to broadening of the absorption spectrum, and the fill factor. We attribute that the high morphology compatibility of the ternary system can benefit to optimize electron/hole mobility and diminish recombination. This study reveals the correlation of the morphology characteristic with the device performance and offers new insight from the perspective of morphology modulation for constructing efficient TOSCs.

11:30 AM *ES18.09.04
Design and Synthesis of Multi-Functional Materials for Highly Efficient and Perovskite Solar Cells
Sung-Ho Jin1 and Hyung Woo Lee2; 1Pusan National University, Busan, Korea (the Republic of); 2Department of Nanoenergy Engineering, Pusan National University, Busan, Korea (the Republic of).

Bulk heterojunction polymer solar cells (BHJ PSCs) and all-polymer solar cells (BHJ all-PSCs) have received great amount of interest in organic electronic applications due to
their unique features such as flexibility, fine tuning of optoelectronic properties and large area application. Even though, the power conversion efficiency (PCE) of PSCs and all-PSCs reached high PCE of 13 and 10%, respectively, the study towards stability and green solvent processable π-conjugated polymers are limited. In this scenario, we have developed two new series of fluorous containing π-conjugated polymers (P1-P3) and (NAP-1 and NAP-2). Especially, the fluorinated alkoxyphenylene-based 2D π-conjugated polymers (P1-P3) owns good compatibility with n-type polymers in all-PSCs and delivered a maximum PCE of 7.3% for P2 based devices in inverted all-PSCs. The second series of alkoxyphenylene substituted benzodithiophene based 2D π-conjugated polymers NAP-1, NAP-2 which effectively foresee the usage of green solvents and delivered a maximum PCE of 8.3% for NAP-2 in conventional BHJ PSCs without any additional treatments. In addition, we designed and synthesized a new efficient solution processable electron injection layer (EIL) PO-TAZ based on 1,3,5-triazine moiety. The application of PO-TAZ as an EIL in inverted PSCs delivered a high PCE of 10% with enhanced device stability.

Fully Stretchable Semiconducting Polymers—Concept, Development and Application to Solar Cells Taiho Park; Pohang University of Science and Technology, Pohang, Korea (the Republic of).

Fully stretchable optoelectronics such as plastic solar cells and displays (e.g., light emitting diodes) have become a core issue in materials and engineering academia and industries. To realize such advanced technology, development of novel concepts in active materials including electrodes, transistors, photo-related organics and substrates should be accompanied with other skills Among them, organic-based transistors employing conducting polymers could be a good model to develop new logics. Various studies have attempted to enhance charge carrier transport by increasing crystallinity. However, these approaches are inevitably limited by the semicrystalline nature of conjugated polymers. Moreover, high-crystallinity conjugated polymers have proven inadequate for soft electronics applications because of their poor mechanical resilience. Herein, we demonstrate that π-π stacking can aid energy dissipation when the polymer film is subjected to strain; furthermore, the π-π stacking prevents the chains from irreversible sliding out of place due to the applied strain.

Optical Design for Advanced Tandem and Semitransparent Polymer Solar Cells Hin-Lap Yip; South China University of Technology, Guangzhou, China.

Optical management is a powerful strategy to enhance the performance of polymer solar cells by maximizing the light harvesting property of the devices. The capability to use optical model to precisely predict the light propagation property and charge generation rate within the devices allows us to design optimal device architectures with improved performance and stability.1 Here I will discuss how to apply high throughputs optical model to rapidly screen more than 10M device structures in order to identify the very best device design for extremely high performance tandem and semitransparent polymer solar cells.2-4 In addition, a multiple-function semitransparent polymer solar cell with both heat insulation and power generation properties will also be highlighted.3

Flexible and Durable Perovskite Solar Cells Using Fullerences and Nanocarbon Materials Yutaka Matsuoka1, 2; 1The University of Tokyo, Tokyo, Japan; 2University of Science and Technology of China, Hefei, China.

Carbon nanotubes (CNTs) have excellent charge carrier transport property and facilitates high flexibility of organic solar cells devices. In order to realize the use of CNTs in solar cells, we need to consider quality and electronic property of CNTs. We employ CNT transparent films made from aerosol CNTs which can be produced with floating iron catalysts prepared by thermal deposition of sublimated ferrocene. To obtain high electronic property of CNTs, we investigated bromsted acid, Lewis acid, and electrophilic fullerences for electronics application. We report CNTs-electrode-based flexible organic and perovskite solar cells. With replacing metal or metal oxide electrodes by CNT transparent electrodes, 1) use of CNTs as hole injection layer to realize stable PSCs with less than 10% efficiency loss under more than 1000 h continuous illumination. Also, we will discuss the use of fullerences for improvement of performance in organic and perovskite solar cells. Topics will be 1) Use of C

Intrinsic Reverse Dark Current in Organic Photodetectors Jonas Kuhlbi1, Donato Spoltore2, Andreas Hofacker1, Hans Kleemann1, Koen Van Den Heuvel2 and Karl Leo1, 1IAPP - Integrated Center for Applied Physics and Photonic Materials, Technische Universität Dresden, Dresden, Germany; 2IMO-IMOMEC, Universiteit Hasselt, Diepenbeek, Belgium.
Light sensing and imaging represent an important important technological field, demanding the use of outstanding photodetectors (PDs). This means a low dark current and high responsivity, resulting in a low noise current and high detectivity. Currently used PDs in the visible and near infra-red spectral region are based on hard solid state materials, namely silicon and InGaAs alloys. While their performance is outstanding, they cannot provide flexible, low cost and lightweight devices and imagers. Organic semiconductors have been shown to be suitable for accomplishing these needs and have already successfully been applied in solar cells and light emitting diodes. However, organic PDs still lack a high detectivity, especially in the near-infrared which is mostly a consequence of their high dark currents ($J_d$) and noise currents at reverse bias voltages, where PDs usually operate.

Due to impurities and their disordered nature, trap and sub-gap states are often observed in organic materials. In this work, we investigate the generation of charge carriers through trap and charge-transfer (CT) states and their influence on $J_d$. When suppressing extrinsic shunt paths, we observe that $J_d$ follows a trend with the energies ($E_{CT}$) of the subgap CT states formed at the charge generating donor-acceptor interface. Low energy CT states result in a reduced effective gap, over which charge carriers are thermally excited, resulting in increased dark currents. Furthermore, in specific donor:acceptor blends, we find trap concentrations of around 10$^{17}$ cm$^{-3}$ with an energy of around 0.45 eV below the transport level of the acceptor material. We were able to vary the trap concentration by varying the donor concentration while keeping $E_{CT}$ constant and observe that $J_d$ increases with increasing trap concentration. Dark current-voltage characteristics were simulated by a drift-diffusion model. By including trap assisted generation (Shockley-Read-Hall like generation-recombination process), we show that the expected value of $J_d$ increases four orders of magnitude and rules the dark $J'$ characteristics, limiting the detectivity.

By using electron/hole blocking layers and optimizing the energetic stack in our devices, we were able to achieve dark currents as low as 500 pA/cm$^2$ at -1V, leading to on/off ration of 10$^4$. To the best of our knowledge, this value of dark current is among the best values reported in literature for organic devices. Moreover, our experimental findings point out to a physical process that might be present in several donor:acceptor structures, explaining the high $J_d$ commonly observed in OPDs.

3:45 PM ES18.11.03

The Impact of Short Range Quadruple Interactions on the Photophysics of Quinquaraines and the Measured Efficiency in their Small-Molecule Photovoltaic Devices. Chris Collins$^{1,2}$, Chenyu Zheng$^{1,2}$, Tyler Wiegand$^{1,2}$, Michael Mark$^3$, Frank C. Spano$^3$, Jeremy Cody$^4$ and David McCamant$^4$, $^1$School of Chemistry and Materials Science, Rochester Institute of Technology, Rochester, New York, United States; $^2$ Nanopower Research Laboratories, Rochester Institute of Technology, Rochester, New York, United States; $^3$ Microsystems Engineering, Rochester Institute of Technology, Rochester, New York, United States; $^4$ Department of Chemistry, University of Rochester, Rochester, New York, United States; $^5$ Department of Chemistry, Temple University, Philadelphia, Pennsylvania, United States.

Electronic coupling and intermolecular charge transfer interactions strongly influence the excited state properties for organic solids, which dictate the effectiveness of these materials in optoelectronic devices. Exciton coupling via long-range coulombic interaction is both theoretically and experimentally well demonstrated for many small molecule crystals. However, the spectroscopic properties of a variety of closely-packed push-pull dyes cannot be explained by established Frenkel exciton models. We will describe our theoretical work with quinquaraines, demonstrating how the quadrupoole-quadrupole interaction must be accounted for when the intermolecular pi-stacking distance is small (< 3-5 Å).

We present the results of subpicosecond transient absorption spectroscopy, which probes the excited state photophysics of an anilino-quinquarine, known for its successful use in the active layer of organic photovoltaic devices. Our samples are designed with a continuum of intermolecular separations from monomers in solution, through solid solution thin films, to the fully condensed phase, demonstrating the increasing contribution of short-range quadrupole interactions. We measure excited state kinetics that confirm species assignments. The experimental results are in excellent agreement with our theoretical modeling.

We further considered the interpretation of theory and excited state characterization with our measured efficiencies in relevant small molecule organic photovoltaic devices. The comprehensive explanation of device efficiencies and time-resolved excited state absorption spectroscopy with our excited state modeling leads us to focus on a far-reaching mechanistic bottleneck for molecular and polymeric bulk heterojunction devices. With the identification of such a bottleneck, we discuss significant predictions for improved materials research for optoelectronic devices in general.

4:00 PM ES18.11.04

On the Design of Organic Solar Cells for Integration with Greenhouses. Eshwar Ravishankar$^1$, Jennifer Swift$^2$, Yuan Xiong$^1$, Long Ye$^1$, Reese Henry$^1$, Jeremy Rech$^1$, Carole Sarazivt$^1$, Wei You$^1$, Harald Ade$^1$ and Brendan T. O’Connor$^1$, $^1$ North Carolina State University, Raleigh, North Carolina, United States; $^2$ University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

Organic photovoltaics have several key advantages over other solar cell technologies that include the ability to tune absorption characteristics through material synthesis and device design, and the ability to make semitransparent devices with a broad range of transmittance across the solar spectrum. Exploiting these features may be the key to successful commercialization of this technology. One promising application is to integrate semitransparent organic solar cells with greenhouses. Greenhouses provide a controlled environment for plant growth that results in significant increases in yield while reducing water consumption compared to conventional farming. However, greenhouses typically require significantly more energy per kg of food produced. Reducing the need for external energy input has the potential to lower the cost of greenhouse-produced food, and enable production in a greater number of geographical locations. Given this desire, there has been interest in solar powered integrated greenhouses for over a decade. However, in many demonstrations the incorporation of traditional silicon-based solar panels has shown poor performance due to the complete shading by the opaque panels. Here, we discuss the opportunity provided by semitransparent organic solar cells. The semitransparent solar cell absorption spectrum can be tuned to complement the absorption of plants rather than compete for the same light. This results in an opportunity to generate power without hindering plant growth. As part of this presentation, we show how the incorporation of semitransparent organic solar cells into greenhouses impacts the plant growth, power produced, and overall energy balance of the greenhouse. We use detailed models determined optimized solar cell designs and deployment strategies for various greenhouse geographical locations across the US. Furthermore, we experimentally demonstrate the modified growth behavior of red leaf lettuce under various semitransparent solar cells. Among the results, we show that the right combination of bulk heterojunction materials results in similar fresh weight of red leaf lettuce over its complete growth cycle compared to plant growth without solar cell coverage, highlighting the potential of this application.

4:15 PM ES18.11.05

Two-Dimensional benzo[1,2-b:4,5-b']difuran-Based Conjugated Polymers for High Performance Polymer Solar Cells. Yong Zhang; Harbin Institute of Technology, Harbin, China.

Polymer solar cells (PSCs) have achieved the significant advancements in the past decade. The power conversion efficiencies (PCEs) have undergone a rapid increment to over 13% for binary PSCs and exceeded 14% for ternary PSCs with the rapid developments of new materials and continuous innovations of the device engineering. Especially, the design of new materials plays the decisive role in pursuing higher PCEs for PSCs. Among the newly emerged materials, the success of non-fullerene acceptors in PSCs in recent years has provided a great opportunity to pursue the promising photovoltaic performances for the practical applications. Currently, the PCEs of the fullerene-free PSCs have reached over 13%, which is comparable or even higher than its PC71BM-based counterparts.

Benzodifuran (BDF), a furan-based derivative, has recently received considerable attention in the developments of conjugated polymers for PSCs. Compared with BDT unit, the furan-based BDF possesses the advantages of i) more planar structure as the smaller oxygen size of furan unit; ii) the lower highest occupied molecular orbital (HOMO) energy level as the strong electron negativity of oxygen atom; iii) the denser π-π stacking behavior. In addition, the furan unit is also available from the biorenewable sources with the low cost. However, the spectroscopic properties of a variety of closely-packed push-pull dyes cannot be explained by established Frenkel exciton models. We will describe our assignments. The experimental results are in excellent agreement with our theoretical modeling.

By using electron/hole blocking layers and optimizing the energetic stack in our devices, we were able to achieve dark currents as low as 500 pA/cm$^2$ at -1V, leading to on/off ration of 10$^4$. To the best of our knowledge, this value of dark current is among the best values reported in literature for organic devices. Moreover, our experimental findings point out to a physical process that might be present in several donor:acceptor structures, explaining the high $J_d$ commonly observed in OPDs.

4:30 PM ES18.11.06

Organic photovoltaics (OPVs) offer several advantages over other solar energy technologies. The ability to solution-process OPVs presents an opportunity for highly scalable and cost-effective manufacturing. Despite this, significant research efforts focus on small area cells that are fabricated using techniques, such as spin coating, that are not amenable to scale-up. This talk will illustrate that the performance of photoactive layer materials in OPVs fabricated using spin coating is not a reliable measure of scale-up potential. Rather, the evaluation of a material’s performance using a scalable coating technique, such as slot-die coating, is crucial. Limitations in materials’ air stability, solids content, and solvent toxicity all present significant challenges to successful scale-up. This talk will highlight advances, such as the use of more air-stable non-fullerene electron acceptors and improvements in materials coating properties that have enabled the fabrication of ~300 nm thick photoactive layer films for 12 cm² OPV modules reaching 8% power conversion processed in air using scalable techniques.

4:45 PM *ES18.11.07
Surface Photovoltage Spectroscopy of Bulk Heterojunction and Dilute Donor Organic Photovoltaic Structures Lakshmi Narayanan Novel Saravana Murthy, Diego Barrera, Aakash Gadi, Liang Xie, Fong-Yi Cao, Cheng-Chun Tseng, Yen-Ju Cheng and Julia W. Hsu; The University of Texas at Dallas, Richardson, Texas, United States; Applied Chemistry, National Chiao Tung University, Hsinchu, Taiwan.

Organic photovoltaic (OPV) devices have attracted significant attention due to the low cost of fabrication, lightweight, and mechanical flexibility. Photogenerated charge transfer from active layer to carrier transport layer is critical for realizing efficient OPV devices. Defect states in the active layer or at the interface between active layer and charge transport layer can impede the charge transfer process by introducing traps, recombination centers, and limiting exciton diffusion. Here, we perform surface photovoltage spectroscopy (SPS) to study defect states in organic photovoltaic structures with different active layer systems. SPS measures surface photovoltage (SPV) as a function of incident photon energy, and has been used for obtaining electronic structure and electrostatically active defects of semiconductors. In SPS, sub-band illumination probes the transition between the band states and defect states within the bandgap. Here, we performed both steady-state (DC) and frequency-modulated (AC) SPS on bilayer structures containing different active layers (P3HT, P3HT:PCBM, PBFT:Se:Th:PC71:BM) and zinc oxide (ZnO) electron transport layer (ETL) to probe photogenerated transfer across this interface. AC SPS measures SPV signals of chopped monochromatic light at specific frequency. DC SPS measures stabilized SPV signals using continuous illumination from longer to shorter wavelengths. DC spectra are broader compared to AC spectra for all active layers. AC spectra overlaps with the absorption spectra of active layers, evident that AC SPS corresponds to band-to-band transitions. The sub-bandgap signals measured by DC SPS also include transitions with the bandgap states. When hole transport layer (HTL) was deposited on top of the active layer, the DC spectra are narrower than without the HTL, suggesting that the surface states are removed. In addition, we study DC SPS on dilute donor active layer (0.1, and 5wt% P3HT in PC71:BM) with conventional (on PEDOT) and inverted (on ZnO) architectures. We observed the positive SPV signal in the conventional structure, indicating that holes transferring to PEDOT and DC SPS magnitude increases with donor concentration. In the inverted structure, negative SPV signal indicates that electrons transferred to ZnO and DC SPS does not change with donor concentration due to the higher electron mobility of PC71:BM. These results give better insight on location and nature of sub-bandgap defects based on their SPS spectral signatures and frequency response.

8:00 AM *ES18.12.01
Developing High Performing Ladder-Type Materials for Organic Solar Cells Martin Heeney; Imperial College London, London, United Kingdom.

Ladder type fused aromatic monomers have been at the forefront of conjugated semiconductor development, finding use in both donor polymers and non-fullerene acceptors for high efficiency solar cell blends. Here we discuss recent efforts to develop flexible synthetic routes to a range of such monomers which allow the ready manipulation of the solubilizing sidechains, as well as the aromatic heterocycle in the fused unit. We show that the nature of the sidechain is important for both donor polymers, and non-fullerene acceptors. Changing from commonly used arylalkyl to simple alkyl sidechains is shown to have a positive impact on the performance of materials in single junction solar cells. The reasons behind these differences will be explored.

8:30 AM *ES18.12.02
Optimizing the Active Layers of High-Performance Organic Photovoltaic Cells Jianhui Hou and Shaoqing Zhang; Institute of Chemistry, Chinese Academy of Sciences, Beijing, China.

Over the last three decades, organic photovoltaic (OPV) cells achieved much significant progress, and power conversion efficiencies (PCEs) of over 14% were recorded.1 The development of organic active materials including electron donors and electron acceptors, device engineering, and device physics contribute greatly to the rapid increase of PCEs. In our work, we prepared many conjugated polymers and used them to fabricate the OPV devices for better performance. In 2008, we first incorporated the benzodithiophene units into the designing of polymer donors and achieved very good results.2 Then we systematically studied this type of polymers and summarized some useful strategies to improve their photovoltaic performance. For example, we used the conjugated side chains to modify the BDT units to improve the charge transport properties. Based on this method, we reported some highly efficient polymer donors for OPV devices. In 2014, we fabricated the OPV devices with over 10% efficiency using the BDT-based polymer PBDB-T1 as an electron donor and PC71BM as an electron acceptor, which was among the top values in the OPV field.3 Over the last few years, the non-fullerene electron acceptors achieved much rapid progress. Many non-fullerene acceptors such as ITIC were reported, which showed very promising features in easily tuned optical absorption and molecular energy levels. We blended a BDT-polymer named PBDB-T with ITIC as active layers and first achieved over 10% efficiency for non-fullerene-based OPV cells.4 Then we further optimized the polymer donor and non-fullerene acceptor via introducing fluorene atoms on PBDB-T and ITIC, respectively.5 The resulting donor PBDB-T:SF and non-fullerene acceptor IT-4F showed synergistically down-shifted molecular energy levels. Interestingly, the newly prepared active layers had broad absorption spectra and higher absorption coefficient. Due to the considerable enhancement of short-circuit current densities, PCEs over 13% was obtained. In our recent work, we designed some small molecules and used them as solid additives to optimize the morphology of the active layers. The small molecular additives were designed to have similar chemical structures with the terminal groups of highly efficient non-fullerene acceptors, resulting in very good miscibility between them. Via the treatment of thermal annealing, the additive could volatilize from the active layer, and meanwhile, the intermolecular pi-pi stacking was enhanced greatly, which benefited the charge transport and led to better photovoltaic performance. Importantly, when we tested the OPV cells processed with some solvent additives with high boiling-point like DIO, the devices fabricated using volatilizable solid additives showed better device stability and reproducibility, which will benefit the largescale production of OPV cells.

Electron-Donating Conjugated Polymers Containing pyrrolo[3,4-f]benzotriazole-5,7-dione Unit for Polymer Solar Cells Lei Ying; Institute of Polymer Optoelectronic Materials and Devices, State Key Lab of Luminescent Materials and Devices, Guangzhou, China.
Based on a moderate electron-deficient 6-alkyl-2-alkyl-5H-pyrrolo[3,4-f]benzotriazole-5,7(6H)-dione (TzBI) as the building block, we developed a series of donor-acceptor type of wide bandgap conjugated polymers based on benzothiophene derivatives as the electron-donating moiety. The resulting copolymers exhibited remarkable solubility in non-chlorinated solvent, such as 2-methylethyltetrahydrofuran, which are benefited from the incorporated solubilizing alkyd side chains in both imide and triazole moieties. By finely tuning the molecular structures of PTzBI-derivatives and non-fullerene acceptors of ITIC derivatives, we achieved an impressively high certified power conversion efficiency (PCE) over 12% at a relatively large device area of 1.0 cm². By combining the donor and acceptor moieties, we demonstrate that Voc loss might be partially originated from a low but non-negligible charge transfer state. These findings highlight that the reduction of the bandgap to improve the efficiency requires a careful materials design to minimize non-radiative Voc losses. By incorporating siloxane substituents into the side chain of the PTzBI, we achieved PTzBI-Si that presents excellent solubility in non-chlorinated green solvents. The all-polymer solar cells constructed based on PTzBI-Si:N2200 gives a remarkable PCE of 10.1% and 11.2% for single junction and tandem all-polymer solar cells, respectively. Our results demonstrate the great potential of using PTzBI derivatives for constructing highly efficient polymer solar cells.

9:15 AM ES18.12.04
Pt-Containing Conjugated “Roller-Wheel”–Shaped Materials for Organic Photovoltaic (OPV) Applications Yang Qin; Department of Chemistry and Chemical Biology, The University of New Mexico, Albuquerque, New Mexico, United States.

Incorporation of transition metals into conjugated structures has been widely applied as an intriguing strategy to give organic materials with novel properties characteristic to metals. Among various transition metal complexes, those of Pt(II) are unique because they intrinsically adopt square planar geometries and can serve as building blocks for linear long-chain structures. These complexes typically show strong spin-orbit coupling effects that induce facile formation of long-lived triplet excitons, which have been considered beneficial for organic photovoltaic (OPV) operations. Consequently, Pt-containing conjugated polymers (CPs) have recently attracted significant attention in OPV research. A variety of CPs containing Pt(II)-bisacetylide building blocks have been prepared and studied in detail. However, except for a handful of examples showing reasonable device performances up to ca. 4% power conversion efficiencies (PCEs), most of the Pt-containing polymers performed very poorly.

We have devised a new structural design motif for Pt-bisacetylide containing materials, namely “roller-wheel” shaped molecules, in contrast to the “dumbbell” type geometries in traditional Pt-containing small molecules and polymers.1,3,4 We have prepared a series of such “roller-wheel” complexes having an identical Pt-containing core (the “wheel”) and different conjugated arms (the “roller”). It was revealed that if the “rollers” are long enough, these molecules can “slip-stack” in the solid state, leading to high crystallinity and charge mobility. OPV devices were fabricated and showed power conversion efficiencies up to 5.9%, out-performing all existing Pt-containing materials. These materials generate long-lived triplet excitons that are mostly dark and not converted to electricity in the current device setup. We thus applied transient absorption studies using different electron acceptors to estimate the triplet energy levels, which shed light on how to capture triplet excitons in OPV devices, a rarely investigated mechanism that can potentially improve device performance.

9:30 AM ES18.12.05
Design and Synthesis of Ladder-Type Organic Conjugated Materials for Organic Photovoltaics Yen-Ju Cheng; Department of Applied Chemistry, National Chiao Tung University, Hsinchu, Taiwan.

Forced planarization by covalently fasting adjacent aromatic units in the conjugated backbone strengthens the parallel p-orbital interactions to elongate effective conjugation length and facilitate electron delocalization, providing an effective way to reduce the band gap and enhances the intrinsic charge mobility. It is envisaged that the well-defined ladder-type small molecules can function as donor monomers to polymerize with acceptor units, leading to a new class of donor-acceptor semi-ladder copolymers that can be suitably used for solution-processable polymer solar cells. Therefore, elegant designs and synthesis have been devoted towards hybridizing electron-rich aromatic subunits into mutually fused structures in the anticipation of extracting their individual intrinsic advantages. Various accessible electron-rich aromatic and heterocycles building blocks can be chemically assembled to afford a range of fascinating ladder-type conjugated skeletons with tunable properties and functions. A series of donor-acceptor conjugated copolymers have been designed and synthesized. On the other hand, the deformylated ladder-type building blocks can be further end-capped with two acceptors to form a new class of A-D-A small type molecules. These molecules can serve as n-type materials to replace traditional fullerene materials. By combining with the suitable p-type polymers to form complementary absorption and matchable energy levels, the devices using ladder-type-based nonfullerene acceptors have achieved high power conversion efficiencies. The applications of these materials in solar cells and OFET transistors will be discussed.

10:30 AM ES18.13.01
Aqueous-Processable Organic Photovoltaic Materials for Green Energy Sources Han Young Woo; Korea University, Seoul, Korea (the Republic of).

Over the past few decades, organic solar cells (OSCs) have made a significant progress, showing their great potential for low-cost, flexible, lightweight, portable and large-area energy-harvesting devices. Although PC61BM and/or PC71BM structures have been exploited successfully in OSC devices, efforts to modify the fullerene structures for further improving the device performance have been tried recently because fullerene derivatives have the inflexibility in molecular design, difficult purification, poor morphological stability, and limited light absorption in the visible region, etc. In recent years, nonfullerene acceptors have emerged as an alternative candidate of n-type materials to overcome the difficulties of fullerene derivatives in tuning optical and electronic properties. The strong and easily adjustable absorption characteristics of nonfullerene acceptors have been considered as a strong point compared to fullerene-like structures, showing a photovoltaic efficiency over ~14%. To further optimize the OSCs for next generation green energy sources, several important points need to be considered carefully. Here we discuss the fundamental correlations between molecular structure, blend morphology and device performance in fullerene- and nonfullerene based PSCs. We will also discuss the indoor light harvesting, single component OSCs and aqueous-based eco- and human-friendly fabrication of OSCs in detail.

11:00 AM ES18.13.02

In the current research, organic photovoltaics (OPVs) with various annealing temperature of TIPS-pentacene between ZnO (Zinc Oxide) interface layer and active layer were
investigated for better current density. The TIPS-pentacene was dissolved in anisole overnight at room temperature, to give the blend solution for device fabrication and we prepared inverted bilayer electron transport layers (ETLs) Devices Structure based on poly[bi(5-(2-ethylhexyl)-5H-thieno[3,4-b]thiophene-alt-(4-(2-ethylhexyl)-2-fluorothieno(3,4-b)thiophene)-2-carboxylate-2,6-diyl)] (PTB7-Th):phenyl-C71-butyric acid methyl ester (PC71BM). The ITO/ZnO/TIPS-Pentacene/PTB7-Th:PC71BM/MoOx/Ag-fabricated solar cell via spin coating provides superior photovoltaic, electrical and optical characteristics when compared with the ITO/ZnO/PTB7-Th:PC71BM/MoOx/Ag solar cell. As a result, annealing temperature of TIPS-pentacene is 100°C that significantly improves the power conversion efficiency from 8.81 to 9.59% in PTB7-Th:PC71BM-based solar cells—a relative increase of 8%, which demonstrates a feasible approach to increase the efficiency of OPVs. We used synchrotron grazing-incidence wide-angle X-ray scattering, ultraviolet-visible spectroscopy, and atomic force microscopy to characterize the internal structures, transmittance, and surface roughness, respectively, of the ZnO/TIPS-Pentacene bilayer ETL films. Consequently, spin coating a slightly thin film of TIPS-Pentacene small molecule onto the ZnO layer altered the morphology of the ZnO layer and resulted in enhanced current densities, fill factors, and PCEs for the devices.

Controlling the Recombination in Ternary Organic Solar Cells—A Path Towards >14% Efficiency Nicola Gasparini1, Xin Song1, Harald Ade2 and Derya Baran1; 1KSC, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 2North Carolina State University, Raleigh, North Carolina, United States.

One key advantage of solution-processable organic semiconductors is the opportunity of blending different materials in order to attain novel material properties and applications. The concept of ternary blend organic solar cells makes use of exactly that idea: three (or more) organic chromophores are combined to better match the solar irradiance spectrum and thus increase the amount of light absorbed, which in turn will increase the power output of the solar cell. However, charge transport limitations of many current generation polymer blends typically require rather low active layer thicknesses (around 100 nm) for optimum performance.1 We have previously shown the design rules for non-fullerene acceptor (NF-As) and fullerene-based solar2 cells with reduced charge recombination processes leading to a high short circuit current density (Jsc) and fill factor (FF) in ternary blends. Here, we report ternary organic solar cells based on a PTB7-Th (commonly known as PCE10) donor and various non-fullerene and fullerene acceptors, by investigating the improvements in photovoltaic parameters in terms of nanomorphology and photo-physics. We utilize a dual acting third component, the small molecule donor BIT-4F-T, which enables concomitant improvement in all binary systems we have tested. By adding this third component into PTB7-Th:IEICO-4F photovoltaic devices, we are able to achieve power conversion efficiencies in excess of 14%. This ternary system clearly outperforms binary reference devices, and its conversion efficiency is among the highest values reported in the literature for ternary organic solar cells. In this study, we further clarify the underlying mechanism contributing to the efficiency of this new blend by combining charge transport measurements and microstructural investigations. We find that adding 10% BIT-4F-T increases the photon harvesting window of the photoactive layers due to its complementary absorption. Moreover, BIT-4F-T also functions as a processing-aid in the ternary systems, increasing the overall volume fraction of the highly ordered region, and thus, improves charge generation and transport. This motivated us to explore the dual effect of the third component on different non-fullerene and fullerene-based binary blends, resulting in highly efficient solar cells. Our findings reveal design rules for a third component moiety that can be used for improving all photovoltaic parameters simultaneously in ternary devices.

Gasparini et al., Energy & Environmental Science, 2017, 10, 885.

Importance of Critical Molecular Weight of Polymer Acceptor on the Mechanical and Electrical Properties of All-Polymer Solar Cells Joonhyeong Choi1, Wansun Kim2, Taek-Soo Kim2 and Bumjoon Kim1; 1Department of Chemical and Biomolecular Engineering, KAIST, Daejeon, Korea (the Republic of); 2Department of Mechanical Engineering, KAIST, Daejeon, Korea (the Republic of).

When considering application in flexible and stretchable sensors as a power source, the bulk-heterojunction (BHJ) polymer solar cell (PSC) field have attracted tremendous attention owing to their advantages like lightweight, flexibility, semi-transparency and roll-to-roll processability. In particular, the PSCs devices are inevitably exposed to repetitive bending or stretching stress, mechanical stability of devices should be guaranteed. In this regard, the all-polymer solar cells (all-PSCs) have been considered to be a successful candidates achieving high stability and efficiency. Recently, there has been successful demonstrations that the all-PSCs exhibited superior mechanical endurance compared to fullerene based PSCs (PCBM-PSCs) due to ducile characteristic of polymer acceptor and interchain entanglements, in contrast to the brittle nature of PCBM molecules. Despite these important progresses, there is a lack of an in-depth understanding on mechanical properties of all-PSCs. In this work, we investigated the molecular weight effect of n-type polymer acceptor on the mechanical and electrical properties of all-PSCs via controlling the number-average molecular weight ([M]n) varying from low to very high [M]n = 15, 20, 48, 103 and 163 kg mol⁻¹. We observed the general increasing trend of power conversion efficiency (PCE) values as a function of [M]n. In particular, the electron mobility of all-polymer blend film was found to increase by a factor of five from lowest [M]n to highest [M]n blend, while the hole mobilities are similar regardless of [M]n. These enhancement of electron mobility induced the well balanced charge transport, resulting in large increment of Jsc values. Furthermore, while the low-[M]n (15, 20 and 48 kg mol⁻¹) blend films exhibited relatively phase-separated BHJ morphology, the finely intermixed phase separation was seen in the high-[M]n (103 and 163 kg mol⁻¹) blends, indicating large interfacial area between polymer donor and polymer acceptor, which are beneficial for charge dissociation. The tensile and fracture properties followed similar trend in device performance with the higher [M]n blend films showing better mechanical robustness, but larger improvements were observed between 48 and 103 kg mol⁻¹ blend films. This better mechanical ductility of 103 and 163 kg mol⁻¹ blend films is mainly attributed to a larger fraction of amorphous regions where the interchain entanglements exist, thereby allowing to dissipate a substantial strain energy. Furthermore, we also demonstrated the contrast in mechanical compliances depending on different acceptor types (small molecule vs. polymer). Despite the very high PCE devices based on ITIC have been reported recently, the active layer including ITIC showed much inferior mechanical stability compared to that of all-PSCs due to the brittle nature of ITIC.

SYMPOSIUM ES19

Excitonic Materials and Quantum Dots for Energy Conversion
April 23 - April 25, 2019

Symposium Organizers
Joseph Luther, National Renewable Energy Laboratory

SESSION ES19.01: Perovskite Quantum Dots
Session Chairs: Joseph Luther and Susanna Thon
Colloidal lead halide perovskite nanocrystals (APbX \(_3\) NCs, A=Cs, FA, PbI\(_2\)) have recently emerged as an alternative to conventional quantum dots, in particular, as versatile photonic sources and light-harvesting materials, due to their easily tunable photoluminescence spectra, unique exciton fine structure and facile synthesis [1-5]. A for warranting the practical utility of such semiconductor NCs in the red and infrared spectral regions, all three archetypal A-site monocationic perovskites—CH\(_3\)NH\(_2\)PbI\(_3\), CH(NH\(_2\))\(_2\)PbI\(_3\), and CsPbI\(_3\)—suffer from either chemical or thermodynamic instabilities in their bulk form. A promising approach toward the mitigation of these challenges lies in the formation of multinary compositions (mixed cation and mixed anion). In the case of multinary colloidal NCs, such as quinary Cs\(_3\)FA\(_2\)\(_x\)Pb(Br\(_y\), I\(_{3-x}\)) NCs, the outcome of the synthesis is defined by a complex interplay between the bulk thermodynamics of the solid solutions, crystal surface energies, energetics, dynamics of capping ligands, and the multiple effects of the reagents in solution. Accordingly, the rational synthesis of such NCs is a formidable challenge. We show that droplet-based microfluidics can successfully tackle this problem and synthesize Cs\(_3\)FA\(_2\)\(_x\)Pb(Br\(_y\), I\(_{3-x}\)) NCs in both a time- and cost-efficient manner. In this showcase study [6], we fine-tune the photoluminescence maxima of such multinary NCs between 700 and 800 nm, minimize their emission line widths (to below 40 nm), and maximize their photoluminescence quantum efficiencies (up to 89%) and phase/chemical stabilities. The excellent transference of reaction parameters from microfluidics to a conventional flask-based environment, thereby enabling up-scaling and further implementation in optoelectronic devices, are demonstrated as well. As an example, Cs\(_3\)FA\(_2\)\(_x\)Pb(Br\(_y\), I\(_{3-x}\)) NCs with an emission maximum at 735 nm were integrated into light-emitting diodes, exhibiting a high external quantum efficiency of 5.9% and a very narrow electroluminescence spectral bandwidth of 27 nm.

Exciton Fine Structure in Cesium Lead Halide Perovskite Nanocrystals

Peter C. Sercel\(^1\), John L. Lyons\(^2\), Noam Bernstein\(^3\) and Alexander L. Efros\(^2\); \(^1\)California Institute of Technology, Pasadena, California, United States; \(^2\)U.S. Naval Research Laboratory, Washington, District of Columbia, United States.

The bright emission observed in cesium lead halide perovskite nanocrystals has recently been explained in terms of a ground bright exciton state [1], a claim which would make these materials the first known examples where the ground exciton state is not an optically forbidden dark exciton. This unprecedented claim has been the subject of intense experimental investigation which has so far failed to detect the “dark” ground exciton which is expected in electron-hole exchange models. [2,3] Here, we explore other tell-tale properties of the exciton fine structure which do not require direct measurement of the dark exciton energy in order to clarify the exciton fine structure. We review the effective mass/electron-hole exchange theory for the exciton fine structure in tetragonal and orthorhombic CsPbBr\(_3\) nanocrystals. The model requires several input parameters, including crystal field terms to parameterize the effect of the lattice distortion from the cubic to the tetragonal [4] or orthorhombic [2] perovskite phases, as well as the electron-hole exchange energy in these materials. We have employed density functional theory (DFT), together with hybrid functionals and spin orbit coupling in order to determine the crystal field parameters and the electron-hole exchange energy for the tetragonal and orthorhombic CsPbBr\(_3\) phases. With these inputs, we determine the exciton fine structure level order within the context of the exchange model. As expected, we find an optically inactive ground exciton level. However, the calculated short range exchange energy is more than an order of magnitude smaller than what would be required to explain the measured fine structure splitting within a short-range exchange model. The possible impact of long-range exchange on the fine structure splitting is discussed. Importantly, we find that even if we add the long-range exchange interaction to explain the magnitude of the splitting, the level order for the optically active excitons in tetragonal CsPbBr\(_3\) nanocrystals calculated in the exchange model is opposite to what has been observed experimentally. [2,3] An alternate explanation for the exciton fine structure splitting in CsPbBr\(_3\) nanocrystals is offered in the context of the effect of Rashba splitting on the exciton fine structure which supports the existence of the bright ground exciton in these nanocrystals.[1]

Materials that can convert absorbed photons to emitted photons with quantum efficiencies exceeding 100% are rare, but of great interest for potentially increasing the overall efficiencies of existing solar-energy conversion technologies beyond their usual thermodynamic limits. This talk will describe some of our group's recent research into understanding, controlling, and exploiting new quantum-cutting doped halide perovskite semiconductor nanocrystals and bulk materials. These unique materials combine broad absorption profiles with photoluminescence quantum yields approaching 200%, making them very attractive for solar spectral conversion in applications such as photovoltaics or luminescent solar concentration. Fundamental spectroscopic and electronic-structure properties will be emphasized as they pertain to understanding the unusual photophysics displayed by these highly luminescent materials. Specific solar applications will also be described.

efficiency of CQD solar cells has been improving quickly in recent years, with certified power conversion efficiency up to 11.3%. The use of quantum dots surface engineering effectively reduced defects and improve carriers transport. In addition, device structure engineering significantly promoted the carriers transporting and inhibited interfacial recombination. Unlike most other solar cells, both normal structure and inverted structure exhibit similar high efficiency, the efficiency of CQD solar cells with inverted structure is generally poor (below 5%). In this work, we fabricated lead sulfide CQD solar cells with inverted structure by using nickel oxide as bottom hole transporting layer. The best device shows short circuit current density of 27.6 mA/cm², open circuit voltage of 0.53 V, fill factor of 65.7% and an overall power conversion efficiency (PCE) of 9.70% under standard 1.5G solar illumination. This indicates that inverted structure, with appropriate material and interface design, could be another opportunity for more efficient CQD-based photovoltaics.

Concentration Factor Thermodynamic Limits in Luminous Solar Concentrators
Megan E. Phelan1, David R. Needell2, Halee Bauser3, Ognjen Ilic4, Colton Bukovsky5, Zachary Nett6, Brent A. Koscher7, Paul Alivisatos8, and Harry Atwater1; 1California Institute of Technology, Pasadena, California, United States; 2University of California, Berkeley, Berkeley, California, United States.

Contemporary designs for luminous solar concentrators (LSCs) employ high radiative efficiency quantum dots in order to achieve high concentration: gain ratios. However, the quantum dot LSC community suffers from a lack of consensus about geometric gain and concentration factor conventions in luminous solar concentrators (LSCs) to validate and measure device performance. In this talk, we explore inconsistencies in the definition of thermodynamic limits for LSCs in the literature, and re-evaluate their theoretical performance in a unified common framework. Using Monte-Carlo ray tracing simulations, we have modeled 6.25cm² LSCs featuring quantum dot luminescent concentrators and photovoltaics oriented in various conventional and unconventional geometries (e.g., coplanar, horizontal, edge-lined, vertical, slanted). We have performed experimental inter-comparison of concentration for LSCs in these configurations that employ highly efficient CdSe/CdS core/shell quantum dots (QDs), which absorb light in the 300-500nm wavelength range and re-emit wavelength luminescence at 635nm, a wavelength that couples to our embedded photovoltaics. The QDs are dispersed throughout a 3.2 mm thick poly(laurylmethacrylate) (PLMA) waveguide layer and the photovoltaic is oriented within the waveguide, according to each target geometry. We standardized each device configuration to conform to a geometric gain of 120. Through our simulations, we have explored the radiative limit for each geometry. These simulations reveal significant discrepancies in measured power output and power conversion efficiency between the different cell geometries tested, and are compared to photovoltaics measurements of fabricated LSC prototypes for each cell geometry. During this talk, we will discuss how performance metrics of LSCs go beyond concentration factors and towards efficiency. We will further propose a new framework for LSC device performance, which aligns with theoretical thermodynamic limits and can be measured experimentally. Our analysis has the potential to standardize performance measurements in the LSC community, independent of device geometry, luminescent, photovoltaic material, or waveguide form factor.

2:15 PM *ES19.02.03
PbS QD/ZnO Nanowire Solar Cells for Series-Connected Triple-Junction Solar Cells with Approximately 30% Efficiency
Takawa Kudo; Hailbin Wang, Shiochiro Nakao, Naoya Miyashita, Yoshihata Okada, Tetsuya Hasegawa, Jota Nakazaki and Hiroshi Segawa; The University of Tokyo, Tokyo, Japan.

In developing low-cost and ultra-high efficiency solar cells, the utilization of the photon energy in a wide range of the solar spectrum is crucial. However, the theoretical maximum of the power conversion efficiency of single-junction solar cells under one-sun illumination remains 31% at best. To surpass the single-junction limit, several concepts have been proposed, including multiple exciton generation, hot-carrier, and intermediate band. Among these concepts, the multi-junction concept has only been proven to overcome the single-junction limit, and multi-junction solar cells are commercially available. However, multi-junction solar cells that can surpass the limit are expensive to fabricate, which hampers the large-scale implementation of solar cells. Thus, development of multi-junction solar cells with low-cost technologies such as solution-based fabrication processes would help to expand their implementation.

Although there have been several reports on multi-junction solar cells including solution-based subcells such as perovskite solar cells, most of the solution-processed solar cells were used as top subcells [3, 4], but little has been reported for solution-processed bottom cells. The highest power conversion efficiency reported so far on solution-processed multi-junction solar cells (Perovskite top subcell/Si bottom subcell) stands at 25.2% at best. We then focused on infrared PbS CQDs and ZnO nanowires (NWs) approximately 1µm long, and constructed heterojunction hybrid structures. The PbS QD/ZnO NW hybrid structures forming a bulk-heterojunction allow almost all the photo-generated carriers to reach the PbS QD/ZnO NW interface even when the active layer is thicker than the carrier diffusion lengths. Our recent study revealed that PbS QD/ZnO NW solar cells could be used to convert a wide range of solar energy to electricity [1, 2].

In the presentation, we report high efficiency infrared PbS QD/ZnO NW solar cells that produce sufficiently large photocurrent in the infrared region, and the results of a proof-of-concept study for multi-junction solar cells.

We constructed infrared PbS QD/ZnO NW solar cells, with the aim of developing solution-processed multi-junction solar cells. Morphology of 1-µm-long ZnO nanowires was optimized, which allowed us to construct otherwise difficult, spatially separated carrier pathways and thick PbS QD layers for high infrared light harvesting. The optical management together with highly infrared-transparent conductive oxide (Ta-doped SnO2; TTO) electrodes were successfully used to enhance the spectral sensitivity in the infrared region. The external quantum efficiency of the solar cell reached 47% at the wavelength corresponding to the first exciton peak (1560 nm): this is the highest value ever reported on the solution-processed solar cells.

We fabricated series-connected triple-junction solar cells by combining the PbS QD/ZnO NW solar cell (as a bottom subcell) with III-V JZ solar cells (InGaP top subcell/GaAs middle subcell). The series-connected triple-junction solar cell achieved approximately 30% under one-sun illumination, verifying that the PbS QD/ZnO NW solar cells have a great potential for solution-processed bottom subcells.

2:30 PM *ES19.02.04
Transport in Quantum Dot Solids
Vanessa Wood; Dept. of Information Technology and Electrical Engineering, ETH Zürich, Zurich, Germany.

This talk will describe why. I will begin by describing the type of structural dynamics that occurs in quantum dot solids and the methods that we can use to measure structural dynamics, such as inelastic neutron scattering and inelastic x-ray scattering, or simulate it, such as ab initio molecular dynamics. Then I will describe the theory of how electrons and vibrations interact, and the challenges we face in calculating non-radiative electronic transitions rates. Finally, I will explain why we should care about structure dynamics, specifically the impact the type of dynamics has on electronic properties such as mobility and Shockley Read Hall non-radiative recombination. In my talk, I will rely on the example of PSS NCs and present a predictive model for electronic and thermal transport. Furthermore, I will describe how changing the structural dynamics (e.g., by changing the surface of NCs) can be used to systematically change the transport by reducing both the thermal displacement of surface atoms and the spatial overlap of the charge carriers with these large atomic vibrations.

3:30 PM *ES19.02.05
Pre-Exchanged Quantum Dot Ink Based Solar Cells
Sung-Yeon Jang; Department of Chemistry, Kookmin University, Seoul, Korea (the Republic of).

Colloidal quantum dot (CQD) based solar cells have emerged as one of the most promising low cost power generators owing to their easy bandgap tunability and solution processability. Recently, the power conversion efficiency (PCE) of CQD solar cells has been expanded to >12% by the development of high-quality CQD materials and device
architectures. However, the fabrication of CQD solar cells often includes tedious multiple layer-by-layer deposition (LbL) by solid-state ligand exchange (SSE), which has been a major obstacle to high-throughput processing. Development of pre-formed CQDs which do not require LbL/SSE procedure will be beneficial for the view point of device fabrication. In this talk, the development of pre-exchanged n-type and p-type CQD inks, and the fabrication of CQD solar cell devices by direct coating method will be presented. Using these CQD inks, the PCE of –11% was achievable. Moreover, the application of doctor-blade coating method was also feasible, which suggests its potential use in other industrially-friendly processes.

4:00 PM ES19.02.06
Ligand Passivation Strategies for CsPbX Nanocrystals Ashley Marshall; Olivia J. Ashton, Bernard Wenger and Henry Snaith; Physics, University of Oxford, Oxford, United Kingdom.

Despite the improvements seen in efficiency of GaAs cells over the years, there remains room for improvement for it to approach the theoretical single junction limit posited by Shockley and Queisser decades ago. One of the most pursued options is the growth of quantum wells within the structure of GaAs to enhance its photon absorption below its bandgap. Multiple Quantum Wells (MQW) have been an ongoing topic of research and discussion for the scientific community with structures like InGaAs/GaAs and InGaP/GaAs quantum wells producing promising results that could potentially improve overall energy conversion. Here, we used WEI2NK, a commercial density functional theory package, to study the ternary compound GaInAs and determine its electronic properties. Using these results combined with experimental confirmation we extend these properties to simulate its application to form a MQW GaAs/GaInAs solar cell. GaInAs is a tunable ternary compound, with its bandgap being strongly dependent on the concentration of In present. Concentrations of In as low as 7% can reduce the bandgap of GaInAs to roughly 1.30 eV from GaAs’s 1.45 eV at room temperature with as little as a 1.7% increase in lattice constant. The change in bandgap, accompanied by the relatively small change in lattice constant makes GaInAs a strong candidate for a MQW cell with little to no strain balancing required within the structure to minimize unwanted defects that impede charge collection within the device. Our GaAs photodiode with TiGaAs MQWs shows an expanded absorption band and improved conversion efficiency over the standard GaAs photovoltaic cell with dilute concentrations of In incorporated into the compound.

4:15 PM ES19.02.07
RGB QLED Device Prepared by Inkjet Printing with Mixed Solvent and Printing Route Tai Yu-Chieh, Shih-Jung Ho, Kuo-Yang Lia and Hsueh-shih Chen; Material Science and Engineering, National Tsing Hua University, Hsinchu City, Taiwan.

Quantum dot (QD) technology has received a lot of attention for the advantages of high quantum yield (QY), narrow full-width at half-maximum (FWHM) and tunable wavelength. Recently, photoluminescence-based QD LCD display equipped with QD film as a light converter has been commercialized. In the near future, electroluminescence QLED is expected to be a next generation display competing with other potential flexible displays. With a similar device structure of OLED, QLED display based on inorganic quantum dots would possess better stability, more color purity and wider color gamut than other displays. Moreover, QD layers in the device are compatible with solution processing, which makes QLED display can be easily scaled up to a large area, mass productive and cost effective. In this research, a solution-processed QLED device with a structure of ITO/PEDOT:PSS/PVK/QD/ZnO/Al was prepared with spin-coating and inkjet-printing. A QD ink with mixed solvent has been developed to reduce coffee-ring effect and enabling light absorptions at higher wavelength regions. QD size manipulation via the microwave technique was further confirmed via transmission electron microscopy (TEM). The properties of CdSe QDs makes them suitable candidates for tunable band gap light harvesting, and plans are in place to incorporate them in P3HT:PCBM heterojunction solar cells as a means of increasing their solar energy power conversion efficiency (PCE).

ES19.03.01
Size-Tunable Synthesis of Cadmium Selenide Quantum Dots to Increase Solar Cell Efficiency Jacob Strimaitis, Taliya Gunawansa, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, Norfolk, Virginia, United States.

Colloidal quantum dots (QDs) present a promising solution to the problem of attaining cheap, size-tunable light harvesters for third generation solar cells. Cadmium Selenide (CdSe) QDs were synthesized using a one-pot microwave irradiation technique to meet this need. Synthesized quantum dots showed excellent luminescent behavior under UV lamp, which was further confirmed by other spectroscopic techniques. Photoluminescence (PL) and ultraviolet-visible spectroscopy (UV-VIS) spectra revealed that changing the time and temperature of the microwave during synthesis changed the size of the QDs from a few nanometers to tens of nanometers, causing their fluorescence intensity to red shift and enabling light absorptions at higher wavelength regions. QD size manipulation via the microwave technique was further confirmed via transmission electron microscopy (TEM). The properties of CdSe QDs makes them suitable candidates for tunable band gap light harvesting, and plans are in place to incorporate them in P3HT:PCBM heterojunction solar cells as a means of increasing their solar energy power conversion efficiency (PCE).

Funder Acknowledgement(s): This work is supported by the NSF-CREST Grant number HRD 1547771 and NSF-CREST Grant number HRD 1036494.

ES19.03.03
Efficient Production of Ultraviolet Light from Kinetically Controlled Synthesis of CdS Nanocrystals Paulina Janies; University of California, Riverside, Riverside, California, United States.

Es19.02.06 GaTiAs Quantum Well Solar Cells for Sub-Band Gap Absorption Ahmed Zayan and Thomas E. Vandervelde; Renewable Energy and Applied Photonics Laboratory, Electrical and Computer Engineering Department, Tufts University, Medford, Massachusetts, United States.
Few methods currently exist to produce UV light from lower energy photons. UV light is useful in photocatalysis and many applications of light in the biological disciplines. The highest photon up-conversion quantum yield for the production of UV light from visible light is 5.2% ± 0.5 using CdS nanocrystals (NC) light absorbers. Here the goal is to increase the energy transfer efficiency with higher quality CdS NCs. Specifically, we investigate a variety of sulfur containing precursors to kinetically controlled nucleation to yield different sizes of CdS NCs with peak absorbances ranging from 398nm to 453nm. The CdS NCs made were characterized using optical absorption and photoluminescence spectroscopy. The goal is to eliminate the current need for the ZnS shell with CdS NCs that have minimal surface trap states. The next step will be to bind ligands to the NC and optimize upconversion parameters. We will report the photon upconversion QYs with 2-naphthoic acid transmitter ligands that enhance triplet energy transfer from CdS NCs to 2,5-diphenyloxazole emitter.

ES19.03.04
Zinc Thiolate Determines the Identity of ZnS Shells on Cu-Deficient Cu-In-S QDs

Frie Hansen, Sophie Bertram, Jason Yoo and Mounqi Bawendi; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Copper Indium Sulfide (CIS) colloidal quantum dots (QDs) are promising candidates for commercially-viable QD-based optical applications, for example as colloidal photocatalysts or in luminescent solar concentrators (LSCs). CIS QDs with good photoluminescence quantum yields (PLQYs) and tunable emission wavelength via size and composition control have been previously reported. However, developing an understanding and control over the growth of electronically-passivating inorganic shells would enable further improvements of the photophysical properties of CIS QDs. To improve the optical properties of CIS QDs, we focus on the growth of inorganic shells via the popular metal-carboxylate/alkane thiol decomposition reaction. We (1) study the role of Zn-carboxylate and Zn-thiolate on the formation of ZnS shells on Cu-Deficient CIS (CDCIS) QDs, (2) leverage this knowledge to yield >90% PLQY CDCIS/ZnS core/shell QDs, (3) demonstrate control over interfacial alloying, and (4) propose a mechanism for ZnS shells grown from zinc-carboxylate/alkane thiol decomposition.

ES19.03.05
Novel Dendritic Large Molecules Exhibiting Thermally Activated Delayed Fluorescence for Simple-Processed Organic Light Emitting Diodes

Hyung J. Kim, Seo Yeon Park, Mallesh Godumula, Su Hong Park, Choe Hoon Jeong, Jiwon Yoon, Chae Yeong Kim, Min Ju Cho and Dong Hoon Choi; Korea University, Seoul, Korea (the Republic of).

Recently, research on an organic light emitting diode (OLED) based on thermally activated delayed fluorescence (TADF) having a high internal quantum efficiency is being actively conducted. In particular, it is recognized that OLED by solution process can be applied to large display devices and flexible display manufacturing because manufacturing process is simple and large area device can be manufactured. In this presentation, we have demonstrated a series of new dendritic TADF emitters applicable in simple structured or all soluble OLEDs. All these new materials exhibit excellent solubility in common organic solvents and apparent TADF characteristics. The TADF emitters used in simple structured OLEDs without any HIL or HTL realized excellent performance with the high EQE. Besides, another series of TADF emitters displaying aggregation induced emission employed in all soluble OLEDs achieved EQE as high as 11%. Therefore, we strongly believe that these results will definitely open the doors to develop “simple structured OLEDs” instead of conventional OLEDs consisting complicated multi-layered device structure and difficult fabrication procedures.

ES19.03.06
Lanthanide Decorated Semiconductor Quantum Dots for Use as Broadly Absorbing Downshifters

Joseph Swaebuck, Stefan Fischer, Noah Bronstein and Paul Alivisatos; 1,2 Department of Chemistry, University of California, Berkeley, Berkeley, California, United States; 3Materiors Science Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Kavli Energy NanoScience Institute, Berkeley, California, United States.

Luminophores with sharp emissions coupled to broad absorption have many applications including solar energy harvesting. Lanthanide ions have very sharp, typically ~10 meV FWHM, emissions that are largely insensitive to temperature or surrounding environment. However, lanthanides do not absorb well outside of these transitions, so their ability to act as luminophores is limited. Doping semiconductors with lanthanides has been pursued in thin films, but these systems typically only show luminescence at cryogenic temperatures. As such, we seek to place lanthanides onto quantum dots to combine the broad absorption of nanomaterials with the narrow emission of the lanthanides. We use lanthanide trifluoroacetates and standard hot injection processes to grow an optically active Yb doped shell around InP quantum dots. The particles are then characterized via a variety of optical and structural methods. The structural methods, which include high resolution electron microscopy, elemental mapping, and extended x-ray absorption fine structure measurements, show that the nanoparticles take on a core/shell structure. Optically, we are able to see that there is a near infra-red emission upon excitation with UV/visible light. The emission is traced back to the quantum dot absorption via a photoluminescence excitation measurement, while the lifetimes of the near infra-red emission show that the Yb ions are somewhat passivated from the surface of the nanoparticle. This work shows the synthesis, optical, and structural characterization of Yb decorated InP quantum dots. These materials could be used as stable and sharp luminescence centres in the near infra-red and beyond.

Critical Casimir Forces Drive Quantum Dot Epitaxy

Emanuele Marino, Bas B. Kluft, Thomas E. Kodger and Peter Schall; 1Institute of Physics, University of Amsterdam, Amsterdam, Netherlands; 2Department of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 3Physical Chemistry and Soft Matter, Wageningen University & Research, Wageningen, Netherlands.

Epitaxy is at the basis of many fabrication protocols in the semiconductor industry, allowing the development of complex architectures for optoelectronic devices. Epitaxial growth critically depends on the interaction between adsorbing particles, and between the particles and the substrate. While this process has been demonstrated for both atoms and microparticles,1,2 the intermediate case of nanocrystals has remained elusive due to our limited understanding of interparticle interactions at the nanoscale.3 Here, we demonstrate the epitaxial growth of semiconductor nanocrystals, quantum dots (QDs), on a flat, unfunctionalized and unpatterned silicon substrate via critical Casimir forces. By tuning the interplay of attractive critical Casimir and repulsive electrostatic interactions, we show that the epitaxial process can be biased towards either 2D layer or 3D island growth, consisting of crystalline or amorphous superstructures. These results demonstrate the potential of the critical Casimir interaction to direct the growth of future artificial solids based on QDs as fundamental building blocks.

SESSION ES19.04: Singlet Fission and Downconversion
Session Chairs: Sean Roberts and Nobuhiro Yanai
Wednesday Morning, April 24, 2019
PCC North, 100 Level, Room 132 A
In recent years, quantum dots (QDs) have gained interest as narrowband emitters for displays, but have traditionally suffered from reliability issues, high manufacturing cost, and toxicity concerns, which prevent them from being incorporated into products beyond displays. At UbiQD, we envision making QDs ubiquitous across many industries with a new kind of QD that is intrinsically more stable, lower-cost, and avoids toxic compounds. We are first focusing on bringing to market QD-tinted films and glass for spectrum-optimized greenhouses. This talk will highlight the recent developments including data from several commercial greenhouse pilot projects, and an overview of the first-ever QD greenhouse product.

8:30 AM *ES19.04.02
Up- and Down-Converting Photons in Molecular Singlet Fission Materials Dirk M. Guldi; University of Erlangen-Nuremberg, Erlangen, Germany.

The Shockley-Queisser limit places an upper bound on solar conversion efficiency for a single p-n junction solar cell at slightly more than 30%. To surpass this limit, multi-exciton generation is being explored in inorganic semiconductors, while singlet fission (SF) is being investigated in arrays of conjugated organic molecules. In an optimal SF process, the lowest singlet excited state of one molecule ($S_1$) that is positioned next to another molecule in its ground state ($S_0$) is down-converted into two triplet excited states ($T_1$) each residing on one of the two adjacent molecules. The two triplet states initially form a correlated pair state ($S(T_1)$), which then evolves into two separated triplet states ($T_1 + T_1$). As such, the energetic requirement for SF is $E(S_1)$ larger than 2 $E(T_1)$.

We have set our focus in recent years on intramolecular SF in molecular materials and their studies in solution rather than on intermolecular SF investigations in crystalline films. Implicit in intramolecular SF is a resonant, direct excitation of the SF material. In pentacene dimers linked by a myriad of molecular spacers, SF takes place with quantum yields of up to 200%. In addition, all key intermediates in the SF process, including the formation and decay of a quintet state that precedes formation of the pentacene triplet excitons, have been identified. This approach is, however, limited to the part of the solar spectrum, where, for example, the pentacene dimers feature a significant absorption cross-section. To employ the remaining part of the solar spectrum necessitates non-resonant, indirect excitation of the SF materials via either up- or down-conversion. For example, the up-conversion approach is realized with singlet excited states in pentacene dimers, which are accessed by two-photon absorptions (TPA). TPA is then followed in the second step of the sequence by an intramolecular SF – similar to what is seen upon resonant, direct excitation. Quite different is the down-conversion approach, which is based on an intramolecular Förster resonance energy transfer (FRET) and thereby the (photo)activation of the SF material. FRET requires the use of a complementary absorbing chromophore and enables funneling its excited state energy unidirectionally to the SF performing pentacene dimer. Again, SF completes the reaction sequence.

9:00 AM ES19.04.03
Counting Triplets on Single Polymer Chains for Solar Cells Benjamin D. Datko1,2, Martin Heeney1, Kevin J. Noonan3 and John Grey1; 1University of New Mexico, Albuquerque, New Mexico, United States; 2Department of Chemistry, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States; 3Department of Chemistry and Centre for Plastic Electronics, Imperial College London, London, United Kingdom.

Current optimization of organic solar cells has hit a wall with optimal power conversion efficiencies stagnating at 12.5 % with only small incremental changes in the past five years. Conjugated polymers are still advantageous to improve organic solar cells, but it is difficult to correlate the structure-activity of these materials due to their intrinsic heterogeneity. To effectively iterate over new molecular design strategies targeting multiple exciton generation (MEG) through heavy atom substitution and singlet fission, new insights are needed. Here we use single molecule photomodulation spectroscopy to resolve multiple triplet populations at the single chain level. This technique ascertains the pulse-induced kinetics of triplet formation through synchronous averaging of the fluorescence emission with a high repetition rate of square pulse excitations. Thus, allowing to resolve singlet-triplet dynamics intrinsic to the conjugated polymer. In parallel, we have utilized the solutions to the probabilistic master equation describing the time-dependent kinetics of triplet formation. Using measured rates from our experiments we can now count the most likely number of triplets on the conjugated polymer. Measuring poly-3-hexylthiophene (P3HT), poly-3-hexyl-selenophene (P3HS), and combinations of S-Se heterocycles containing polymers we can systematically map the kinetics of triplet formation to the structure activity for these materials.

9:15 AM ES19.04.04
Conformational Preference for Triplet Production in Multichromophoric Molecules via Single Molecule Spectroscopy David J. Walwark, Benjamin D. Datko and John Grey; University of New Mexico, Albuquerque, New Mexico, United States.

Multichromophoric molecules have great potential in optoelectronic applications but their electronic properties are extremely sensitive to conformation, making molecular design difficult. We employ modulated polarized light to interrogate single molecules of tetrakis(perylene-diimide) spiro-bifluorene, simultaneously correlating ordering and photophysics, with a focus on triplet dynamics with excimeric parentage. Widefield fluorescence microscopy excels at building reliable distributions of photophysical states via quantified fluorescence response to modulated linearly polarized excitation. Allowing the analyte to react with oxygen during the experiment lets us implicate certain levels of ordering with increased production of triplet excited states. Further analysis with confocal microscopy in oxygen-free conditions links emission lifetimes and microsecond emission dynamics explicitly to single-chromophore and excimer excited states via dichroic detection. Using linear polarization modulation across all experiments combines the robust statistical distributions and proven oxygen reactivity of the widefield results with the fast timescale sensitivity of the confocal data to yield a comprehensive photophysical profile of multichromophoric arrays in a polymer environment.

Polariton Assisted Photophysics—Remote-Energy Transfer, Singlet-Fission and Triplet Harvesting Joel Yuen-Zhou; University of California, San Diego, La Jolla, California, United States.

When an ensemble of molecules interacts with the optical modes of a microcavity or an electromagnetic nanostructure, the collective excitations of the strongly coupled light-matter (polariton) system are no longer purely molecular nor electromagnetic, but hybrid superpositions of the two. In this talk, I will discuss our recently developed theoretical models that explain the mechanisms whereby polaritons can enhance excitonic processes such as singlet-fission and harvesting of triplets in organic materials.

10:00 AM BREAK

10:30 AM *ES19.04.06

Singlet fission in organic semiconductors provides an efficient means to achieve exciton multiplication. To realise useful applications for efficiency enhancement in photovoltaic devices requires that the energy of each of the triplet excitons is efficiently harvested. I will describe an all-optical approach where triplet excitons from fission are transferred to inorganic semiconductor nanoparticles which can then emit at energies close to the photovoltaic bandgap. The challenge here is to achieve high efficiencies for nanoparticle luminescence whilst still allowing triplets to tunnel into the particles. I will describe measurements where fission takes place in solution and the triplets are efficiently transferred to nanoparticles. The key to achieving this is the use of acene ligands attached to the particles, providing adequate passivation of the particles whilst facilitating the transfer of triplets into the particles.

I will also describe measurements using electron spin resonance and luminescence at high magnetic fields to probe the interactions between triplets generated by fission in acene
films. These measurements demonstrate the presence of bound triplet pairs with overall singlet, triplet and quintet characters, and allow their binding energies to be determined. I will present recent results using transient electron spin resonance techniques and magneto-photoluminescence at very low temperatures to study the mechanisms by which quintet pair states are formed from pair states with initial singlet character.

11:00 AM ES19.04.07
Singlet Fission in Designed Architectures for Triplet Exciton Harvesting  Justin Johnson1, Nadia Korovina1, Natalie Pace1, 2, Melissa Gish1, Obadiah Reid1, 2 and Garry Rumbles1, 2; National Renewable Energy Laboratory, Lakewood, Colorado, United States; 2University of Colorado Boulder, Boulder, Colorado, United States.

Approaches to utilizing triplet excitons born from singlet fission require consideration of schemes for triplet state lifetime elongation and either exciton dissociation or energy transfer. To isolate triplets after singlet fission, molecular design principles can be used to provide pathways for exciton migration and localization. Subsequently, an interface with a charge or energy acceptor can be introduced. This interface and the associated dynamics have nanoscale components and are often complex structurally and chemically. I will describe our efforts to characterize charge and energy transfer at interfaces involving singlet fission molecules and designed molecular charge acceptors, quantum dots, and oxides. In some cases molecular assembly at the interface naturally alters the intermolecular coupling and thus the intrinsic singlet fission dynamics, which leads to a kinetic competition between various pathways that is challenging to elucidate. Covalently bound chromophores (i.e. dimers and oligomers) can then be attractive alternatives due to their well-defined interchromophore geometries. We use a combination of synthesis, electrochemistry, and various forms of transient spectroscopy to monitor the relationship that molecular structure and electronic state energies have on the processes of singlet fission, exciton migration, energy transfer, and exciton dissociation.

11:15 AM ES19.04.08
Two Temperature Regimes of Triplet Transfer in the Dissociation of the Correlated Triplet Pair in Singlet Fission  Jin Lee1, YunHui L. Lin2, Hwon Kim3, Barry P. Rand4, 5 and Gregory D. Scholes1; 1Chemistry, Princeton University, Princeton, New Jersey, United States; 2Electrical Engineering, Princeton University, Princeton, New Jersey, United States; 3Andlinger Center for Energy and the Environment, Princeton University, Princeton, New Jersey, United States.

The ability to undergo spin-allowed exciton multiplication makes singlet fission materials promising for photovoltaic applications. The majority of studies to date have emphasized understanding the first step of singlet fission, where a correlated triplet pair is produced. Here we examine the separation of correlated triplets, \( \langle T^+ T^- \rangle \), in polyacrylamide pentacene films via temperature dependent transient absorption spectroscopy. Single wavelength analysis reveals a profound delay in \( \langle T^+ T^- \rangle \) dynamics. Moreover, the dynamics of \( \langle T^+ T^- \rangle \) exhibit temperature dependence while other features shown discernable temperature dependence. Previous literature have suggested that correlated triplet separation is mediated by a thermally activated hopping process. Surprisingly, we find that the time constants governing triplet pair separation display two distinct temperature-dependent regimes of triplet transport. The high temperature regime follows a thermally activated hopping mechanism. The experimentally derived reorganization energy and electronic coupling is verified by density matrix renormalization group quantum chemical calculations. In addition, we evaluated the low temperature regime and show that the trend can be modelled by a Miller-Abrahams-type model that incorporates the effects of energetic disorder. We conclude that the correlated triplet pair separation is mediated by thermally activated hopping or a disorder driven Miller-Abrahams-type mechanism at high and low temperature, respectively. We observe that the time constants governing triplet pair separation is mediated by thermally activated hopping or a disorder driven Miller-Abrahams-type mechanism. The high and low temperature regimes are – 226 K. We find the time constant for triplet-triplet energy transfer to be 1.6 ps at ambient temperature and 21 ps at 77K.

11:30 AM •ES19.04.09
The Potential of Singlet Fission for More Efficient Solar Cells  Bruno Ehler; Center for Nanophotonics, Institute AMOLF, Amsterdam, Netherlands.

Singlet fission, the conversion from one high-energy singlet exciton into two lower-energy triplet excitons in organic semiconductors can be used to overcome the Shockley-Queisser efficiency limit for single-junction solar cells. However, increasing the photocurrent by singlet fission requires efficient charge generation from triplet excitons. While such charge generation has been shown in purely organic solar cells, and in quantum dot/organic hybrids, it has never been shown in combination with the most important solar cell material, silicon.

Here we will first calculate the efficiency potential of such singlet fission solar cells given realistic device parameters. We will show how the efficiency depends on the quantum yield of all processes, the optical properties, and the energetics involved. This model reveals that direct charge transfer from the triplet exciton allows for the highest efficiency gain compared to more indirect paths, and, surprisingly, that the highest efficiency can be achieved with a relatively low (singlet) bandgap of around 1.9 eV.

With optimistic, but realistic device parameters, the efficiency of the record-efficiency silicon solar cell could increase from 27% to 38%, even more than optimistic models predict for tandem solar cells. We will also show that singlet fission cells behave differently than tandem cells under real-life operation conditions, and have a different dependence on the silicon base-cell efficiency. Finally, we will present experimental evidence for charge transfer on aromatically passivated silicon surface using a spatially-resolved quenching experiment.
Many inorganic semiconductors of interest for solar energy conversion applications have indirect band gaps, which means that access to the lowest energy excited state via photon absorption requires coupling to a lattice phonon. The most famous example of an indirect semiconductor used in solar energy conversion is, of course, silicon, but many metal oxide semiconductors that have recently emerged as promising photoelectrodes for solar fuels generation, such as BiVO₄ and CuFeO₂, also have indirect band gaps. This talk presents recent data that identify spectral signatures of indirect transitions in transient absorption spectra of solution-processed nanostructured thin films of transition metal oxide semiconductors. Comparison of transient absorption spectra to thermal difference spectra generated by taking the difference between a steady-state absorption spectrum collected at elevated temperature and one collected at room temperature enables distinction of spectral features associated with thermal energy (i.e., phonons) in the semiconductor lattice from features associated with purely electronic transitions of photoexcited carriers. These distinctions not only enable accurate assignment of transient absorption spectra of metal oxide thin films, which is critical to their meaningful interpretation, but they also provide a means to probe directly the generation and evolution of thermal lattice energy in these films. Further characterization of these thermal processes will provide important insights into the function of metal oxide thin film semiconductors in devices for solar energy conversion.

Designing Organic—Inorganic Junc tions for Photon Conversion
Michael S. Azzaro, Jon A. Bender, Emily Raulerson, Inki Lee and Sean T. Roberts; Chemistry, The University of Texas at Austin, Austin, Texas, United States.

The negligible spin-orbit coupling in many organic molecules creates opportunities to alter the energy of excited electrons by manipulating their spin. In particular, molecules with a large exchange splitting have garnered interest due to their potential to undergo singlet fission (SF), a process where a molecule in a high-energy spin-singlet state shares its energy with a neighbor, placing both in a low-energy spin-triplet state. When incorporated into photovoltaic and photocatalytic systems, SF can offset losses from carrier thermalization, which account for ~50% of the energy lost by these technologies. Likewise, compounds that undergo SF’s inverse, triplet fusion (TF), can be paired with infrared absorbers to create structures that upconvert infrared into visible light. However, designing functional applications based on either of these processes requires organic/inorganic junctions that readily transfer energy from one material to the other. In this presentation, we will describe our group’s recent efforts to produce organic/inorganic junctions that transmit excitons in a particular spin state. Specifically, we will describe work examining peryleneimide (PDI) films grown on Si(111) surfaces. Photoexcitation of the PDI layer produces a spin-singlet exciton that undergoes SF over a few hundred picoseconds to yield a triplet exciton pair. Transient reflectivity measurements indicate these triplets exhibit a reduced lifetime in PDI:Si bilayers relative to PDI films grown on quartz, suggesting triplet energy transfer from PDI to Si. We will also describe work on quantum dot superlattices wherein the quantum dot surface ligands have been replaced with exciton delocalizing ligands, molecules with valence orbitals that strongly hybridize with quantum dot band edge states. We have recently show ligands of this type can significantly speed exciton transport in quantum dot solids, leading to dot-to-dot energy hopping rates as short as 200 fs.

Work using exciton delocalizing ligands to produce quantum dot structures that effectively deliver energy to triplet excitons accepting molecules for photon upconversion will be described.

4:00 PM *ES19.06.02
Photon Upconversion in Molecular Assemblies and Hybrid Materials
Nobuhiro Yanai¹, ²; ¹Department of Chemistry and Biochemistry, Kyushu University, Fukuoka, Japan; ²JST-PRESTO, Kawaguchi, Japan.

We show exciting research opportunities when the concept of molecular self-assembly meets photon upconversion (UC) based on triplet-triplet annihilation (TTA). In dense dyne assemblies, triplet excitons can efficiently migrate and annihilate. Highly efficient photon upconversion has been realized in a wide range of chromophore assemblies, such as non-solvent liquids, ionic liquids, amorphous solids, gels, supramolecular assemblies, liquid crystals, and crystals. The control over their assembly structures allows for unexpected air-stability and efficient upconversion at weak excitation intensity.

In addition, we would like to introduce our recent progress in developing new UC mechanisms. NIR-to-vis UC is particularly important for various applications, however, it remains challenging mainly due to the energy loss during the S₁-to-T₁ intersystem crossing (ISC) of sensitizers. We circumvent this energy loss by employing a sensitizer with direct S₂ absorption in the NIR region. Sensitizer-doped emitter nanoparticles are dispersed into an oxygen-barrier polymer. The obtained composite film shows a stable NIR-to-vis UC even in air, expanding the scope of molecular sensitizers for NIR-to-vis UC.

We have also unveiled the potential of three-dimensional (3D) metal-halide perovskites to sensitize organic triplets. Nanocrystals of surface-modified inorganic cesium lead halide perovskite CsPbX₃ (X = Br/I) are found to work as efficient triplet sensitizers for TTA-UC at low excitation intensity.

Photon Upconversion—Novel Annihilators for Photoedox Catalysis
Andrew Pun¹, Luis Campos¹ and Dan Congreve²; ¹Columbia University, New York, New York, United States; ²Rowland Institute at Harvard University, Cambridge, Massachusetts, United States.

Photon upconversion is the process by which low energy photons are converted into one higher energy photon. This process has seen wide advancements in recent years owing to its broad scope of potential applications. However, the number of materials that can be used as upconversion annihilators are quite limited. Here I will discuss our groups’ efforts towards expanding the library of annihilators for upconversion. This includes exploring new families of chromophores, as well as synthetic modifications to existing materials for more efficient upconversion. Finally, I will detail a new application of upconversion: performing photoedox catalysis with infrared radiation.

4:30 PM *ES19.06.04
Progress Using Hybrid Nanomaterials for Excitonic Photon Conversion
Mark W. Wilson; Department of Chemistry, University of Toronto, Toronto, Ontario, Canada.

The ability to efficiently convert low-intensity light between the visible and infrared would be an enabling technology—particularly for applications such as 3rd-generation photovoltaics, biological imaging, and cost-effective sensitized silicon focal plane array detectors with response in the short-wave infrared (SWIR; λ:1–3µm). Accordingly, we are advancing recent approaches that combine two excitonic materials—organic semiconductors and colloidal nanocrystals—to achieve broadband, non-coherent photon up-
The dynamics of electronic degrees of freedom is propagated by a Redfield equation of motion for the reduced density matrix. The influence of momentum dispersion on hot-electron relaxation rates and nonradiative lifetimes for SiNWs with <100> and <111> crystallographic directions. Photoexcited dynamic processes in semiconductor nanowires are influenced by continuous sampling of momentum in growth direction. Here, motivated by our previous studies, we show that the electron relaxation time in <100> SiNW is longer than in <111> SiNW. Our study also indicates that the electron relaxation time in <100> SiNW is longer than in <111> SiNW.

Multifunctional phosphor nanoparticles based on lanthanide ions have gained significant interest due to their potential applications in various multifunctional devices for solid-state lighting, optoelectronics, and scintillation. Currently, it is a big challenge to synthesize nanophosphors with high emission intensity, radioluminescence (RL) efficiency and excited state lifetime comparable to traditional phosphors. In this work, La2H2O3:Sm3+ (LHOS) nanoparticle (NPs) prepared by a molten salt synthesis method at relatively low temperature have characterized by X-ray diffraction (XRD), Raman spectroscopy, Fourier transform infrared (FTIR) spectroscopy, and scanning electron microscopy (SEM). The LHOS NPs show highly efficient, orange-red emitting properties as UV-based phosphor. X-ray scintillator and luminescence thermal decay kinetics study is carried out for both photoluminescence (PL) and RL. The emission characteristics show different behaviors under UV and X-ray excitations in terms of controlling magnetic dipole transitions. When LHOS NPs are exposed to energetic X-ray beam, Sm3+ ions situated at symmetric environment get excited along with those located at asymmetric environment, which results in high asymmetry ratio of Sm3+ under RL compared to PL. The PL and RL mechanisms are proposed based on Van Uitert equation. The important parameters such as thermal quenching activation energy and thermal sensitivity are also evaluated to evaluate the performance of the LHOS NPs as a thermal sensor. Our results indicate that these samarium activated Ln2H2O3:NP can serve as UV, X-ray and thermographic phosphor.

The synthesis of two-dimensional GaN offers new opportunities for this important commercial semiconductor in optoelectronic devices because the extreme quantum confinement enables additional control of its optical properties. Using first-principles calculations based on many-body Green’s function theory, we demonstrate that in monolayer GaN, a large band gap of 5.387 eV is governed by enhanced electron–electron correlations. Strong electron-hole interactions due to weak screening lead to strongly bound excitons with a large binding energy of 1.272 eV. These tightly bound excitons result in a strong absorption peak in the middle ultraviolet region. The dynamical screening between electron–hole pairs is totally different from bare Coulomb interaction. Long quasiparticle (quasielectron, quasihole, and exciton) lifetimes are observed as a result of the many-body interactions. Because of the large binding energies, long exciton lifetimes, and large quantum degeneracy, an excitonic Bose-Einstein condensate can be observed experimentally. Our results indicate the importance of the many-body effects in exploring the optical performance of novel GaN optoelectronic nanodevices.

One of the holy grails of the photon upconversion is to convert near infrared photons to high energy photons in the ultraviolet or violet spectrum. The solar panel at sea level is around 50%[2] low energy infrared photons that current solar panels do not absorb. By utilizing the strong absorption of inorganic nanocrystals (NC), and the ability of conjugated organic emitters to undergo triplet-triplet annihilation (TTA), a hybrid tunable system can be designed with high upconversion Quantum Yields (QYs). A thin layer of this upconversion system may potentially improve solar panel efficiency beyond the Shockley Queisser limit of 30%[1]. Here, the organic emitter of interest is perylene. Perylene has many qualities that make it a promising emitter, such as a high fluorescence QY, a low-lying triplet energy state and fluorescence in the violet wavelengths. However, these high fluorescence QYSs are only observed in dilute solvent, and perylene needs to be tightly bound to the NC surface for efficient energy transfer. In this poster, we address the first problem with bulky substituents on perylene to increase solubility and minimize excimer formation. As for the second limitation, we investigate the covalent binding of perylene to CdSe NCs of various sizes for experimental evidence of the Marcus inverted regime. Information about the relationship between the driving force for triplet energy transfer and its rate will help design better ligands once the reorganization energy, or the coupled vibrations that participate are identified.

Silicon nanowires (SiNW) exhibit unique opto-electronic properties originating from 1-D confinement. All opto-electronic properties: bandgap, charge carrier relaxation rates, and electron nonradiative lifetimes all are influenced by continuous sampling of momentum in growth direction. Here, motivated by our previous studies, we show that the electron relaxation time in <100> SiNW is longer than in <111> SiNW.

Photostimulated Auger Processes in Carbon Nanotubes

Rohit B. Choudhury, Naval Research Laboratory, Washington, District of Columbia, United States.

Carbon nanotubes possess unique electronic band structures that make them ideal for applications ranging from transistors to field emitters. The study of electronic processes in CNTs is of great interest since it can lead to new insights into fundamental physics. The Auger process in semiconductors is a competing non-radiative decay channel that can lead to increased losses in high-power applications. In this study, we present photostimulated Auger processes in carbon nanotubes.

ES19.07.06

Singlet Fission in a Hybrid PbS Nanocrystal-Diphenylhexatriene System

Helen M. Thayer, Carter S. Gerke, Zhiyuan Huang and MingLee Tang; Chemistry, University of California, Riverside, Riverside, California, United States.

Solar cell efficiency could potentially be increased by exceeding the Shockley-Queisser limit through singlet fission. The Shockley-Queisser limit on photovoltaic efficiency is the theoretical maximum efficiency of a p-n junction given our sun. It states that nearly more than half of the light energy incident on a conventional single junction photovoltaic material is not converted to electrical energy. Some of this lost energy could be harvested through singlet fission. Here, inorganic colloidal PbS nanocrystals (NC) are used to harvest the energy from triplet excitons generated by organic 1,6-diphenyl-1,3,5-hexatriene (DPh). In DPh, singlet fission occurs efficiently, whereby an excited photon creates a singlet state that splits into two triplet states—one in the original chromophore and one in a neighboring chromophore. The energy transfer is known as the Dexter process, which is a simultaneous, correlated transfer of charge or energy from a donor to an acceptor non-radiatively. In this work, DPh is the donor while PbS is the acceptor, and Dexter transfer is enhanced by covalently attaching both species to promote wavefunction overlap between donor and acceptor. Synthesis of soluble DPh derivatives with specific functional groups that allow DPh to bind to PbS allow the surface density of molecules on nanocrystals to be controlled. Specifically, phosphonic acid and carboxylic acid functional groups are designed to bind the DPh to the surface of the PbS NC. Energy transfer from DPh to PbS characterized by steady-state and ultrafast absorbance and emission measurements will be presented.

SESSION ES19.08: Photophysical Properties: from the Bulk to the Nanoscale

Halide Perovskites Bulk vs. Nanoparticles—What is different? What is similar?

Ivan Mora-Sero; Universitat Jaume I, Castello de la Plana, Spain.

Halide perovskites are receiving a huge attention in the recent few years. Undoubtedly this attention is mainly due to the outstanding power conversion efficiencies, surpassing 23%, reported for photovoltaic devices, fabricated with polycrystalline films from low cost techniques. The great success of halide peroviskites boosted also the interest on the nanoparticles (NPs) of these materials. Perovskite NPs are also generating a huge interest as relative easy preparation methods yield a simple core structure, without need for passivating shells, reach photoluminescence quantum yield (PLQY) higher than 90%. This remarkable PLQY points to low non-radiative recombination and consequently shows excellent potential for the development of solar cells and optoelectronic devices. In this talk I show the interest of perovskite NPs in the development of different optoelectronic systems and analyze the similarities and differences with standard bulk perovskite thin films. Interestingly the use of NPs can help to overcome some limitations of bulk perovskites stabilizing new interesting crystalline phases or avoiding mixed halide ion migration. In addition, the interaction of perovskites with other materials can provide useful synergies and their potentialities commented.

8:30 AM -ES19.08.02

Subpicosecond Photoionization of Mn-Doped CdSe Quantum Dots Mediated by Spin-Exchange Auger Interactions

Rohan Singh, Wenyong Liu, Jaehoon Lim, Istvan Robel and Victor Klimov; Los Alamos National Laboratory, Los Alamos, New Mexico, Los Alamos, New Mexico, United States.

Diluted magnetic semiconductors (DMS), especially those containing Mn dopants, have been the subject of numerous studies [1]. A key property of these materials is strong interactions between electronic states of a semiconductor host and Mn dopants mediated by spin-exchange interactions [2, 3]. An interesting aspect of these interactions is their influence on multicharge Auger-type phenomena. In the case of Mn-doped II-VI DMSs, the spin-exchange Auger effect has been invoked to explain highly efficient excitation transfer from a semiconductor to a Mn ion leading to characteristic emission via the internal $^{1}T_{1} \rightarrow ^{3}A_{1}$ transition of a 3d electron. This effect has been observed in both bulk and quantum dot (QD) forms of II-VI DMS materials [1, 4]. Previous studies also indicate that the reverse Auger process whereby the Mn excitation is transferred to the conduction-band electron is also highly probable [5]. In particular, Auger de-excitation was cited to rationalize Mn-emission quenching by injected electrons [6]. Furthermore, there are several direct observations of hot Auger electron produced by this process [7, 8]. Despite the initial indications of a considerable strength of exchange interactions in Mn-doped II-VI QDs, the quantitative understanding of this effect is still lacking. The purpose of the present study is to quantify temporal characteristics of Auger-mediated exchange of excitations between the magnetic ion and the semiconductor by conducting femtosecond transient absorption (TA) measurements of Mn: CdSe QDs. Using low-intensity (sub-single exciton) near band-edge excitation (515 nm), we are able to resolve both “forward” transfer of a band-edge exciton to a Mn ion as well as “backward” transfer. We find that the direct transfer takes place on a ca. 100-fs timescale. The rate of the back transfer, on the other hand, strongly (exponentially) depends on the energy difference between the Mn $^{1}T_{1} \rightarrow ^{3}A_{1}$ transition and the QD band gap, exhibiting a thermally activated behavior. Furthermore, in the case of above-band-gap excitation (343 nm) and high pump intensities (multielectronic regime), we detect the excitation of a “hot” electron from the QD to an external “vacuum” state accompanied by de-excitation of the Mn ion. This indicates an extremely strong exchange coupling of the excited Mn d-d transition to the intraband QD transition, which leads to sub-ps Auger-assisted reexcitation of the “hot” electron prior to its relaxation to the band edge. As a result, the energy transferred from the Mn ion adds up with the kinetic energy of the unrelaxed carrier, which allows it to escape from the QD.
Colloidal semiconductor quantum dots (QDs) have been envisioned as promising materials for application in traditional light-emission devices and prospective single-dot light sources. While QD displays have already entered the market place, realization of single-dot applications still requires overcoming several challenges including elimination of strong spectral fluctuations at the individual-QD level. Recently, there has been considerable progress in suppressing intensity fluctuations by encapsulating an emitting core (usually CdSe) into an extra-thick protective shell (commonly CdS) [J. Am. Chem. Soc. 130, 5026, 2008, Nat. Mater. 7, 659, 2008]. Despite nearly “blinking-free” emission intensity, these dots, however, still show considerable fluctuations in both emission energy and linewidth. Here we demonstrate a new class of QDs that overcome both deficiencies. In these dots, the CdSe core is enclosed into a compositionally graded, asymmetrically-strained Cd$_{1-x}$Zn$_x$Se shell [Nat. Mater. 17, 42, 2018]. These structures exhibit a highly stable emission energy (~0.5 meV standard deviation versus ~10 meV in CdSe/CdS QDs) and an unprecedentedly narrow, subthermal room-temperature linewidth (~20 meV). These unusual properties are derived from unique structural features of these QDs, which leads to strong suppression of exciton-phonon coupling and reduction in propensity for random photoccharging. The remarkable spectral characteristics along with fast emission rates (~1/15 ns) and high emission quantum yields (up to ~85%) make these novel structures well suited for practical realization of single-dot light sources.

**Colloidal Synthesis of Ternary and Heterostructured 2D Semiconductor Nanocrystals**

Alina Schimnich; UC San Diego, La Jolla, California, United States.

Colloidal semiconductor nanocrystals have played an important role in the search for and development of next-generation technologies, owing largely to their potential for solution processability and size-tunable optical properties. Two-dimensional semiconductor nanocrystals have recently gained much attention for their unique, layer-dependent electronic, optical and magneto-optical properties, making them attractive for myriad applications in catalysis, energy conversion and optoelectronic devices. Although accessing lateral quantum confinement in these materials may be difficult, their properties may be tuned via other strategies including the formation of heterostructures or multinary alloys. Herein we present colloidal syntheses of heterostructures based on binary and ternary two-dimensional semiconductors such as WSe$_2$ and Cu$_2$WSe$_4$. These syntheses take advantage of nanocrystal conversion chemistry to access otherwise difficult compositions and structures.

**Mixed-Anion Semiconductors for Photocatalytic Water Splitting Under Visible Light**

Ryu Abe; Graduate School of Engineering, Kyoto University, Kyoto, Japan.

Photo-induced water splitting using semiconductor photocatalysts has attracted considerable attention for producing H$_2$ as a clean energy carrier, while the effective utilization of visible light is imperative to achieve the desired efficiency for practical applications. [1] Recently, mixed-anion compounds such as oxyanides have been intensively studied as promising candidates since one can expect that higher energy p orbitals of non-oxide anions (e.g., N-2p) elevate their valence band maximum (VBM) values. Unfortunately, most of them are subject to facile self-oxidation by photogenerated holes, while highly dispersed cocatalyst particles certainly improve the stability of some oxyanides. [2] We have recently demonstrated that Silvan-Aurivillius type perovskite oxycalixes such as Bi$_2$NbO$_6$Cl can stably and efficiently oxidize water to O$_2$ under visible light without any surface modifications, and also exhibits a stable Z-scheme water splitting when coupled with a H$_2$-evolving photocatalyst. [3] It was revealed that the VBMs of these materials consist mainly of O-2p orbitals, instead of Cl-3p (or Br-4p), but their positions are much more negative than those of conventional oxides. [4, 5] Thus, they possess narrow bandgaps for visible light absorption as well as sufficiently negative CBMs for water reduction. DFT calculation visualized a fairly strong hybridization between the Bi-6s and O-2p orbitals, which can explain why the O-2p orbitals are elevated in energy, combined with the result on Madelung site potential analysis that can rationalize the origin of high energy of O-2p orbital in these materials. Since O-2p orbitals are known to be relatively stable, generated holes populated at the O-2p orbitals will not lead to self-decomposition but to oxidize water. These results could provide new strategies for developing durable photocatalytic materials for water splitting under visible light, by manipulating the interaction between post-transition metal s orbitals and O-2p orbitals.

**Size Dependent Donor and Acceptor Pair Recombination in Colloidal Silicon Quantum Dots**

Hiroshi Sugimoto and Minoru Fujii; Kobe University, Nada Kobe, Japan.

Defining the optoelectronic features of semiconductors quantum dots (QDs) by introducing a few impurity atoms is a novel way to tailor new functionalities towards the photonic applications. Formation of localized impurity states in the energy gap enables to engineer the emission properties exceeding the range that can be achieved by size and shape control. In fact, attempts to exploit emission properties of QDs by impurity doping have initiated for compound semiconductor such as Cu or Ag-doped CdSe QDs and Mn-doped ZnSe QDs. In contrast to the great advancements in compound semiconductors, impurity-doping in Si QDs is still at the fundamental level despite its importance in optoelectronics and biophotonics applications.

In this work, we present the development of colloidal Si QDs codoped with boron (B) and phosphorus (P) [1,2] The codopants introduce donor and acceptor levels in the band gap of Si QDs and thus enable the optical transition with the energy below bulk Si bandgap (~1.1 eV). The emission energy is tunable in the range of 0.9-1.8 eV [1] which is optimal for...
carrier multiplication facilitated solar cell power conversion. In this work, to extract the information on impurity-induced effects quantitatively, we apply the size-purification process for lifting the size inhomogeneity. We have succeeded in preparing almost monodispersed codoped Si QDs. In the size-purified and selected QDs, we determine the degree of doping-induced shrinkage of the optical band gap over a wide size range. From the comparison of the optical data with recent results on single QD analyses including scanning tunneling spectroscopy, we discuss the size dependence of donor-acceptor (D-A) states in Si QDs. We present the number of D-A pairs in a QD in a wide size range by the comparison with theoretical calculation. In addition, we investigate the decay dynamics of D-A pair recombinations as a function of emission energy and the QD size. The results indicate that around 5.5 nm is a critical dimension, where the behavior of D-A pairs in a Si QD changes drastically. Finally, we demonstrate the potential of codoped Si QDs as near-IR luminescent probes in bio-imaging. These results demonstrate that codoped Si QDs offering efficient below 1.1 eV emission could be leveraged for not only QD-based solar energy conversion but also bio-imaging operated in the transparent window of biological tissue (700-1300 nm).

Excited-State Charge-Transfer Reactivity of QD-Linker-Metal Oxide Heterostructures with Amine-Bearing Bifunctional Molecular Linkers

Natalia Rivera-Gonzalez and David Watson; Chemistry, University at Buffalo, The State University of New York, Buffalo, New York, United States.

Semiconductor quantum dots (QDs) are intriguing harvesters of light and donors of excited charge carriers for solar energy conversion. To exploit this potential requires the localization of QDs at interfaces with appropriate energetic offsets for charge separation. We and others have reported the use of mercaptalanoic acids and related thiol-bearing linkers to tether organic-capped CdS and CdSe QDs to nanocrystalline TiO2 thin films. Electrons can be transferred efficiently from photoexcited QDs to the TiO2 substrate through mercaptoalanoic acid linkers. Unfortunately, adsorbed thiolates can accept valence-band holes efficiently from photoexcited QDs, reducing the distance between photogenerated electrons in TiO2 and holes in the thiolates, and additionally promoting the deleterious oxidative degradation of linking ligands.

To address this issue, we are exploring the use of amine-bearing linkers as alternatives to the thiolated linkers. Amines are attractive because they can coordinate to cadmium chalcogenide QDs without accepting holes, which maximizes the spatial separation of charge carriers following electron transfer to metal oxides. In addition, amines enhance band edge emission, shifting trap-state emission to higher energy and eliminating electron-hole recombination pathways. This presentation will focus on (1) synthesis of the heterostructures via both in situ and ex situ synthetic approaches, which differ in the ordering of surface-functionalization events, and (2) spectroscopic and photoelectrochemical characterization of excited-state charge-transfer within the heterostructures. In ex situ synthesis, CdSe QDs are first functionalized with the linking ligand, and these linker-functionalized CdSe QDs are then attached to the metal oxide. We have developed a two-step ligand-exchange mechanism to obtain para-aminobenzonic acid (PABA)-functionalized CdSe QDs by using oleate-capped CdSe QDs as the starting QDs and pyridine-CdSe QDs as the intermediate QDs. We subsequently optimized the attachment of PABA-CdSe QDs to TiO2. Time-correlated single-photon-counting of QD-TiO2 heterostructures reveal charge-transfer induced dynamic quenching of emission from QDs with excited-state electron-transfer rate constants on the order of 10^9 s^-1. This presentation will emphasize insights into the mechanism and time scale of photoinduced electron transfer at QD-TiO2 interfaces as a function of interfacial properties and the mechanism (in situ or ex situ) by which heterostructures were prepared. Results of ongoing photoelectrochemical experiments on QD-sensitized solar cells will also be presented.

11:30 AM ES19.09.04

Molecularly-Localized Energy of Exciton Confined in the One-Dimensional Nanostructures of Single-Walled Carbon Nanotubes

Tomohiro Shiraki1-2, 1Department of Applied Chemistry, Kyushu University, Fukuoka, Japan; 2ICNER, Kyushu University, Fukuoka, Japan.

Single-walled carbon nanotubes (SWNTs) are one dimensional (1D) nanomaterials with a diameter of ca. 1 nm and a length of a few hundred nm or ~μm. The tubular structures are composed of rolled up single graphene, and the rolled-up manner, which is identified by chiral indices, determines their optical and electronic properties, such as metallic and semiconducting features. The semiconducting SWNTs show photoluminescence (PL) in near infrared (NIR) regions through a relaxation process of exciton generated by photo-excitation. Single-walled carbon nanotubes (SWNTs) are one dimensional (1D) nanomaterials with a diameter of ca. 1 nm and a length of a few hundred nm or ~μm. The tubular structures are composed of rolled up single graphene, and the rolled-up manner, which is identified by chiral indices, determines their optical and electronic properties, such as metallic and semiconducting features. The semiconducting SWNTs show photoluminescence (PL) in near infrared (NIR) regions through a relaxation process of exciton generated by photo-excitation. SWNTs have different electronic structures by the modification, and can trap the migrating excitons and then emit PL efficiently, giving PL intensity enhancement with wavelength shifts. Recent studies are revealing that doped site structures of the IF-SWNTs relate to the resultant PL functions. This presentation reports new findings based on our molecular design approach to create structurally-designed doped sites, in which unique PL properties appear based on the functionalized molecules.[1-6] For example, bisaryldiazonium salts (2Dz) were synthesized and used for the modification of SWNTs with (6,5) chiral index (lf-SWNTs/2Dz), providing new red-shifted PL.[1] Namely, the PL peak appeared at 1256 nm which was significantly red-shifted than those of non-functionalized SWNTs (985 nm) and mono-functionalized SWNTs (lf-SWNTs/1Dz, 1129 nm). In another project, substituted aryl isomers were introduced as a moiety of the doped site structures of lf-SWNTs. The observed PL was varied with strong dependence on the isomeric substituent positions.[3] Thus, these molecular structure-dependent spectral changes are expected to modulate the NIR PL in a wide wavelength range. As another function of the IF-SWNTs, dynamic wavelength shifting is achieved through creation of the doped sites that selectively bind molecules and ions.[2, 5, 6] The local binding occurred by employing molecular recognition motives for the doped site structures. The first example was phenylboronic acid-modified lf-SWNTs that showed PL in situ and ex situ and in situ synthesis, CdSe QDs are first functionalized with the linking ligand, and these linker-functionalized CdSe QDs are then attached to the metal oxide. We have developed a two-step ligand-exchange mechanism to obtain para-aminobenzonic acid (PABA)-functionalized CdSe QDs by using oleate-capped CdSe QDs as the starting QDs and pyridine-CdSe QDs as the intermediate QDs. We subsequently optimized the attachment of PABA-CdSe QDs to TiO2. Time-correlated single-photon-counting of QD-TiO2 heterostructures reveal charge-transfer induced dynamic quenching of emission from QDs with excited-state electron-transfer rate constants on the order of 10^9 s^-1. This presentation will emphasize insights into the mechanism and time scale of photoinduced electron transfer at QD-TiO2 interfaces as a function of interfacial properties and the mechanism (in situ or ex situ) by which heterostructures were prepared. Results of ongoing photoelectrochemical experiments on QD-sensitized solar cells will also be presented.

Colloidal quantum dots can be used to engineer band degeneracies and connectivities that may result in fundamentally new solid-state physics. Here, a compact fluorinated ligand, trifluoromethylthiolate, is used to functionalize PbS semiconductor quantum dots (QDs). The electron-withdrawing fluorinated shells allow band energies to be engineered to introduce a depletion layer in a QD thin film and thus improve charge transport in a device. Importantly, the self-assembled superlattices have strong electronic coupling between constituent QDs arising from the short interdot distances. Thin-film transistor measurements show current staircases, reminiscent of Coulomb blockades recorded at 4K on single particles, despite the fact that our measurements are performed at RT on micron-sized devices over 1000-10000 QDs. This talk will discuss the charge transport in these PbS QD thin films.

Formation of Electronically and Chemically Passive Termination on PbSe Quantum Dot Superlattices

Colloidal synthesized nanocrystals are attractive ‘designer atoms’ that can be used to engineer band degeneracies and connectivities that may result in fundamentally new solid-state physics. Here, a compact fluorinated ligand, trifluoromethylthiolate, is used to functionalize PbS semiconductor quantum dots (QDs). The electron-withdrawing fluorinated shells allow band energies to be engineered to introduce a depletion layer in a QD thin film and thus improve charge transport in a device. Importantly, the self-assembled superlattices have strong electronic coupling between constituent QDs arising from the short interdot distances. Thin-film transistor measurements show current staircases, reminiscent of Coulomb blockades recorded at 4K on single particles, despite the fact that our measurements are performed at RT on micron-sized devices over 1000-10000 QDs. This talk will discuss the charge transport in these PbS QD thin films.

Achieving ordered macroscopic crystal-like assemblies has been in the focus of researchers for years, since it would allow for exploitation of the quantum confinement-based electronic properties with tunable dimensionality, but was considered by many as a mere academic game as the polidispersity of colloidal systems should have hindered the emergence of collective behaviors. Lead-chalcogenide colloidal quantum dots show especially strong tendencies to self-organize into 2D superlattices with micron-scale order, making the array fabrication fairly simple. However, most work concentrates on the fundamentals of the assembly process, and none have investigated the electronic properties and their dependence on the nanoscale structure induced by different ligands. In my presentation, I will show the formation of large arrays of colloidal quantum dots and the dependence of the nanostucture, the optical and the electronic transport properties of the superlattice on chemical treatment (ligand exchange) performed. Transistors with average two-terminal electron mobilities of 13 cm^2/VS and contactless mobility of 24 cm^2/VS are obtained for small area superlattice FETs [1]. Such mobility values are the highest reported for CQD devices wherein the quantum optical is substantially still present, and are comparable to those reported for heavy sintering. The next step to make an electronic metamaterial which could be highly relevant for optoelectronics, is to use the surface of the quantum dots to change their stoichiometry and tune their transport properties. I will show that more than two orders of magnitude improvement in the hole mobility, from below 10 to above 0.1 cm^2/VS, by substituting iodide ligands with sulfide, while keeping the electron mobility stable (~1 cm^2/VS) were achieved [2]. The considerable mobility, the possibility of tuning their transport properties with the simultaneous preservation of the optical band gap displays the vast potential of colloidal QD superlattices for optoelectronic applications.

[1] Balazs, D.M.; Matysiak, B. M.; Momand, J.; Shulga, A. G.; Ibáñez, M.; Kovalenko, M.V.; Kooi, B. J.; Loi, M. A.: Electron Mobility of 24 cm^2V-1s-1 in PbSe Colloidal-Superlattices for optoelectronic applications. The considerable mobility, the possibility of tuning their transport properties with the simultaneous preservation of the optical band gap displays the vast potential of colloidal QD superlattices for optoelectronic applications.

Towards Electronic Minibands—Superlattices with PbS QDs in a Fluorinated Matrix

PbS colloidal quantum dot colloids are attractive systems for optoelectronic applications due to their quantum confinement-induced optical properties and electronic transport properties. The electron-withdrawing fluorinated shells allow band energies to be engineered to introduce a depletion layer in a QD thin film and thus improve charge transport in a device. Importantly, the self-assembled superlattices have strong electronic coupling between constituent QDs arising from the short interdot distances. Thin-film transistor measurements show current staircases, reminiscent of Coulomb blockades recorded at 4K on single particles, despite the fact that our measurements are performed at RT on micron-sized devices over 1000-10000 QDs. This talk will discuss the charge transport in these PbS QD thin films.

Photocontrollable Optoelectronic Devices Consisting of an Assembly of Photochromic Compounds

In molecular electronics, photochromic compounds are considered to be promising candidates for optoelectronic molecular electronic devices. In diarylethenes the π-system of the two aryl rings is separated in the open-ring isomer, while the π-system is delocalized throughout the molecule in the closed-ring isomer. The magnetic interaction in the open-ring isomer is inherently weak from the disjoint nature of the n-system. On the other hand, in the closed-ring isomer resonant closed-shell structure brings about strong magnetic interaction. Based on this idea we have demonstrated that the exchange interaction between two nitrolyl nitroxide radicals connected by a diarylethene unit was photowitching reversally along with photoluminescence from the measurement of the magnetic susceptibility, ESR signal intensity, and ESR signal splitting. By preparing the diarylethene-gold nanoparticles network made of diarylethene dithiophenol, the completely reversible photoswitching of conductance through the organic molecule has been achieved. Diarylethenes, which have same core structures but have different positions of thiol groups that are bound to gold nanoparticles, were prepared. In one diarylethene, which has two thiol groups at the positions equivalent to 5,5'-positions of di(3-thienyl)ethene, but in the other diarylethene, which has two thiol groups at 2- and 5-positions of one of the 3-phenyl group. The gold nanoparticle networks of these diarylethenes were prepared and the charge in conductance was measured upon alternate irradiation with UV and visible light. For two diarylethenes, the direction of the photoswitching was opposite, reflecting the difference in the π-connectivity. The result suggests that the topology of π-conjugation between electrodes is the decisive factor in the conductance of gold nanoparticle network (J. Phys. Chem. Lett. 2016, 7, 2113).

Optical switching organic field-effect transistors (OFETs) provide a new direction for optoelectronics based on photochromic molecules. However, the patterning of OFETs is the decisive factor in the conductance of gold nanoparticle network (J. Phys. Chem. Lett. 2016, 7, 2113).
difficult because conventional fabrication processes, including lithography and ion etching, inevitably cause severe damage to organic molecules. We demonstrated laser patterning of one-dimensional (1D) channels on an OFFET with a photorefractive diethylenetriamine (DAE) layer. A number of 1D channels can be repeatedly written and erased in the DAE layer by scanning focused ultraviolet and visible light laser beams and the conductance of the 1D channel can be controlled by the illumination conditions. This result will open new possibilities for realizing various optically reconfigurable, low-dimensional organic transistor circuits (Nano Lett. 2016, 16, 7474).

3:30 PM *ES19.10.05

Spectral Engineering for Narrow-Band Colloidal Quantum Dot Optoelectronics Susanna M. Thon, Ebuka S. Arinze, Botong Qiu, Yida Lin, Arlene Chiu, Yan Cheng and Lulin Li; Electrical and Computer Engineering, Johns Hopkins University, Baltimore, Maryland, United States.

Colloidal quantum dots (QD)s are attractive materials for energy harvesting and sensing applications because they combine flexible, low-cost solution-phase synthesis and processing with internalized infrared. PbS-based QDs with band gaps that can be tuned throughout the near and mid-infrared wavelengths via the quantum confinement effect are a promising materials system for photovoltaics and photodetectors that harvest non-visible radiation. The ability to achieve true wavelength-selectivity for applications such as transparent and multijunction photovoltaics, narrow-band photodetectors, and tailored emission sources has been lacking to this point, however. Here, we discuss several new strategies for achieving spectral selectivity and color-tuning in QD thin films. We use thin layer interference engineering and multiojective optimization algorithms to design devices with controlled absorption, reflection, and transmission profiles while simultaneously maintaining high current in QD solar cells. We also discuss an alternate method for achieving spectral selectivity in optoelectronic thin films: the use of photonic band engineering within the absorbing region of a semiconductor in which resonant states are strongly coupled to the external reflectivity and transmission spectra. Using optical models and proof-of-principle experiments, we show that photonic bands can be maintained in a new regime: with strongly absorbing materials. We further showed that this effect can be used as a tuning mechanism for enabling spectrally-selective absorption and transmission of light. We demonstrate the viability of this method in experiment by making new materials based on photonic crystal structures consisting of PbS QDs infiltrated into an inverse opal structure provided by self-assembled dielectric nanospheres. This work represents a new spectral tuning mechanism and should additionally enable applications such as current-matching in multi-junction solar cells and miniaturized wavelength-selective photodetectors for sensing applications.

4:00 PM ES19.10.06

I-III-VI: Semiconductor-Based Colloidal Nanorod Heterostructures for Multifunctional Optoelectronics Nuri Ob1, Logan Keating2, Gryphon Drake2 and Moonsub Shim2; 1Materials Science and Engineering, Hanyang University, Seoul, Korea (the Republic of); 2Materials Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Beyond the conventional core/shell structures of colloidal semiconductor nanocrystals, the incorporation of active heterojunctions in emerging anisotropic structures has brought about new capabilities for optoelectronic applications. Recently, it has been demonstrated with double-heterojunction nanorods to independently control over electron and hole injection/extraction processes, allowing improved electroluminescence and simultaneous photodetection/photovoltaic capabilities. However, most efforts thus far have been made in Cd-based II-VI materials that face severe usage restrictions in consumer products. Hence, expanding the composition space for colloidal nanocrystal heterostructures of varying shapes should facilitate practical implementation. One of the interesting candidates is I-III-VI: compound semiconductors, which have similar crystal structures as the II-VI materials. Above all, much of the chemistry developed for II-VI nanocrystal heterostructures can be adapted for ternary compounds. However, the direct formation of I-III-VI: based nanocrystal heterostructures has rarely been reported due to the compositional complexity. Even the previous approaches via sequential cation exchange from II-VI based dot-in-rod structures have several limitations including non-selectivity for co-existing cations and formation of undesired defects and impurities. Here, we examine and develop synthesis of colloidal I-III-VI: nanorods and subsequent epitaxial growth of heterostructures. Starting with CuGaS2/ nanorods, sawtooth-shaped CuGaS2/CuInS2 and CuGaS2/CuInSe2 nanorod heterostructures (NRHs) are achieved with subtle variations in shape caused by differences in lattice mismatch. Growth of ZnS shell on CuGaS2/CuInSe2 NRHs leads to enhanced PL and other interesting/useful optical properties, including large pseudo-Stokes shift and charge separation within the NRHs. Changing the final stoichiometry of ZnSe to ZnSe leads to similar features as those of ZnSe shell initially but continued growth results in unusual brush-like heterostructures. Building on our synthetic strategy to extend anisotropic nanocrystal growth to introduce the multiple active heterojunctions should pave the way for developing application-specific design and synthesis of multifunctional optoelectronic materials.

4:15 PM ES19.10.07

Direct Measurement of Charge and Electric Field in Quantum Dot Light-Emitting Diodes Han Zha1, Giovanni Azzellino1, Matthew Chua1, Jason Yoo1, Mounig Bawendi1 and Vladimir Bulovic1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Colloidal quantum dot light-emitting diodes provide a highly promising platform for efficient, color-tunable, and stable solid-state lighting and display technologies. A quantitative understanding of its device physics is required to achieve high efficiency across a large range of brightness and emission wavelength. While studies have demonstrated the detrimental effects of excess charge carriers, large electric field, and leakage current on device efficiency, these internal state variables have never been directly measured. This leads to challenges in validating quantitative physical models that relate device parameters, internal state variables, and device performance.

In this work, we perform differential absorption measurements using a sub-millisecond laser to directly measure both charge density and electric field strength in a working QD-LED at high current density (up to 1000 mA/cm2) and output brightness. We observe that charge density in the quantum dot film drastically increases with bias before eventually reaching a plateau, a trend that is consistent with multiple injection regimes of charge balance characterized by different efficiency loss mechanisms. We show that the amount of injected charge can be controllably adjusted from 0.5 electrons per QD to 2 electrons per QD by simply varying the thickness of the quantum dot layer by less than 15nm. This leads to differing degrees of loss through Auger recombination and can offer insights into the dynamics of excitation formation at the interface of the quantum dot film and neighboring semiconducting transport layers. Finally, we use independent measurements of charging and electric field strength to characterize the transition from interface limited conduction to space-charge limited conduction. These results provide a significant improvement in the quantitative understanding of the operation QD-LEDs and can lead to better rationalization of device performance.

4:30 PM ES19.10.08

Low-Threshold Optically Pumped Lasing in LED-Like Stacks Based on Colloidal Quantum Dots Heojung Kim1, Young-Shin Park1,2 and Jae-Hoon Lim1,3; 1Chemistry Division, Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 2Center for High Technology Materials, The University of New Mexico, Albuquerque, New Mexico, United States; 3Department of Chemical Engineering & Department of Energy System Research, Ajou University, Suwon, Korea (the Republic of).

Colloidal quantum dots (QDs) have gained considerable attention as promising candidates for realizing solution-processible lasing devices including laser diodes. Important milestones on the way towards a QD-based laser technology have been recent demonstrations of low-threshold optically pumped devices operating under pulsed (Nano Lett. 15, 7319, 2015) and continuous-wave (Nature 544, 75, 2017) excitation. However, demonstration of lasing with electrical pumping remains challenging because of fast optical gain decay via intrinsic nonradiative Auger recombination and thermal instabilities in the QD gain medium under high excitation conditions. Recently, we demonstrated a population inversion and optical gain under electrical pumping in a QD light-emitting diode (QD-LED) using continuously graded QDs with suppressed Auger recombination and employing a current focusing architecture which allowed for achieving high current densities of (~20 A cm2) without device overheating (Nat. Mater. 17, 42, 2017). The next step towards an electrically pumped laser diode is integration of an optical cavity into the QD-LED structure. In this study, we demonstrate optically pumped laser in a multilayer waveguide structure whose architecture is similar to that of a standard QD-LED. A one-dimensional periodic distributed feedback (DFB) grating was imprinted onto an ITO transparent electrode using laser interferometric lithography. In order to improve optical mode confinement within the gain-active QD layer, we engineered the refractive index of ITO so as to reduce the mode leakage into the underlying electrode. The developed structure exhibited strong lasing performance (~630 nm) with optical feedback provided by the in-plane 2nd order scattering and out-of-plane light outcoupling due to the 1st order scattering. Despite the presence of a “lossy” conductive electrode, our fully optimized structures exhibited a very low lasing threshold of ~5.5 μJ/cm2 which was on-a-par with the lowest thresholds reported for QD lasers of any type (Nano Lett. 15, 7319, 2015). As the next step, we employed a zinc oxide (ZnO) interlayer, which was commonly used in QD-LEDs as an
electron-transport layer (ETL), and investigated lasing performance of an ITO-DFB/ZnO/QD multilayer structure. We found that the QD DFB laser with ZnO still exhibited excellent lasing performance with a low threshold (~5.7 µJ/cm²) achieved upon full optimization of all elements of our multilayer stacks. Finally, we deposited 4,4',4''-tris(carbazol-9-yl)-triphenylamine (TCTA) as a hole-transport layer (HTL), on top of the QD layer to form a nearly complete LED stack comprised of transparent electrode/ETL/QD/HTL. Importantly, the deposition of TCTA did not distort optical properties of the DFB resonator, which retained a well-defined photonic gap. As a result, the developed device stacks showed good lasing performance although with a moderately increased threshold of ca. 17 µJ/cm², which was expected to become lower upon device optimization. The results of this work along with the recent demonstration of optical gain in QD-LEDs reaffirm the feasibility of solution processible QD-based laser diodes.

**Bridge the Gap Between Photoluminescence and Electroluminescence of Colloidal Quantum Dots**

Xingliang Dui; Zhejiang University, Zhejiang Province, China.

Colloidal Quantum dots (QDs) are a unique class of emitters with size-tunable emission wavelengths, saturated emission colors, near-uniform luminescence efficiency, inherent photo- and thermal-stability and excellent solution processability. The superior photoluminescence properties of QDs have already initiated applications as back-lighting for liquid-crystal displays to improve color gamut, which rapidly grows into multi-billion dollar business. Fully exploiting the superior luminescence properties of QDs in electroluminescence devices promises low-cost, large-area, flexible and yet high-performance LEDs, which shall revolutionize display and solid-state lighting. For the past two decades, a lot of efforts concentrated on materials and device structures of quantum dot light emitting diode (QLED) have been paid to improve devices performance. But the efficiency and lifetime of QLEDs are far behind the requirements for practical applications. Clearly, there is a performance gap between photoluminescence and electroluminescence of QDs. To bridge the photoluminescence-electroluminescence gap of QDs, in-depth understanding of the formation and decay processes of electrically excited states in QDs is urgent and indispensable. In the past few years, we designed a conceptually new device structure containing an ultrathin insulating layer for QLEDs and integrated almost functional layers by solution process. The insulating layer modulate the electron injection to optimize charge balance and maintain superior emissive properties of QDs, forming efficient exciton generation and radiative decay cycle. Finally we realized the state-of-the-art solution-processed red LEDs with sub-bandgap turn-on voltage (1.7 V), record efficiency (EQE > 20%) and outstanding operational stability (~10⁵ hours @100 cd m⁻²). The two functions of the insulating layer can be decoupled and addressed separately. Suppressing exciton quenching at electron-transport-layer (ETL)/QDs interface, which is identified as being obligatory for high-performance devices, is achieved by adopting ZnₓMgᵧ₋ₓO nanocrystals, instead of ZnO nanocrystals, as ETLs. Optimizing charge balance is readily addressed by other device engineering approaches, such as controlling the oxide ETL/cathode interface and adjusting the thickness of the oxide ETL. Insights revealed by device physics studies further help us to bridge the photoluminescence-electroluminescence gap of QDs, realizing much extended QLED operation stability. These devices show a Tₜₜ operation lifetime of more than 3,500 h at an initial brightness of 1000 cd m⁻² for red LEDs, representing the most stable QLEDs so far. These achievements bring QLED technologies a step closer towards real-life applications.

**TUTORIAL**

**Young Scientist Tutorial on Characterization Techniques for Thin-Film Solar Cells**

Monday Morning, April 22, 2019

PCC North, 100 Level, Room 132 B

This tutorial is intended for young researchers (students and post-graduates within 3 years of degree completion) who are active in the field of thin-film solar cells and would like to learn the fundamentals of characterization methods that are being used in research and development of these materials and devices. All presentations will be given (mostly) by young, yet experienced researchers who are active in the characterization of Si-, III-V-, chalcogenide-, kesterite-, as well as perovskite-based solar cells. Although these materials will be discussed as model systems, the presentations will primarily focus on the characterization and simulation techniques and thus should be of interest to participants from other symposia as well.

---

**8:30 AM**

**Electrical Device Characterization and Modeling of Thin-Film Solar Cells**

Mike Scarpulla; The University of Utah

I-V and C-V DC analyses, AC characterization (CV, DLCP, DLTS and related techniques), localized state and band-structure-related responses; simulations using 1D solvers such as SCAPS and extensions to 2D; “hands-on” simulation demonstration.

**10:00 AM BREAK**

---

**10:30 AM**

**Soft X-Ray and Electron Spectroscopies: Investigating the Chemical and Electronic Structure of Surfaces and Interfaces**

Dirk Hauschmidt; Karlsruhe Institute of Technology

Introduction to several soft x-ray and electron characterization techniques, including x-ray (XPS) and UV (UPS) photoelectron spectroscopy, inverse photoemission spectroscopy (IFES), x-ray excited Auger electron spectroscopy (XAES), and x-ray emission spectroscopy (XES). The tutorial includes a discussion of experimental requirements, information content, as well as data analysis and interpretation. Examples how the techniques can be used to determine the electronic and chemical structure of surfaces and interfaces in thin-film photovoltaic devices will be given.

**1:30 PM**

**Time-Resolved Terahertz Spectroscopy on Energy Materials**

Hannes Hempel; Helmholtz-Zentrum Berlin für Materialien und Energie

Introduction to measurement, analysis and application of time-resolved terahertz spectroscopy (TRTS). Determination of charge carrier mobility, bulk lifetime and surface recombination velocity demonstrated on the example of perovskites, kesterites and metal oxides. Impact of these key properties on solar cell efficiencies. Comparison of TRTS to alternative measurement techniques.
Introduction to scanning transmission electron microscopy and the accompanying analytical techniques including atomic number contrast annular dark field imaging, electron energy loss spectroscopy (EELS) and Energy Dispersive X-ray spectroscopy (EDX). The focus will be the application of these techniques on understanding structure and composition in solar materials, with examples from CdTe and CIGS solar cells. In addition, state-of-the-art in-situ heating technique will be discussed as a powerful means of understanding solar materials growth.

4:00 PM
Atomistic Modeling of Defects in Materials Kyoung Eun Kweon; Lawrence Livermore National Laboratory

Understanding defects and their roles in determining materials properties. Demonstration on how to compute thermodynamic and kinetic properties of (point) defects and defect complexes, particularly in Cu(In,Ga)Se2. Discussion includes how the atomistic calculations can be used to interpret/understand experimental observations.

SYMPOSIUM ES20

Thin-Film Chalcogenide Semiconductors Photovoltaics
April 23 - April 26, 2019

Symposium Organizers
Shubhra Bansal, University of Nevada, Las Vegas
Nicolas Barreau, Universite de Nantes
Alex Redinger, University of Luxembourg
Mike Scarpulla, The University of Utah

Symposium Support
AVANCIS GmbH
Codex International
First Solar
University of Luxembourg/Fonds national de la recherche (Luxembourg)

SESSION ES20.01: Device Modelling
Session Chairs: Stephan Lany and Pawel Zabierowski
Tuesday Morning, April 23, 2019
PCC North, 100 Level, Room 132 B

10:30 AM *ES20.01.01
Development of an Integrated ACIGS Solar Cell Device Model at MiaSolé Hi-Tech Jeff Bailey, Geordie Zapalac, Dmytro Poplavsky and Rouin Farshchi; MiaSolé Hi-Tech, Santa Clara, California, United States.

Thin-film Ag-CIGS (or ACIGS) solar cells and modules produced by MiaSolé Hi-Tech yield high efficiencies rivaling polycrystalline silicon-based modules but are based on a high-throughput, PVD-based deposition process on flexible stainless steel substrates. The process is unique among thin-film solar manufacturers in that a complete device stack is produced without a vacuum break in less than one hour. Using this manufacturing system, a high level of process control and stability is possible via real-time control of the deposition process.

To continue performance improvements that close the gap between manufacturing material and champion small devices, a better understanding of the fundamental device properties is required. This requires development of a device model that accounts for electrical performance characteristics observed under light and voltage stress over time for comparison to real-world solar cell performance.

Our recent effort to generate a fundamental device model began with employing a wide variety of characterization results from our own measurements, those of our research partners, and features of many CIGS materials that have previously been excluded in prior device models. Additionally, device parameters must be based on actual device measurements and constituents, as heterojunction ACIGS solar cell devices are complex and errors compound quickly. The overall objective was to keep the model as simple as possible and look for generally good agreement among a variety of simulated measurements.

Most of the effort has been devoted to understanding the defect structure of the ACIGS absorber layer. Conventional capacitance-voltage profiling is supplanted in our measurements by high-speed C-V profiling (HSCV) that avoids many complications of transient charge effects in highly defective materials such as ACIGS. An important consequence of these measurements is the discovery that MiaSolé absorber layers (as well as other CIGS devices) can be defined by an acceptor-rich layer (ARL) adjacent to the CdS buffer layer. This ARL has been shown to have profound consequences for device electrical performance, as it can degrade fill factor and reduce efficiency.

The physical basis for the ARL is a matter of some debate. A variation in static shallow acceptor concentration is one possible source, but it predicts neither device metastability nor measured high concentrations of DLTS-visible defects. Charge accumulation at high concentrations of deep acceptors would be possible, but accounts for neither metastability nor carrier capture kinetics observed in DLTS. Instead we hypothesize that V(Se)-V(Cu) divacancy defects are responsible for charge accumulation in the ARL, and their simulated response to light- and voltage-stressing is consistent with our measurements. This hypothesis is qualitatively consistent with positron annihilation spectroscopy (PAS) measurements of our absorber. Predicted shallow acceptor and donor levels of the divacancy also provide an explanation for the long-observed high dopant compensation in CIGS, and at the concentrations predicted by our model, it is possible that the divacancies alone can be used to explain most of the charge and doping profile of the absorber.

Emphasis of the divacancy defect in our device model can guide MiaSolé Hi-Tech to new directions for device improvement that leverage our ability to directly manipulate absorber stoichiometry in our unique thin-film solar manufacturing system.

Diagnosing Recombination and Resistive Losses in Thin-Film Chalcogenide Solar Cells Using a Silicon-Inspired Characterization Platform Arthur Onno1, Amit Munshi2,
Spatial Inhomogeneities of Carrier Transport Properties in Polycrystalline Thin-Film Solar Cells

Several characterization techniques are usually performed on a localized region of any material because of convenience in a routine basis. However, lateral non-uniformities in chemical composition, structural defects and even the presence of voids can be found in a polycrystalline solar cell, i.e. CIGS, influencing the local carrier properties of the material. This implies that some of the material properties extracted from local characterization methods may not be representative of the full device performance complicating the correlation between measurements. For example, time-resolved photoluminescence (TRPL) is typically measured locally, and the effective lifetime values determined (including the influence of front/back recombination, etc.) are closely related to the open circuit voltage which is a macroscopic parameter that might be affected by any carrier lifetime non-uniformity. Therefore, information about the influence of spatial inhomogeneities on the carrier transport is important to assess whether it is enough to use local parameters to correlate different characterization results —and to predict the performance of the solar cell—, or to what extent it is required to consider non-uniform parameters that could be more representative of the whole device.

In this contribution, we use transient PL measurements spatially resolved in the micrometer-scale range to access the carrier properties of different absorbers. The TRPL setup is coupled into a microscope enabling to operate in confocal or widefield illumination mode. Widefield mode is used to map the samples in a broader range while confocal mode attempts to resolve the influence of the grains inside the structure with the highest optical resolution of the system (< 1 µm). Besides all the mechanisms involved in the determination of the effective carrier lifetime such as surface recombination, charge separation, etc., the use of confocal mode requires the consideration of lateral diffusion of carriers as well as the proper evaluation of the sample performance due to possible high injection effects. Accordingly, the interpretation of the measurements in both modes is aided by 2D simulations, which are also based on the macroscopic I-V parameters of the devices. Specifically, 2D device simulations allow us to quantify the lateral diffusion of carriers as well as to include other key parameters involved in TRPL measurements, i.e. surface recombination or carrier mobility. All simulations use as input measured absorption coefficient as a function of the bandgap grading for improved modelling. Finally, results from other spatially resolved techniques will be shown to correlate device performance with TRPL mapping and support the main findings.

Numerical simulations of solar cell device physics for predicting the performance, design and optimization of solar cells is a well explored active area of research. There are many tools and software packages like AFORS-HET, SCAPS-1D, AMPS-1D, PC1D, Silvaco TCAD, Sentaurus TCAD, etc., which are available freely or commercially, to perform numerical simulation of solar cells. The fundamental physics equations solved are continuity equations for charge carriers, namely electrons and holes, and the Poisson equation for electrostatic potential. In the continuity equation for electrons and holes the generation and recombination term is modeled through radiative processes, the SRH process, the Auger process etc. For the SRH generation recombination process an effective lifetime is assumed in the modeling. Combining this model with the boundary conditions, light and temperature simulation conditions, one can calculate I-V curves, efficiencies, fill factors etc., for the solar cell. As the solar cell ages performance is affected. This can be microscopically explained through the transport of different defects present in the solar cell. The transport of defects can also cause metastability in solar cells. In our previous work we explained the metastable behavior of CdTe solar cells by studying the Cu related defect transport along with the carrier transport.

In this work, we present a novel Unified Solver for studying carrier and defect transport on an equal footing. The generation recombination term in the continuity equation for defects corresponds to the formation and transformation of defects. This formation and transformation of defects along with generation and recombination process for charge carriers is represented as a defect chemical reaction. Hence, we call our model as reaction-drift-diffusion modeling of solar cell. The drift-diffusion equations for defects require the diffusion constants and activation energies of the defect to be known and the defect chemical reaction require reaction rate constants to be known. These parameters are calculated using Density Functional Theory (DFT).

Since the main goal of our research work is to study short time metastability and long-time reliability concerns of cadmium telluride (CdTe) photovoltaics, special attention has been placed in the design of the solver to be able to produce results ranging from ns to hours/days/years. The solver gives us possibilities to explicitly account for all transient effects with free carriers (simulation of time resolved photoluminescence) and defects (simulation of performance instabilities, IV hysteresis etc). Various generation recombination processes can be represented as additional defect chemical reactions. Moreover, the Unified Solver supports accurate treatment of interfaces and grain boundaries that are crucial for the explanation of the operation of CdTe and other chalcogenide PV technologies.

The Unified Solver is benchmarked against Silvaco simulation in homojunction and heterojunction solar cell. Excellent agreement is observed between the Unified Solver and Silvaco results for the key solar-cell parameters (short-circuit current and open-circuit voltage). Next, the Unified Solver is employed in constant temperature 2D simulation of chlorine diffusion annealing in a cadmium telluride (CdTe) system under insulating boundary conditions (isolated system). Chlorine is introduced in the system as a neutral interstitial at a half corner of the (1nm×1.2nm) structure. The concentration of chlorine interstitial is 1e16 cm⁻³ and the system is kept at a temperature of 750K. The sample is annealed for 240s using the test case of chlorine defect reactions. The time evolution of chlorine substitutional defect (Cl⁺) is presented. Emulation of process temperature profiles is also presented in the talk.
For solar technology to compete with traditional energy sources, a continued decrease in photovoltaic (PV) energy generation cost is needed. Next-generation PV technology can achieve this by utilizing earth-abundant materials and low-cost processing techniques. Chalcogenide compounds are of particular interest in this area due to their prolific use in energy applications and amenability to high-throughput, low-cost processing techniques. Chalcogenides semiconductors have shown particular success in PV applications with materials such as Cu(In,Ga)(S,Se)$_2$ (CIGS), Cu$_2$ZnSn(S,Se)$_4$ (CZTS), and CdTe. However, developing new materials and processing techniques require extensive research efforts to achieve the required high-performance goals. Complex device processing and non-ideal optoelectronic properties associated with early stage materials often prolong material development.

In this work, our approach to developing next-generation semiconductors for PV is shown. We utilize low-cost, scalable solution-based processing techniques which are amenable to high-throughput optimization and a variety of chalcogenide precursors. Furthermore, we utilize advanced optoelectronic and structural characterization to guide the material development process; this provides rapid feedback for accelerated material development through accurate screening of early-stage materials for relevant optoelectronic properties and optimal synthesis parameters. In particular, we focus on the extraction of optoelectronic properties relevant for device performance – without the need for device fabrication – through optical techniques. Previous work using these techniques for developing CZTS, CIGS, and perovskites will be shown, with application to new materials currently in development. Ultimately, the successful development of new semiconductor materials requires a cross-disciplinary approach linking fundamental material properties and processing to the device-relevant optoelectronic properties.

2:00 PM ES20.02.02

Sb$_2$(Se$_3$) is becoming a relevant thin film chalcogenide semiconductor with different technological applications such as: superconductivity, electronic components, electrode for sodium-ion batteries, photodetectors and as emerging photovoltaic absorber. In particular, and for this last application, the material has shown remarkable improvements in the last few years, demonstrating solar cells in substrate configuration with different conversion efficiencies reaching 7.6%. In fact, and similarly to CdTe, most of the devices reported in the literature so far have been prepared using this configuration. This has opened interesting perspectives for their use in solar energy conversion applications, also taking into account the 1D crystalline organization of the material, with in principle benign grain boundaries and anisotropic conduction properties. Additionally Sb$_2$(Se$_3$) has shown a high flexibility degree in terms of substrate type, due to the relatively low synthesis temperatures required for optimal high quality polycrystalline growth (300-400 C), allowing deposition onto polymeric, steel, ceramic and TCO/glass substrates. This versatility makes this compound very promising for ubiquitous applications such as building integrated photovoltaics (BIPV) (flexible, bifacial, and semi-transparent), wearables, or autonomous IOT applications among others.

In this work we present a systematic optimization study of the synthesis of Sb$_2$Se$_3$ thin films using substrate configuration solar cells, by a sequential process based on reactive annealing under Se atmosphere of thermally evaporated Sb$_2$ layer precursors. The study is centered in the analysis of the Sb precursor thickness and reactive thermal annealing conditions (annealing temperature, time, and pressure) on the compositional, structural and morphological properties of the layers. We observe the formation of continuous layers with large and homogeneous crystals, reporting for first time a weak photoluminescence signal close to 1.3eV in agreement with the band gap value obtained by IQE, and a systematic vibrational characterization under resonant and non-resonant Raman conditions that allows report 15 peaks of the expected order. After a first optimization on Mo coated soda lime glass substrates, we report a promising power conversion efficiency of 5.3% in substrate configuration with a Voc of 403 mV (the highest value reported for this configuration to the best of our knowledge), close to the 7.6% certified world record in superstrate one.

Additionally the study is complemented with a wide characterization of the fundamental properties of Sb$_2$Se$_3$ layers and devices using morphological and physical-chemical characterization (Photoluminescence, SEM, XRF, XRD), and with a complete analysis of the impact of the absorber stoichiometry under different regimes (Se-rich, Se-poor, Sb-rich and Sb-poor conditions). This will be correlated with the optoelectronic characterization (JV, IQE, CV) of the solar cells. Finally, the main challenges to develop Sb$_2$Se$_3$ type solar cells in substrate configuration will be reviewed in the frame of the obtained results.

2:15 PM ES20.02.03

Antimony Chalcogenide with Tunable One-Dimensional Ribbons Thin-Film Solar Cells Grown by Close-Space Sublimation Liping Guo, Baiyu Zhang, Lin Li, Xiaofeng Qian, and Feng Yan; 1The University of Alabama, Tuscaloosa, Alabama, United States; 2Texas A&M University, College station, Texas, United States. 3IREC, Barcelona, Spain; 3IN2UB, Departament d'Electrònica, Universitat de Barcelona, Barcelona, Spain.

The non-cubic antimony chalcogenides, i.e., Sb$_2$Se$_3$, formed by quasi-one-dimensional ribbons can enhance light absorption and carrier transport by tuning the ribbon direction using the close-space sublimation (CSS) deposition. The power conversion efficiency (PCE) ~7% is found to be associated with the ribbon direction, which was investigated with theoretical calculation and experimental measurement in the Sb$_2$Se$_3$ films and devices. The substrate temperature and film thickness are critical for the fine-tuning of ribbon orientations during the CSS deposition. Our results show that [211] preferred orientation leads to the minimum series resistance and highest light absorbance in the device. The device reliability measurement and in-depth elemental profiling analysis suggest that the interdiffusion between window layer and absorber layer dominate the degradation mechanism. This observation demonstrates that Sb$_2$Se$_3$-like quasi-one-dimensional profilings with van der Waals boundaries can achieve scalable production at low cost and hold great potential for next-generation solar cell.

2:30 PM ES20.02.04

Recent Advances in Si/CIGS Tandem Cells Daniel Lincoat; CNRS-IPVF, Palaiseau, France.

Tandem cells are considered as the next generation solar cell to overpass the intrinsic efficiency limitations of single junction solar cells, fixed by the Shockley Queisser limit below 33% and more probably below 30%. Silicon solar cells are already approaching the theoretical limit of about 29%, and represent 95% of the present PV Market. Tandem solar cells on silicon would make possible to reach 43% theoretical limit, making practical module efficiencies of more than 30%. Combinations with hybrid perovskite and III-V top cells are presently focusing a lot of attention, but an alternative is to develop top cells based on chalcogenide materials, which technologies are well proved on the market (CdTe and CIGS). This presentations will review on researches carried out on silicon/CIGS solar cells. Based on the experience on single junction CIGS low band solar cells (1.15 eV) at about 20% efficiency, wide gap CIGS solar cells (1.6-1.8 eV) are grown on single crystal silicon substrates by coevaporation, with lattice parameters matching with silicon, thanks to compositional adjustments (Ga to In, S to Se). In order to give more flexibility in interface electrical engineering, the silicon substrate is functionalized by a thin III-V buffer layer, based on GaAlAsP lattice matched alloys. Epitaxial growth of CIGS has been successfully demonstrated and first devices have been elaborated for the formation of high efficiency top cells alone, using Si/III-V as a selective back contact. Further structural, chemical and luminescence characterization will be reported.

Ref: 1D. Lincoat et al., Proceedings of EUPVSEC 2018

3:00 PM BREAK

3:30 PM ES20.02.05

A large gap still remains between the achieved conversion efficiencies and the Shockley-Queisser limit for Cu(In,Ga)Se$_2$ (CIGS) based solar cells. Some of the current limitations such as parasitic absorption losses are known and solutions are being developed. For some other limitations the origin is not well understood yet, but is required for knowledge based improvements. Thorough materials and device characterization of highly efficient solar cells can help to understand the origins of the remaining losses. We used advanced materials and device characterization including high resolution transmission electron microscopy, time-of-flight secondary ion mass spectrometry, and time resolved photoluminescence (TRPL) combined with multidimensional device modelling to confine the origins of the remaining losses. We will summarize our recent findings on...
optical, compositional, structural and electronic properties in multi-stage co-evaporated CIGS layers and at interfaces to adjacent layers. In particular, we will describe how surface recombinations velocities, minority carrier lifetime and mobility can be extracted from TRPL measurements and what we can learn from these findings. Further, we will present the presence of undesired compositional non-uniformities & voids and discuss their formation mechanism and role on device performance. Combined with recent findings obtained on narrow band gap CIS absorbers our results indicate possible inherent limitations originating from current fabrication methods and device architecture, which leads to new strategies how the actual CIGS solar cell efficiency can be pushed closer to the Shockley-Queisser value.

4:00 PM ES20.02.06
12.2% CIS and 13.6% CIGS Solar Cells Fabricated from Copper-Rich DMF Molecular Precursor Solutions Jingjing Jiang, Shaotang Yu, Sanping Wu, Weibo Yan and Hao Xin; College of Materials Science and Engineering, Nanjing University of Posts & Telecommunications, Nanjing, China.

Recently, 22.8% efficient Cu(In,Ga)Se₂ (CIGS) thin film solar cell has been reported, demonstrating its great potential as a competitor to silicon solar cells. Adopting solution method to prepare highly efficient CIGS light absorption materials is crucial for reducing the cost of CIGS solar cell fabrication and achieving large-scale production. We have previously reported 10.3% copper indium selenide (CIS) solar cell with the absorber fabricated from single DMF molecular precursor solution, demonstrating the great potential of DMF as environmentally benign solvent for solution processed thin film solar cells. The metallic element ratio (Cu/In or Cu/(In+Ga)) is the key factor to affect the quality of absorber materials. Here, we have systematically investigated the effect of the Cu/In ratio (0.85 to 1.2, from Cu-poor to Cu-rich) in the precursor solution on the CIS device performance. We found that solar cell efficiency increases with the Cu/In ratio from 0.85 to 1.05 and then decreases from 1.05 to 1.2. The best device was achieved from a ratio of 1.05 with a peak power conversion efficiency (PCE) of 12.20%, a short circuit current density (Jsc) of 36.12 mA/cm², an open circuit voltage (Voc) of 0.499 V, and a fill factor (FF) of 67.57%. Further, by gallium alloying, CIGS solar cell with a PCE of 13.6% has been fabricated with a Voc of 0.600 V, Jsc of 34.78 mA/cm² and FF of 65.17% under similar Cu-rich (Cu/(In+Ga)=1.05, Ga/(In+Ga)=0.2) condition. Our results for the first time demonstrate highly efficient CIS/CIGS solar cells can be achieved from absorbers grown under Cu-rich conditions. Characterization of the absorber materials and solar cell devices are undergoing to understand the mechanism behind the phenomenon observed.

4:15 PM ES20.02.07
Wet-Chemical Treatment of Cadmium Telluride (CdTe) Photovoltaics for Enhanced Open-Circuit Voltage (Voc) and Fill Factor (FF) Ebin Bastola and Randy J. Ellingson; University of Toledo, Toledo, Ohio, United States.

Cadmium telluride (CdTe) thin film solar cells are renowned photovoltaic materials for its high absorption coefficient, suitable band gap and low manufacturing cost. The fabrication of highly efficient devices has achieved reduced intrinsic defects and improved interfaces at front and back contacts. The back-contact processing includes the formation or deposition of tellurium (Te) layer to make an ohmic contact with a metal. Here, we report wet-chemical treatments of CdTe using various iodine compounds and sodium tetrafluoroborate (NaBF₄). The iodine compounds tested are elemental iodine (I₂), ammonium iodide (NH₄I), mixture of iodine and ammonium iodide (I/F₄) and formamide iodide (FAI). The treated surfaces were studied using Raman spectroscopy, X-ray diffraction (XRD), scanning electron microscopy (SEM), and energy dispersive X-ray spectroscopy (EDS). The treatment with iodine compounds produced Te rich layer on the back surface based on Raman, XRD patterns and changed surface morphology. The fabrication of the devices after these treatments, except 1-propanol, improved the open-circuit voltage (Voc) and fill factor (FF) of the devices. The 1-propanol etching produced tellurium iodide (TeI) in β-phase on the surface which reduced device performance. The photocurrent conversion efficiency of CdTe devices after treatment is up to 14.0% (Voc= 841 mV and FF 78%) while untreated devices have an efficiency of about 12.7% (Voc= 814 mV and FF 73%). In case of BF₄⁻ treated samples, it did not produce Te rich layer, but it seems BF₄⁻ ions are passivating CdTe surface with enhanced Voc and FF compared to standard devices.

4:30 PM +ES20.02.08
Status and Challenges of CdTe Photovoltaics Wyatt Metzger; National Renewable Energy Laboratory, Golden, Colorado, United States.

CdTe solar technology is producing electricity at costs less than conventional fuels in many regions. Yet despite its commercial maturity, there is still headroom to increase performance significantly by addressing fundamental material challenges including compensation, hole density, carrier lifetime, and interfaces. This presentation will describe ongoing work to understand and overcome these challenges.

SESSION ES20.03: Poster Session I: Material Growth

Tuesday Afternoon, April 23, 2019
5:00 PM - 7:00 PM
PCC North, 300 Level, Exhibit Hall C-E

ES20.03.01
Revealing the Optimal Conditions for the Synthesis of High Efficiency Cu₂ZnSnGe₂ Wide Band Gap Absorber Nada Benhaddou 1, Meco Lamo Molanda 1, Zakaria Laghourami 2 and Zouheir Sekkat 3; 1IRCAM, Barcelona, Spain; 2Optics & Photonics Centre, Moroccan Foundation for Advanced Science & Innovation & Research, MASCIR, OCP Foundation, Rabat, Morocco; 3Department of Chemistry, Faculty of Sciences, Mohammed V University in Rabat, Rabat, Morocco.

Last advances on kesterite (Cu₂ZnSn(S,Se)₄) corroborate the importance of doping and alloying strategies, not only for tuning the properties of this family of materials, but also for achieving higher efficiencies and broadening their possible range of application. Alkaline (Li, Na, K) and Ge doping; as well as Ag, Cd and Ge alloying are demonstrating a high potential by enhancing different aspects of these materials. Here, we have systematically investigated the effect of the Cu/In ratio (0.85 to 1.2, from Cu-poor to Cu-rich) in the precursor solution on the CIS device performance. We found that solar cell efficiency increases with the Cu/In ratio from 0.85 to 1.05 and then decreases from 1.05 to 1.2. The best device was achieved from a ratio of 1.05 with a peak power conversion efficiency (PCE) of 12.20%, a short circuit current density (Jsc) of 36.12 mA/cm², an open circuit voltage (Voc) of 0.499 V, and a fill factor (FF) of 67.57%. Further, by gallium alloying, CIGS solar cell with a PCE of 13.6% has been fabricated with a Voc of 0.600 V, Jsc of 34.78 mA/cm² and FF of 65.17% under similar Cu-rich (Cu/(In+Ga)=1.05, Ga/(In+Ga)=0.2) condition. Our results for the first time demonstrate highly efficient CIS/CIGS solar cells can be achieved from absorbers grown under Cu-rich conditions. Characterization of the absorber materials and solar cell devices are undergoing to understand the mechanism behind the phenomenon observed.

For this purpose, Cu₂ZnGeSe₂ thin films were synthesized onto Glass/Mo substrates by a sequential process, based on the sputtering of Cu, Zn and Ge metallic layers, followed by a reactive annealing under a Se₂/Ge atmosphere inside a graphite box. Parameters like metallic stack order; annealing temperature (450-550 °C), pressure (1-1000 mbar), routine (one or two-step annealing) and time; as well as the composition and of the use of chemical etchings were investigated. Additionally, a combinatorial sample with compositional gradients was prepared covering the full Cu/Zn, Cu/Ge and Zn/Ge range of interest, in order to correlate composition with the formation of secondary phases and defects. All the samples were fully characterized using a complete set of techniques (XRF, Raman spectroscopy, XRD, SEM and EDX) and by preparing and measuring solar cell devices. After trying several stack orders, Cu/Ge/Zn/Ge is selected as the most promising one, leading to the formation of less secondary phases. The optimization of the annealing parameters confirms that a two stage process is the best strategy for obtaining high quality absorbers. This includes a stage at relatively low temperature (330 °C) for the synthesis of the CZGSe compound, and a second step at relatively high temperature (480 °C) for its crystallization, revealing that lower annealing temperatures than in the case of the pure Sn compound are required. The compositionally graded sample shows that best efficiencies are obtained for absorbers with Cu/Ge ratio around 0.67 and Zn/Ge around 1.10, suggesting that Cu and Zn-poorer conditions than for pure Sn kesterite are required. Using this compositionally graded sample, we will present a deep analysis of the correlation of the different optical, electrical parameters with composition, including the analysis of secondary phase and possible point defects formation. We will highlight the importance of the Cu/Ge ratio which includes an etching of the absorbers in KCN, a champion cell with an efficiency of 6.5% (Voc = 556 mV, FF = 59.6%, Jsc = 19.6 mA/cm²) is reported. Additional experiments introducing different sources of Ge during the annealing process (GeSe, GeS, and pure Germanium) in order to change the partial pressure inside the graphite box will also be presented.

ES20.03.02
Beyond 13% Efficient CuSbS₂ Films Exhibited Optical Absorption Coefficients Higher than 10^4 cm⁻¹ after Heating. The optical band gap of the as-deposited films was of 1.6 eV, which decreased to 1.46 and 1.24 eV after heating the films at 300 and 500 °C, respectively. All the deposition parameters were kept constant: temperatures, from 300 to 500 °C, to make them crystalline and form the ternary compounds. The results showed that the film thickness depends on the sulfur load, deposition time, and temperatures.

Researchers have developed either transition metals-doped SnS films or the synthesis of novel semiconductor ternary materials based in Sn and S such as Sn-Sb-S (TAS): SnSb₂, SnSb₃₄, and Sn₃Sb₃₄. Conventionally, ternary compounds are synthesized by deposition of individual intercalated layers of SnS and SbS₃, followed by annealing at high temperatures.

In this work, SnS and SbS₃ thin films have been obtained by in-situ chemical bath deposition. The effect of the sulfur load, time deposition and pH bath solution has been studied. Antimony and tin chloride were used as metal ion sources, thioacetamide as sulfur ion source, and tartaric as the complexing agent. Chemical bath deposition was carried out at 80°C varying the concentration of sulfur and time of deposition while the pH of the solution was kept between 8 and 9. Then, the resulting samples were heated in nitrogen at temperatures from 300 to 500 °C to make them crystalline and form the ternary compounds. The results showed that the film thickness depends on the sulfur load, deposition time, pH and the temperature during the heating. The thickness of the as-deposited film without excess of sulfur was of 117 nm for a time deposition of 2 h. An increase on the sulfur load produced thicker films with thickness above of 250 nm. The SEM image of the as-deposited films showed a morphology of elongated grains of 100 nm, which increase their size after heating. The optical band gap of the as-deposited films was of 1.6 eV, which decreased to 1.46 and 1.24 eV after heating the films at 300 and 500 °C, respectively. All the TAS films exhibited optical absorption coefficients higher than 10^4 cm⁻¹. Moreover, the photo-conductivity of the as-deposited films was of 10^7 Ω⁻¹ cm⁻¹ while those heated at 300 and 500 °C showed photo-conductivities of 10^4 to 10^7 Ω⁻¹ cm⁻¹. Finally, the evaluation of these ternary absorbers into the FTO/CdS/TAS/C structure gave a Voc of 462 mV and a Jsc of 2.37 mA/cm² under white-LED light. These preliminary results showed that TAS absorbers could be good candidates to obtain higher Voc values than those obtained with the SnS-based SCs.

Beyond 13% Efficient CuZnSn(S,Se)₂ Solar Cells from DMSO Molecular Precursor Solution Yunchai Gong, Yifan Zhang, Weibo Yan and Hao Xin; Key Laboratory for Organic Electronics and Information Displays & Jiangsu Key Laboratory for Biosensors, Institute of Advanced Materials (IAM), Jiangsu National Synergetic Innovation Center for Advanced Materials (JINAM), Nanjing University of Posts & Telecommunications, Nanjing, China.

Kesterite CuZnSn(S,Se)₂ (CZTSSe) semiconductors, composed of non-toxic and earth-abundant elements, have great potential as low cost and mass production photovoltaic absorber materials. However, the best CZTSSe solar cell, obtained from hydrazine based ink by IBM in 2014, only has an efficiency of 12.6% [1], much lower than similar structured Cu(In,Ga)Se₂ (CIGS) solar cell (22.6% [2]). The development of kesterite CuZnSn(S,Se)₂ thin-film solar cells is currently hindered by the large open-circuit voltage deficit (Voc-oc). The possible reasons for the large Voc-oc include large tail states (electrostatic potential fluctuation and bandgap fluctuation), Cu-Zn antisite order-disorder, formation of deep defects and interface formation, which is dominate still under debating. Here, we have explored different strategies to understand the Voc deficit in DMSO solution processed CZTSSe solar cells. First, we found that the Voc-oc as well as efficiency of DMSO solution processed CZTSSe solar cells is strongly affected by the pressure and temperature of DMSO solution (Sn²⁺:Sn³⁺) in the solution. The power conversion efficiency achieved from Sn²⁺ solution was 13.2% with a Voc-oc of only 0.570 V, much lower than the current world record CZTSSe device (0.617 V), whereas the efficiency obtained from Sn³⁺ solution was only 7% with Voc-oc higher than 0.680 V. Investigation by solution chemistry and film morphology characterization reveals that the huge difference comes from different complexation of the Sn with ligand (thiourea) and solvent (DMSO) which lead to different reaction pathways from solution to solid state film and thus dramatic absorber quality and device performance. Second, we have used Ag or Ge alloying to further investigate the effects on the Voc-oc of Sn²⁺ solution processed CZTSSe solar cells. Characterization of CZTSSe absorber materials including XRD, Raman, SEM, EDX, TEM, and PL and device performance show positive effect of the alloying on Voc-oc issue. Our results shed new light on how to suppress CZTSSe solar cell Voc-oc and improve their efficiency to higher level.

Crystalline antimony-based nitrides have long posed fabrication challenges due to the high nitrogen chemical potential required for formation and the tendency of antimony to react with oxygen and moisture to form amorphous oxynitrides. To date, Zn₂SnN₂ is the only reported crystalline antimony nitride in which Sn functions as a cation with a positive oxidation state. This material warrants further investigation not only due to its unique nature, but also due to its advantageous optoelectronic properties, which may be tunable like those of other ternary nitrides. Theoretical calculations predict this material to have a direct band gap of 5.9 eV, which suggests that Zn₂SnN₂ has promise as a photoactive absorber. [1] Experimental measurements show room-temperature photoluminescence and band edge alignment appropriate for the hydrogen evolution reaction.

In this work we report on the detailed investigation of the optoelectronic properties of thin-film Zn₂SnN₂ and their correlation to the films’ composition. Films were grown through combinatorial co-sputtering and characterized by spatially-resolved measurements. Experimental results show that the wurtzite-derived crystal structure is stable over a large range of composition (Zn/Zn₂Sn₂N₂ = 60-80%) as determined by X-ray fluorescence. 4-point-probe measurements reveal 200-400 KΩm resistance, tunable with composition. UV-visible spectroscopy shows an absorption onset around 1.7 eV. This will be further investigated through photoluminescence and Hall effect measurements. Growth parameter space will be mapped by varying factors such as growth rate, substrate temperature, and the use of a N₂-cracker to enhance the nitrogen chemical potential. A fuller understanding of the relationship between fabrication conditions and film properties will help evaluate the attainability of this new ternary nitride’s predicted utility as a photovoltaic material.

CZTS Solar Cells Absorbers Produced by Sputtering or Pulsed Laser Deposition Jorgen Schou1, Mungunshagai Gansukh2, Filipe Martinho3, Simon Lopez-Martino4, Moises Espindola-Rodriguez2, Alireza Hajijafarassar5, Eugen Stamatie6, Sara Engelberg1, Andrea Crovetto1, Stela Cataneescu2 and Ole Hansen3; 1TU Denmark, Roskilde, Denmark; 2DTU Fotonik, TU Denmark, Roskilde, Denmark; 3DTU Nanotech, TU Denmark, Kgs. Lyngby, Denmark.

Currently CZTS sulfide absorbers for solar cells with the highest efficiency have all been produced by vacuum techniques which thus seem to be superior to solution processing for CZTS cells. Sputtering and pulsed laser deposition are typical vacuum deposition techniques, which are employed for solar cell absorbers of complicated stoichiometry. Both techniques are well-known for stoichiometric transfer of chemical compounds such as metal oxides and nitrides from a target to a substrate. The two techniques are non-thermal since the emitted atoms from the target are quite energetic and may have an energy distribution with a tail up to more than 10 eV. This non-thermal arrival energy is also known to be beneficial for growth of layers with high crystallinity.

In the photovoltaic literature there seems to be a limited number of examples of a comparison between the absorbers and cells produced by either sputtering deposition (SD) or pulsed laser deposition (PLD) except for an inconclusive study without production of solar cells by Sun et al. [1].

We have recently produced solar cells by co-sputtering deposition and PLD with a record efficiency of 6.6 % for SD, while that by PLD reached 5.2 % [2]. While the efficiency was comparable, there were several processing differences, in particular in the thermal annealing steps. It is not clear how different the ideal thermal profiles for the two techniques are.

In the photovoltaic literature there seems to be a limited number of examples of a comparison between the absorbers and cells produced by either sputtering deposition (SD) or pulsed laser deposition (PLD) except for an inconclusive study without production of solar cells by Sun et al. [1].

We will discuss a few other PLD experiments: The CZTS-films can be doped with additional elements, e.g. by Ag using doped targets without any additional complications in the PLD process. Also the production of oxide precursor films is comparatively easy with an oxide target for PLD, while it is not yet clear how successful a detour via metal oxides to
sulfides would be for co-SD.

Detailed results for the comparison between films made by SD and PLD as well as examples PLD-films of other compositions will be shown in this contribution.

ES20.03.06 Engineering Ga Profile in Low Temperature-Processed Cu(In,Ga)Se₂ Thin Film by Using a Thin Ag Precursor Layer Jong-keuk Park

Low-temperature-processed Cu(In,Ga)Se₂ (CIGS) thin film absorber is important for demonstrating a functional CIGS solar cell on plastic substrates. However, control of the band profile mainly dominated by the Ga concentration profile in the CIGS film has been challenging due to slow atomic diffusion at low temperatures. Here, a systematic engineering of Ga profile in CIGS films is reported by employing a thin Ag precursor layer prior to CIGS co-evaporation. By increasing the Ag precursor layer thickness, Ga gradient was mitigated along with improved CIGS grain size, which enhanced overall solar cell performance. Formation of liquid-phase Ag-Se could provide mobile channels for Ga diffusion along the grain boundaries and expedite CIGS recrystallization process at such a low temperature.

ES20.03.07 Enhanced Optical and Electronic Properties of 2D n-MoS₂ by Thin-Layer Al₂O₃ Surface Passivation for Photovoltaic Applications Atteq U. Rehman and Soo H. Lee

Transition Metal Di-Chalcogenides (TMDs) have shown a great promise for being used as a 2D layered semiconductor materials and offers excellent photon absorption and electronic transport properties for photovoltaic applications. Among these TMDs, layered molybdenum disulfide (MoS₂) is one of the most promising candidate for ultrathin-film solar cell fabrication with excellent performance, superior flexibility and lower costs. An n-type bulk like MoS₂ deposited on p-Si, establishes a built in potential at n-MoS₂/p-Si interface that governs the carrier separation for photovoltaic operation. We present an aluminum oxide (Al₂O₃) based surface passivation on multilayered n-MoS₂/p-Si solar with enhanced photoelectric properties. This improved performance is due to the fact that Al₂O₃ helps in reducing the interface trap density at the MoS₂ surface and performs n-type field effect passivation by fixed charges present in Al₂O₃ layer. By adding Al₂O₃ based MoS₂ surface passivation to our device an improved power conversion efficiency (PCE) of 5.6% with enhancement in Jₚ, Voc, and FF was observed. In addition to improvement at MoS₂ surface by passivation and superior Jsc, Al₂O₃ effectively enhanced the built-in potential at n-MoS₂/p-Si junction, that help to promote the e⁻ – h⁺ pairs separation. Our work demonstrates the integration and effectiveness of the surface passivation for the bulk-like MoS₂ films with Si-based electronics to develop highly efficient photovoltaic cells.

ES20.03.08 Solution-Processed Earth-Abundant Cu₄BaSn(S₅Se₅)₂ Solar Absorber Using a Non-Toxic Solvent Beentu Teymur, Yihao Zhou, Edgard Ngaboyamahina, Jeffrey T. Glass, and David B. Mitzi

Optically transparent p-type conductors enable development of transparent electronics, and opportunities to develop high-efficiency bifacial photovoltaic devices. Sulfide materials offer an interesting alternative to oxides for the photovoltaic applications due to better hole transport properties. We report on the structural, optical, and electronic properties of earth-abundant p-type transparent conducting barium copper sulfide (BCS) thin films fabricated using solution-processing. The BCS thin films were characterized using scanning electron microscopy (SEM), X-ray diffraction (XRD), UV–Vis–NIR spectroscopy, and spectroscopic ellipsometry (SE). A BCS film of thickness 100 nm can transmit > 70% of the visible light with band gap ~ 2.4 eV. Based on SEM images, initial BCS films look compact with a grain size of ~15 nm. Our studies show that these films are conductive with a carrier concentration of ~10¹⁷ cm⁻³, making them promising hole transport materials for photovoltaic applications. We will discuss cadmium telluride (CdTe) devices fabricated using BCS layer as an interfacial layer between CdTe and a standard Cu/Au. Additionally, we will extend our study to fabricate bifacial CdTe devices employing the transparent BCS buffer layer and a conducting oxide as the back contact.

ES20.03.09 Chemical, Structural and Photovoltaic Properties of Cd Chalcogenide Thin Films Grown by Chemical Bath Deposition on GaAs(100) Ollir Friedman, Omri Moschovitz and Yuval Golan

Cd chalcogenide films are direct band gap semiconductors that can harvest photon energy in a wide energy range from 2.42 eV (CdS) to 1.74 eV (CdSe) by compositional tuning or chemical gradient. Growth of such films using chemical bath deposition is advantageous due to low production costs and the ability to easily control bath composition and resulting film microstructure. We have recently demonstrated monocrystalline CdS and CdSe deposited on GaAs substrates by chemical bath deposition.1,2 In this work we present the chemical, structural and photovoltaic properties of Cd(S,Se) solid solution thin films.3 We present evidence for the formation of chemically graded films which can be expected since thiourea (S precursor) decomposes faster than sodium selenosulfate (Se precursor) and as a result, S anions are first to react with the substrate surface. The physical and chemical properties of the films were characterized using x-ray powder diffraction, scanning electron microscopy, analytical transmission electron microscopy and energy dispersive spectroscopy mapping. Finally, current-voltage measurements of a GaIn-eutectic/GaAs/Cd(S,Se)/In device were conducted at room temperature under 1 sun. We demonstrate increasing photo-response with S/Se ratio in CdS,Se₁₋ₓ based photovoltaic cells. This work presents a comprehensive and applicable study on chemical bath deposited Cd chalcogenide thin films.

ES20.03.10 Semi-Transparent P-Type Barium Copper Sulfide as an Interface Layer for Cadmium Telluride Solar Cells Kamala Khanal Subedi, Ebin Bastola, Indra Subedi, Nikolai Podrza and Randy J. Ellingson; The University of Toledo, Toledo, Ohio, United States.

Optically transparent p-type conductors enable development of transparent electronics, and opportunities to develop high-efficiency bifacial photovoltaic devices. Sulfide materials offer an interesting alternative to oxides for the photovoltaic applications due to better hole transport properties. We report on the structural, optical, and electronic properties of earth-abundant p-type transparent conducting barium copper sulfide (BCS) thin films fabricated using solution-processing. The BCS thin films were characterized using scanning electron microscopy (SEM), X-ray diffraction (XRD), UV–Vis–NIR spectroscopy, and spectroscopic ellipsometry (SE). A BCS film of thickness 100 nm can transmit > 70% of the visible light with band gap ~ 2.4 eV. Based on SEM images, initial BCS films look compact with a grain size of ~15 nm. Our studies show that these films are conductive with a carrier concentration of ~10¹⁷ cm⁻³, making them promising hole transport materials for photovoltaic applications. We will discuss cadmium telluride (CdTe) devices fabricated using BCS layer as an interfacial layer between CdTe and a standard Cu/Au. Deposition of Cd$_{1-x}$Zn$_x$Se$_{1-y}$Te$_y$ by Closed-Space Co-Sublimation for Wide-Bandgap Top Absorbers in Tandem Photovoltaic Devices
Cayre Reich$, Arthur Onno$,
Joe Carpenter*, Tushar Shimp†, Amit Munshi†, Andrew Ferguson‡, Wyatt Metzer‡, Walajabab Sampath* and Zachary Holman$; Colorado State University, Fort Collins, Colorado, United States; *Arizona State University, Tempe, Arizona, United States; National Renewable Energy Laboratory, Golden, Colorado, United States.

Wide bandgap Cd$_{1-x}$Zn$_x$Te (CZT) is of interest for a top cell in tandem devices because it has a tunable bandgap and is expected to leverage the low cost CdTe fabrication process. However, the vapor pressure of CdCl$_2$ is orders of magnitude higher than that of CdTe; at activation temperatures, which results in Zn loss during processing, thereby reducing the bandgap. In the CZT films, the Zn can be replaced with the Cd of the CdCl$_2$ treatment or simply leave Zn vacancies in the film. Either of these effects are detrimental to device performance and make it challenging to fabricate higher bandgap absorbers based on CdTe. Here, we investigate CZT composition for films activated in an enclosed box with varying CdCl$_2$ and ZnCl$_2$ vapor pressures. We will determine how controlling the vapor pressure of the two Cl sources affects the evolution of the CZT film. These results will allow us to determine if Zn loss can be avoided.

ES20.03.12
Efficiency Improvement of Cu$_2$ZnSnS$_3$, Solar Cell by Optimizing the Interface Chemistry
Kaiwen Sun, Chang Yan, Jialiang Huang and Xiaoqing Hao; University of New South Wales, Kensington, New South Wales, Australia.

High bandgap kesterite Cu$_2$ZnSnS$_3$ (CZTS) has attracted world-wide attention in recent years owing to the earth-abundance and non-toxicity of its constituents and the realization of high and stable performance [1]. The large deployment of photovoltaic (PV) in the future would demand stable, abundant and non-toxic materials similar to Si, in either flexible/rigid single junction thin film solar cells or tandem cells with Si bottom cell. In this regards, CZTS is more advantageous over other single junction cells and their associated top cell for tandem cells. For its industrial-scale deployment, obtaining high efficiency CZTS is the first prerequisite. Until recently, however, state-of-the-art CZTS devices were limited under 10%, being far below the Schockley-Queisser (SQ) limit of about 33% efficiency under terrestrial conditions [2]. Major limitations lie in the large open circuit voltage deficit (Voc-deficit) and a comparably low fill factor (FF). The loss mechanisms for the Voc and FF have been extensively investigated and the hetero-junction interface quality is one of the most proposed factors that contribute to the performance limit. One of the critical elements of forming a desirable interface structure in hetero-junction PV technology is the junction-formation step [3]. At present, the preferred approach in CZTS community is to deposit a thin CdS layer by chemical bath deposition (CBD) method, where a suitable amount of ammonium hydroxide (ammonia) is applied as the complexing agent. The function of the ammonia has been extensively studied in CIGS (1) clean the absorber surface before the deposition, (2) control the cation slow release, (3) suppress the formation of detrimental impurity like Zn(OH)2 at the interface and (4) minimize the metastability behaviour of the device. In our successive ionic layer adsorption and reaction (SILAR) process for alternative ZnCdS buffer deposition, however, no ammonia has been applied. In order to further optimize the interface quality, we explored adding ammonia in the cation solution to realize its similar function in CdS deposition process. In summary, the CZTS/ZnCdS interface quality is optimized by applying ammonia as complexing agent in the precursor solution during the SILAR process for ZnCdS deposition. Excess oxide and hydroxide impurities formed at the interface are limited to a low level, which reduces the related electronic defects in the depletion region and alleviates the metastability behavior caused by the Zn(OH)$_2$. The application of ammonia also enables the control of reaction mechanism, improving the epitaxial growth, thereby reducing the interface recombination. Finally, efficiency of up to 10% is achieved by modifying the interface structure thanks to the chemical method.

ES20.03.13
Understanding and Controlling Zn Loss During CI Activation of Cd$_{1-x}$Zn$_x$Te Films
Adam Phillips, Fadhill K. Alfallahi, Geethika K. Liyanage, Bhujiyan Anwar, Manoj K. Jamarkattel, Jacob Gibbs and Michael Hebben; University of Toledo, Toledo, Ohio, United States.

Wide bandgap Cd$_{1-x}$Zn$_x$Te (CZT) is an attractive absorber material for thin film solar cells fabrication because it has a tunable bandgap and is expected to leverage the low cost CdTe fabrication process. However, the vapor pressure of CdCl$_2$ is orders of magnitude higher than that of CdTe; at activation temperatures, which results in Zn loss during processing, thereby reducing the bandgap. In the CZT films, the Zn can be replaced with the Cd of the CdCl$_2$ treatment or simply leave Zn vacancies in the film. Either of these effects are detrimental to device performance and make it challenging to fabricate higher bandgap absorbers based on CdTe. Hence, we deposited the quaternary alloy Cd$_{1-x}$Zn$_x$Se$_{1-y}$Te$_y$ using a modified close space sublimation (CSS) process from sources containing Cd$_x$Se$_{1-y}$Te$_y$ and Zn. The deposited films were characterized by Transmission and Scanning Electron Microscopy, Energy Dispersive X-Ray Spectroscopy, and X-ray Diffraction in order to assess their material properties and composition as a function of deposition parameters. Optoelectronic properties were assessed with Transmittance, Photoluminescence, and Time-Resolved Photoluminescence measurements. Preliminary device results will be reported.

ES20.03.14
Fabrication and Characterization of Selenized Stacked CISGe Absorber Layers by Evaporation Technique
Ganesh Regmi, J.S. Narro-Rios and S. Velumani; Sección de Electrónica del Estado Sólido (SEES), Departamento de Ingeniería Eléctrica, Centro de Investigación y de Estudios Avanzados del Instituto Politécnico Nacional (CINVESTAV-IPN), Mexico City, Mexico.

Policrystalline CuIn$_{x}$Ga$_{1-x}$S$_3$ (CIGSe) quaternary semiconducting material is a mesmerizing absorber layer to fabricate the high-efficiency thin film photovoltaic device. Among the different evaporation growth processes of CIGSe thin film, the deposition of copper, Indium, Gallium, and selenium stacking layer structure is one of the versatile methods due to its simplicity, good stoichiometry, and resulting throughput efficiency in photovoltaic devices. In the experiment, the metallic elements copper (Cu), indium (In), and gallium (Ga) were deposited in specific orders at room temperature and then the whole structure was selenized at (450-550 °C) with different time of selenization (30-60 min). Selenization effect on structural, morphological, optical, and electrical properties of prepared films was studied. Results showed that the structural, morphological and optical properties of CIGSe thin films strongly depend on the growth mechanism, annealing temperature, time of selenization and chemical composition. X-ray diffraction (XRD) pattern showed the chalcopyrite structure of CIGSe with (112) preferred plane. The surface morphology and chemical composition of selenized thin films were investigated by scanning electron microscope (SEM) equipped with energy-dispersive X-ray spectroscopy (EDS). The grains were transmuted from featureless melted to well faceted bladed tetragonal grains of CIGSe by SEM images. Raman spectroscopy exhibited A$_1$ mode peak along with B$_2$ mode peak. The root mean square (RMS) roughness of the films was studied by atomic force microscopy (AFM) and was ranged between 60 to 90 nm. The depth profile study showed that the distribution of elements depends upon the elemental order in the stacking structure. Optical testing was conducted by UV spectrophotometry and observed the absorption coefficient in the order of 10$^5$ cm$^{-1}$. The carrier concentration was varying from 10$^{10}$ to 10$^{17}$ cm$^{-3}$ by half effect Van der Pauw method. The results showed that 450 °C and 500 °C of selenization temperature was not sufficient for the inter-diffusion of all elements forming a good CIGSe absorber layer. Instead, the film selenized at 550 °C for 60 min showed a better result which could be a good absorber layer for highly efficient CIGSe based thin film solar cells.

ES20.03.15
XPS Analysis of the CuGaSe$_2$ - CuAlSe$_2$ Single Crystals Grown by CVT
dBarys Korzun*, Shanti Raykin†, Tai-De Li² and Jonathan Adam³; The City University of New York, Borough of Manhattan Community College, New York, New York, United States; ²Advanced Science Research Center at the Graduate Center of CUNY, New York, New York, United States.

Copper gallium diselenide (CuGaSe$_2$) and copper aluminum diselenide (CuAlSe$_2$) belong to the I-III-VI$_2$ group of compounds and are extensively studied as absorbing materials in solar cells and as active elements in optical filters. To optimize their properties, it is necessary to control their surface properties. The goal of the present paper is to investigate the effects of etching on the surface of the CuGaSe$_2$ – CuAlSe$_2$ single crystals and compare the results of chemical etching and argon ion beam sputtering.
Single crystals of seven alloys of the (CuGaSe)\textsubscript{x}(CuAlSe)\textsubscript{1-x} system, with \(x = 0.20, 0.40, 0.50, 0.60, 0.70, 0.80, 0.90\), were grown by chemical vapor transport (CVT) in an evacuated quartz tube using iodine as a transporting agent. Typical dimensions of the grown plate-like single crystals were about 10 mm \(\times\) 5 mm \(\times\) 0.5 mm with a well-developed surface (112).

X-ray photoelectron spectroscopy (XPS) measurements were performed with PHI 5000 VersaProbe II XPS system using a monochromatic Al K\(\alpha\) source (15 kV). The pass energy was 117.4 eV for survey scans and 29.35 eV for high-resolution scans. The pressure in the analysis chamber was maintained below \(5 \times 10^{-8}\) Pa for data acquisition. The data was processed using Multipak software, version 9.6.0. The XPS data was internally referenced to the C-C C1s peak (BE for C-C of 284.78 eV). The optical transmission was measured using a Cary 500 spectrophotometer in the wavelength interval from 400 nm to 2800 nm. Studies of the effects of illumination on the surface voltage were taken using surface photovoltage (SPV) technique in the energy range of 0.5 – 5.0 eV.

Thick films on glass substrates were deposited by flash evaporation technique from previously prepared ingots of haycockite CuFeS\(_2\). Morphology of thin films and their chemical composition were investigated using the Hitachi TM3000 Tablopt Microscope equipped by Energy Dispersive Spectrometer (EDS). The magnification was varied from \(\times 50\) to \(\times 10000\). The X-ray studies were carried out using monochromatic Cu K\(\alpha\) radiation (1.5406 \(\AA\), step size 0.01\(^\circ\) or 0.04\(^\circ\), counting time 10 s). The Retrived analysis of the X-ray powder diffraction data was done using the FullProf software. X-ray photoelectron spectroscopy (XPS) measurements were performed with PHI 5000 VersaProbe II XPS system using a monochromatic Al K\(\alpha\) source (15 kV). The pass energy was 117.4 eV for survey scans and 29.35 eV for high-resolution scans. The pressure in the analysis chamber was maintained below \(5 \times 10^{-8}\) Pa for data acquisition. The data was processed using Multipak software, version 9.6.0. The XPS data was internally referenced to the C-C C1s peak (BE for C-C of 284.78 eV). The optical transmission was measured using a Cary 500 spectrophotometer in the wavelength interval from 400 nm to 2800 nm. Studies of the effects of illumination on the surface voltage were taken using surface photovoltage (SPV) technique in the energy range of 0.5 – 5.0 eV.

It was found that thin films have the chemical composition with the atomic content of Cu, Fe, and S of 25.21, 27.77, and 47.02 at. % with the atomic ratios of Cu/Fe and S/(Cu + Fe) equaling to 0.91 for the atomic ratio Cu/Fe and 0.90 for the atomic ratio S/(Cu + Fe) while these theoretical values for haycockite CuFeS\(_2\) are equal to 0.80 and 0.89 respectively. Thin films of chalcopyrite consist of separate grains with the approximately equal areas of about \((1000 – 2000)\) \(\mu\)m\(^2\). It may be proposed that this structure appeared during cooling thin films because it completely covers the surface of thin films. The small inclusion of the second phase with the chemical composition close to talnakhite CuFeS\(_2\) was detected. The most common occurrence of the inclusion of the second phase along the borders of grains was equal to about \((1000 – 2000)\) \(\mu\)m\(^2\) which is the presence of Se\(_{3d}\) peak on the composition of the solid solutions were investigated and explained by the binding behavior of the Se atoms in the (CuGaSe)\textsubscript{x}(CuAlSe)\textsubscript{1-x} system. There was a correlation of the Raman active modes with the change in chemical composition of this system.

The untreated, chemically etched, and Ar\(^{+}\)-sputtered surfaces of single crystals were investigated, and the effects of chemical etching and then Ar\(^{+}\) sputtering on the same surface of a crystal were determined. The spectra of the untreated samples showed a typical oxidized surface, strong O1s and C1s signals. The Se3d spectra revealed an additional component (Se\textsuperscript{2-}\(^{\pm}\)) due to the existence of Se\(_2\)O\(_2\) at the surface of the untreated samples. An additional signal corresponding to I\(_{3d3,2}\) at 619.1 eV was detected, showing the presence of single crystals of CuI on the surface of the untreated samples. Chemical etching for 30 s, the oxygen and carbon contamination at the surface was removed. After the treatments, no detectable lattice damage was observed. The change of parameters of Ar\(^{+}\) sputtering from 4 mm\(^2\), 2 kV, 1 \(\mu\)A to 5 kV, 25 mA, resulted in the appearance of an Al sub-peak corresponding to the neutral state of Al.

The position and shape of the Se3d peak on the composition of the solid solutions were investigated and explained by the binding behavior of the Se atoms in the (CuGaSe)\textsubscript{x}(CuAlSe)\textsubscript{1-x} system. There was a correlation of the Raman active modes with the change in chemical composition of this system.

The recent efficiency advances in solar cells based on Cu\(_2\)ZnSnS\(_4\) (CZTS) have raised hopes for reaching high efficiency and low cost with robust and durable devices. However, in fabrication of monolithic CZTS/Si tandem structures, two major problems must be overcome: 1) a proper interlayer between top and bottom cell has to be developed, since the tunnel junctions typically used in III-V tandem cells are not trivially available, and 2) unlike in their Perovskite/Si tandem counterpart, the processing of the CZTS top component (Se\(_{3d}\)) is equally to 0.91 for the atomic ratio Cu/Fe and 0.90 for the atomic ratio S/(Cu + Fe) while these theoretical values for haycockite CuFeS\(_2\) are equal to 0.80 and 0.89 respectively. Thin films of chalcopyrite consist of separate grains with the approximately equal areas of about \((1000 – 2000)\) \(\mu\)m\(^2\). It may be proposed that this structure appeared during cooling thin films because it completely covers the surface of thin films. The small inclusion of the second phase with the chemical composition close to talnakhite CuFeS\(_2\) was detected. The most common occurrence of the inclusion of the second phase along the borders of grains was equal to about \((1000 – 2000)\) \(\mu\)m\(^2\) which is the presence of Se\(_{3d}\) peak on the composition of the solid solutions were investigated and explained by the binding behavior of the Se atoms in the (CuGaSe)\textsubscript{x}(CuAlSe)\textsubscript{1-x} system. There was a correlation of the Raman active modes with the change in chemical composition of this system.

Monolithic Tandem Solar Cell Potential of CZTS on TOPCon Si
Filipe Martinho, Alireza Hajijafarassar, Simon Lopez-Marino, Moises Espinola-Rodriguez, Stela Canuelsen, Eugen Stamate, Mungunshagai Gansukh, Sara Engberg, Ole Hansen, Andrea Crovetto and Jorgen Schou; Technical University of Denmark, Roskilde, Denmark.

The recent efficiency advances in solar cells based on Cu\(_2\)ZnSnS\(_4\) (CZTS) and related high bandgap alloys make them promising compounds for application in tandem cells, in particular when monolithically integrated with a Si-based bottom cell, with the prospect of an all earth abundant, stable, efficient and industrially feasible tandem solar cell. However, in fabrication of monolithic CZTS/Si tandem structures, two major problems must be overcome: 1) a proper interlayer between top and bottom cell has to be developed, since the tunnel junctions typically used in III-V tandem cells are not trivially available, and 2) unlike in their Perovskite/Si tandem counterpart, the processing of the CZTS top cell involves at least one high temperature step (>500 C) which must not damage the bottom Si cell structures nor contaminate them with elements such as Cu or S diffusing from CZTS.

In this contribution, we approach these problems by using a thermally resilient n-type Si Tunnel Oxide Passivated Contact (TOPCon) bottom structure with a thin (<25 nm) TiN layer at the interface between the top and bottom cells, serving both as diffusion barrier and recombination layer. Using Microwave Detected Photoconductance Decay (\(\mu\)-PCD) and Secondary Ion Mass Spectrometry (SIMS), we that a regime for CZTS production exists where contamination of the bottom Si cell is kept at low levels, with post-process carrier lifetimes exceeding 1.5 ms, corresponding to an implied Voc (iVoc) of above 700mV. Based on these findings, we develop and characterize a series of monolithic CZTS/Si tandem devices with different interface configurations and barrier layer thicknesses. We discuss the optical impact of the different tandem interfaces used on the overall tandem performance. Moreover, we compare the photovoltaic properties of the CZTS films used as the top cells with our single junction CZTS baseline, based on co-sputtering. Although a natural trade-off exists which narrows down the processing regimes necessary to simultaneously achieve efficient top and bottom cells, our results do not reveal any priori fundamental limitations to achieving efficient monolithically integrated CZTS/Si tandem solar cells.

Development of CIS and Perovskite Solar Cells for all Thin-Film Tandem Applications
Thomas Feurer\(^1\), Stefano Pisoni\(^2\), Thierry Moser\(^1\), Yan Jiang\(^1\), Fan Fu\(^2\), Romain Caron\(^1\), Shiro Nishiwaki\(^1\), Stephan Buecheler\(^2\) and Ayodyha N. Tiwari\(^3\); Empa-Swiss Federal Laboratories for Materials Science and Technology, Dubendorf, Switzerland; \(^2\)Photovoltaics and Thin Film Electronics Laboratory (PV-LAB), EPFL, Neuchatel, Switzerland.
For all thin film tandem configuration, perovskite and Cu(In,Ga)Se₂ (CIGS) solar cells represent ideal candidates for top and bottom devices due to their suitable energy band gaps. In this contribution we will show how CuInSe₂ (CIS) based absorbers can be pushed from 15% to beyond 19% without changing the optical bandgap of 1.0 eV. To do so we suppress back contact recombination by adding a graded composition to the back interface, increase carrier lifetime by additional post deposition treatment and increase absorber quality by shifting to a more stoichiometric composition between Cu and group III elements. Combined with semitransparent perovskite top cells we demonstrate efficiencies above 24% in four-terminal tandem configuration on rigid substrate. Further, the possibility to develop highly efficient perovskite and CIGS solar cells on flexible substrates lays the foundations to lightweight flexible tandem devices by high-throughput roll-to-roll manufacturing. We present a multistage vacuum-solution deposition method for perovskite absorber to tailor PbI₂ growth morphology. With this approach, we demonstrate a steady-state efficiency of 14.0% for NIR-transparent perovskite solar cells (average transmittance of ~74% between 800 and 1000nm), on a flexible front sheet which is used for flexible CIGS module encapsulation. Flexible perovskite/CIGS tandem with 19.6% efficiency is obtained in four-terminal configuration. Our work represents a step forward towards highly efficient low band gap CIS solar cells and provides insights into growth of layers and interfaces for high efficiency flexible perovskite solar cells. Furthermore, latest results on both four-terminal as well as monolithic two-terminal thin film tandem devices will be discussed.

Zn₁₋ₓMgₓO Contact Layer Integration with Wide Band Gap CuGaSe₂ Absorbers
Imran S. Khan¹, Christopher Muzzillo², Craig Perkins³, Nicolas Gaillard⁴ and Andriy Zakutayev⁵; ¹National Renewable Energy Laboratory, Lakewood, Colorado, United States; ²University of Hawaii, Honolulu, Hawaii, United States.

CuGaSe₂ thin film is polycrystalline thin band gap material related to chalcopyrites. It is a promising absorber candidate for top cell application in both for tandem photovoltaic (PV) solar cells and photoelectrochemical (PEC) water splitting devices. Zn₁₋ₓMgₓO is an attractive n-type contact layer for CuGaSe₂ and other PV absorber technologies due to its tunable conduction band offset as a function of Mg concentration. In this study, Zn₁₋ₓMgₓO is being investigated as the buffer/contact layer for CuGaSe₂ based PV and PEC devices.

CuGaSe₂ thin films with Cu/Ga = 0.36 composition are deposited by single-stage co-evaporation, and Zn₁₋ₓMgₓO films are deposited using combinatorial RF sputtering. The electrical, optical and structural properties of the Zn₁₋ₓMgₓO films as function of Mg compositions are characterized. A baseline device is fabricated in a similar fashion to CIGS devices, with CdS window layer and i-ZnO buffer layer. Zn₁₋ₓMgₓO is studied as replacement for both CdS and i-ZnO, and is grown as as-deposited, water-treated, and Cd²⁺ solution treated CuGaSe₂ absorber thin films. X-ray photoelectron spectroscopy (XPS) is performed on the treated films to study the surface defect chemistry.

The resulting CuGaSe₂/Zn₁₋ₓMgₓO device JV and EQE performance is observed to be dependent on the temperature and the duration of the treatments. Replacing CdS/i-ZnO with Zn₁₋ₓMgₓO improves the carrier collection in the short wavelengths due to the higher bandgap of Zn₁₋ₓMgₓO. The measured device performances are directly related to the Zn/Mg ratio in the contact layer, and supports the significance of conduction band optimization. Open circuit voltage up to 920 mV is measured, which is important for PEC water splitting and tandem PV application.

Studies on MoS₂ Thin-Film Matrix by Meaning of Atom Probe Tomography
Manuel A. Ramos¹, ², John Nogán², Jose L. Enríquez-Carrejó², Claudia A. Rodríguez-González³, Roberto C. Ambrosio-Lazaro¹, Torben Böhl¹, Delphine Chassaing¹, Martin Heinmaier² and Sandra Kauffmann-Weiss³; ¹Universidad Autonoma de Cd. Juarez, Cd. Juarez, Mexico; ²Integration, Center for Integration of Nanotechnologies, Albuquerque, New Mexico, United States; ³Ciencias Básicas, Facultad de Ciencias de la Electrónica, Puebla, Mexico; ⁴Institute for Technical Physics, Karlsruhe Institute of Technology-Institute for Applied Materials, Karlsruhe, Germany.

A characterization study using atom probe tomography to understand crystal growth and other micro-structural aspects on molybdenum di-sulfide (MoS₂) thin films is presented in this paper. The film was deposited on silicon dioxide (SiO₂) coupons using radio frequency at 275W at high vacuum~10⁻⁹ from commercial MoS₂ 99.9% purity target. From scanning electron microscopy, it was possible to observe vertically crystal growth with high-porosity and three-dimensional reconstruction from spatial distribution from atom probe tomography indicates low impurities and no grain boundaries within molybdenum disulfide crystallites on film matrix. As complementary, electrical transport -3V to 3V at room temperature and X-ray pole figures were also measured on the films to understand crystal grain orientation.

Progress and Challenges in Absorber and Interface Fabrication of Polycrystalline CdTe Photovoltaics
Amit H. Munshi¹, Jason M. Kephart², Ali Abbas³, Thomas Fiducia², Adam Danielson¹, Carey Reich¹, Tushar Shimpi¹, John M. Walls⁴ and Walajabad Sampath¹; ¹Mechanical Engineering, Colorado State University, Fort Collins, Colorado, United States; ²CREST, Loughborough University, Loughborough, United Kingdom.

Polycrystalline thin-film CdTe device efficiency of over 19% has been demonstrated at Colorado State University using a repeatable and scalable sublimation process. Record efficiency for research scale CdTe photovoltaics has been reported to be over 22% and highest reported module efficiency is over 18% by First Solar Inc. Use of Se alloying with CdTe to form a lower band-gap CdSe₄Te₅, (CST) alloy has led to higher devices efficiencies with better current collection. Recent materials characterization has revealed that Se may be responsible for more than just reduction of band-gap. With CdCl₂ treatment Cl₁ is known to very effectively passivate defects at CdTe grain boundaries. Recent materials and electrical characterization have shown that Se has a very similar behavior to Cl₁ at the grain boundaries of polycrystalline CdTe. These include Se decorating the grain boundaries like Cl₁ in the while cross-section cathodoluminescence maps show substantially higher signal intensity in regions with Se. Double heterostructures fabricated using CdS/CdTe with Al₂O₃ as a passivating oxide have been measured to have several hundred nanosecond bulk recombination lifetime. These films were also measured to have surface recombination velocity of under 100 cm/s. These results among others emphasize that Se also helps in passivation of grain boundaries. High absorber quality may help in mitigating voltage deficit that has traditionally been the largest limiting factor in CdTe photovoltaics in achieving efficiency closer to Shockley-Queisser limit. In addition to graded absorber devices and double heterostructures, replacing the traditional Cu doping with more advanced group V doping is an important research effort that maybe critical for future improvements in device efficiency. Nitrogen, Phosphorous, Arsenic and Antimony doping has been investigated by several research groups. Advanced co-sublimation hardware developed at Colorado State University a unique capability of depositing films for group V doping under over pressure of Cd. Such deposition under Cd overpressure causes formation of V₂, that is known to be favorable for incorporation of group V dopant and activation. Utilizing the high absorber and interface quality material and higher doping, efforts are in progress to fabricate polycrystalline devices with open-circuit voltage over 1 and device efficiency over 20%.

11:00 AM ES20.05.02
Introduction of K From the Back Electrode in an All-PVD Ag-CIGS Manufacturing Process
Dmytro Poplavskyy, Roun Farshevi, Neil Mackie, Ben Hickey and David Spaulding; MiaSolé Hi-Tech, Santa Clara, California, United States.

We report on simultaneous incorporation of sodium and potassium in the absorber layer of all-sputtered Ag-CIGS solar cells fabricated in a MiaSolé roll-coater multi-chamber manufacturing tool. The MiaSolé process begins with a stainless-steel substrate, which is unwound into the roll-coater where the following layers are consecutively deposited by sputtering: diffusion barrier layer, alkali-doped Mo back electrode, absorber layer, CdS buffer layer, and TCO window layer. Addition of potassium to the absorber has been reported to lead to higher cell efficiency, and in the majority of cases potassium is introduced via a post-deposition treatment (typically as KF, after CIGS deposition). In the MiaSolé process, both sodium and potassium are introduced from the molybdenum back electrode, which is sputter-deposited from Mo rotary targets, doped with sodium and potassium molybdates, respectively. Changing the sputter deposition power and varying the depth of the doped layer inside the Mo electrode allows us to vary the amount of alkali
metals delivered to the absorber. Addition of the K-doped back electrode to the Na-doped Ag-CIGS baseline process leads to a higher solar cell efficiency (up to 0.5%abs), mostly driven by higher FF and Voc as a result of reduced interfacial recombination and reduced voltage dependent collection losses. Auger electron spectroscopy (AES) and secondary-ion-mass spectroscopy (SIMS) results indicate that potassium primarily accumulates near the main junction and leads to reduced Cu/(Ga+In) in that region, similarly to observations reported in the literature. However, in contrast to numerous reports, we do not observe any evidence for the formation of secondary phases, such as e.g. K-In-Se, according to x-ray photoelectron spectroscopy (XPS) measurements.

In the Misaéinline sputtering process, the last stage of the absorber growth converts the absorber film to a Cu-poor composition via sputtering from targets with reduced Cu content. We demonstrate that lower surface Cu content is required for high efficiency in the presence of potassium. Furthermore, the degree of potassium accumulation at the junction appears to increase linearly with decreasing Cu/(Ga+In) ratio in that region and correlates with increased cell efficiency.

Flexible modules made from the optimized baseline (Na-only) and K-doped (Na+K) cells yield comparable light-soaking (24 hours under 1 sun) and accelerated damp-heat (85°C/85%RH at 1000hrs) performance suggesting no adverse impact of introduction of K on module reliability.

11:15 AM ES20.05.03
P-Type Hydrogenated Amorphous Silicon—A Hole-Selective Contact to Cadmium Telluride Based Solar Cells
William Weigand1, Carey Reich2, Amit H. Munshi3, Arthur Onno4, Adam Danielson5, Walajabad Sampath6 and Zachary Holman7; 1Arizona State University, Tempe, Arizona, United States; 2Colorado State University, Fort Collins, Colorado, United States.

In recent years, the quality of cadmium telluride based solar cells has increased with efficiencies exceeding 22%. This high efficiency can be attributed to the improved bulk quality of the CdTe bulk. As with silicon-based solar cells, an improved bulk quality warrants the development of a passivating and carrier-selective contact structure that is capable of extracting holes and repelling electrons or vice-versa. Such a structure has already been well-developed for silicon based solar cells through the implementation of an amorphous silicon (a-Si:H) based contact structure and is the basis of the highest efficiency silicon solar cell to date. In the CdTe world, a similar contact based on p-type a-Si:H on monocrystalline CdTe produced a open-circuit voltage of greater than 1 V indicating the potential of a-Si:Hp) to act as a hole-selective contact. Ultimately, the fill factor of this high Voc device was fairly low at 65.5%—one of the major requirements for a passivating and carrier-selective contact—indicating that the contact stack may not be majority-carrier conductive. Furthermore, the Voc of this device was fairly low at 65.5%.—one of the major requirements for a passivating and carrier-selective contact—indicating that the contact stack may not be majority-carrier conductive. Finally, the fill factor of this device was relatively low with a value of 65.0% indicating that the a-Si:Hp contact stack is not currently majority-carrier conductive. By manipulating the interface and bulk properties of our a-Si:H(p) based stack we show that a-Si:H(p) can indeed act as a carrier-selective contact to solar cells based on CdTe and its alloys.

11:30 AM ES20.05.04
Determining the Properties of Cd1-xInx2-4δS4+a Thin Films—A Key to Better Understand CIGSe/CdS Heterojunction?
Nicolas Barreau1, Thomas Lepetit2, Pawel Zabierowski3, Ludovic Arzel4, Camille Latouche5, Sylvie Harel5 and Stéphane Jobic1; 1Institut des Matériaux Jean Rouxel (IMN), Nantes, France; 2Warsaw University of Technology, Warsaw, Poland.

The optoelectronic properties of CdInS4 spinel single crystal have been widely investigated until the end of the 1980s. Interestingly, these studies report the presence of defect levels which usually lie in the band gap strongly depends on cationic In-Cd exchanges in the tetrahedral sites. Since a compound derived from this phase is suspected to be formed at the interface between KF-treated Cu(In,Ga)Se2 and (CB/CD)S, re-investigating this material as thin film makes sense and is the purpose of the present contribution. Thin films of Cd1-xInx2-4δS4+a, with x going from 0 to 1, were grown through the co-evaporation of indium, sulfur and CdS. The fluxes of indium and CdS were adjusted so that films of the following compositions could be achieved: x=0 (CdS), x=0.6 or x=1 (InS). Those 325±5 nm-thick layers were deposited on glass substrates heated at 400°C. The structural properties of these thin films were investigated by X-ray diffraction; they all crystallize in the spinel structure, but the cationic disorder could hardly be determined. All of these films were also characterized optically; they showed an absorption coefficient with incident energy is strongly dependent on x. Their electrical characteristics were investigated through Hall-effect measurements, temperature dependence of conductivity, and photoconductivity. In addition, the formation energies of point defects were theoretically evaluated by DFT. These studies all converge toward the conclusion that the optoelectronic properties of Cd1-xInx2-4δS4 strongly depend on x (which is likely to imply cationic disorder), but most probably also on another parameter difficult to control, that is sulfur deficiency. To explore this latter parameter, all kinds of films (x=0, 0.6 or 1) were annealed for 72h at 300°C in an evacuated sealed tube with or without additional sulfur pellets. Thereby, the parameter δ (denoting the amount of sulfur vacancies) could be qualitatively investigated. The films obtained, Cd1-xInx2-4δS4, were also structurally, optically and electrically characterized. The conclusion of these investigations is that there exists a complex correlation between Cd/(In ratio and the amount of S vacancies, strongly influencing defects level distribution within the band gap of this spinel.

The structural and optoelectronic characterizations of these thin films lead us to conclude that the electronic nature and distribution of the defect levels is dependent on both x and δ. This may explain the electronic properties of these materials diversely wavelength dependent. Such a conclusion is likely to provide new bricks to the understanding of CIGSe/CdS hetero-junction photovoltaics.

11:45 AM ES20.05.05
ALD-ZnTiO as Window Layer in Cu(In,Ga)Se2 Solar Cells
Johannes Loeckinger1, Shiro Nishiwaki2, Christian Andres3, Stephan Buecheler4, Yaroslav E. Romanyuk5 and Ayodhya N. Tiwari; Empa–Swiss Federal Laboratories for Materials Science and Technology, Duebendorf, Switzerland.

The most commonly applied buffer layer in photovoltaic devices employing Cu(In,Ga)Se2 is CdS. The parasitic optical absorption of CdS (Eg = 2.4 eV) results in a reduced photocurrent density. A simple reduction of the CdS layer thickness, however, leads to a reduced device performance due to a loss in open-circuit voltage (Voc) attributed mainly to insufficient coverage on the rough surfaces and possible sputter damage of the CISG absorber surface during the deposition of the window layer. In this contribution an alternative window layer is presented replacing the sputtered Zno. Highly resistive and transparent ZnTiO is deposited by atomic layer deposition (ALD) onto the substrate/Mo/CIGS/CdS stack. The finished devices are then characterized by current-voltage and external quantum efficiency (EQE) measurements. ALD is chosen for this purpose since for thin and resistive oxide layers a conformal coverage of the rough surface and a precise thickness control are paramount. Further, ALD allows for a compositional grading of ZnTiO at a nanometer scale. It is found that with ALD-ZnTiO instead of sputtered Zno the CdS thickness can be reduced without adversely affecting the Voc (~0.7 V) and therefore a gain in current density (~0.8 mA cm−2) from a reduced parasitic absorption of both CdS and Zno is achieved. Temperature dependent I-V measurements and its correlation with the FF support the benefit of a compositional grading of ZnTiO.

Different Alkali-Fluoride Post-Deposition Treatments of Cu(In,Ga)Se2 Investigated by Kelvin Probe Force Microscopy
Nicoletta Nicolara, Rody Manaligod, Philip Jackson, Dimitrios Hariskos, Giovanna Sozzi, Roberto Menozzi, Wolfiam Witte and Sascha Sadawasser; 1International Iberian Nanotechnology Laboratory, Braga, Portugal; 2SW, Stuttgart, Germany; 3University of Parma, Parma, Italy.

A series of efficiency improvements of Cu(In,Ga)Se2 (CIGSe) thin-film solar cells have been achieved over the last 7 years by the development of alkali-fluoride post-deposition treatments (PDT) [1]. These processes modify the optoelectronic properties of CIGSe providing an improved surface for subsequent buffer growth by chemical bath deposition (CBD) [2,3] and favoring a reduction of the buffer thickness, as compared with non-PDT interfaces [4]. We present a Kelvin probe force microscopy (KPFM) study of the influence of different alkali-fluoride PDTS on the CIGSe absorber surface properties and the interface formation
to the CBD buffer layers. The surface potential variation at more than 200 grain boundaries was measured, allowing for a meaningful statistical analysis. A strong difference for different alkali elements (K, Rb, and Cs) is found, which shows a clear correlation to the open-circuit voltage of reference solar cell devices. For the KD-PDT samples strong variations in the potential at the grain boundaries are observed, exhibiting large hole and electron barriers, whereas for RbF and CsF we only observe small electron barriers and neutral grain boundaries, suggesting an effective passivation effect.

For the interfacial formation between co-evaporated CIS layers subjected to a RbF-PDT with the solution-grown buffer layers CdS and Zn(O,S) we studied the evolution of the work function with increasing buffer layer thickness. Information about effective charge carrier separation at the forming interface was obtained from positive surface photovoltage (SPV) measurements. Surprisingly, for the Zn(O,S) buffer layer a negative SPV was found, which could be explained with the help of simulations by the presence of acceptor-type defects at the surface of Zn(O,S).

Our KPFM results provide valuable insights for the further improvements of CIS solar cell efficiencies.

4:00 PM ES20.06.02
Role of Alkali Metals at Grain Boundaries of Cu(In,Ga)Se2 Thin Films

Daniel Abou-Ras1, Aleksandra Nikolaeva1, Sebastian Caiicedo Davila1, Marcin Morawski2 and Roland Scheer; 1Helmholtz-Zentrum Berlin, Berlin, Germany; 2Institute of Physics, Photovoltaics Group, Martin-Luther-Universit ät Halle-Wittenberg, Halle, Germany.

Currently, the Cu(In,Ga)Se2 (CIGSe) solar-cell devices exhibiting highest conversion efficiencies of close to 23% have been fabricated using polycrystalline absorber layers which contained alkali metals already during or after which alkali metals were introduced via a postdeposition treatment (see, e.g., Ref. 1). The beneficial effects of alkali metals on the materials and device properties of CIGSe solar cells are diverse, and it is convenient to divide them into those affecting the bulk properties (such as the net doping density of the CIGSe layer), as well as into those acting at the interfaces to the films (such as the net doping density of the CdS layer). Surprisingly, for the Zn(O,S) buffer layer a negative SPV was found, which could be explained with the help of simulations by the presence of acceptor-type defects at the surface of Zn(O,S).

Our KPFM results provide valuable insights for the further improvements of CIGSe solar cell efficiencies.

4:15 PM ES20.06.03
Ultra-High Vacuum Scanning Tunneling Spectroscopy on CuInSe2 Thin-Film Solar Cell Absorber Layers

Karien Kameni Boumengo1, Thiibaut Gallet1, Evandro Lanzoni2, Finn Babbe1, Michele Melchiorre1, Conrad Spindler1, Jérôme Guillot2, Susanne Siebentritt1 and Alex Redinger1, 1University of Luxembourg, Luxembourg, Luxembourg; 2Luxembourg Institute of Science and Technology, Belvaux, Luxembourg.

Polycrystalline Cu(In,Ga)Se2 (CIGS) appears nowadays as one of the most promising candidates for the fabrication of high efficiency thin film solar cells. However, the current record efficiency (22.9% [1]) is still lower than the one of the single crystalline GaAs thin film solar cells (28% [1]). The discussion about whether this lower performance is attributed to the nature of the surface or grain boundaries (GBs) electronic properties is still ongoing [2].

In this work, we investigated the surface and grain boundary properties of CuInSe2 (CIS) with scanning tunneling microscopy (STM) and spectroscopy carried out under ultra-high vacuum conditions. This technique enabled us to measure the local density of states (LDOS) with nanometer precision. In particular, we studied the effect of potassium cyanide (KCN) etching, the influence of heating in vacuum and pre-electrolyte treatment with CdS and NH4OH. We found that in both cases, the surface is Cu-depleted (in agreement with most reports in literature) and most of the Cd was confined to the first few nanometers. We measured signatures of a defective surface with a high density of surface states, which can be improved, to a certain extend via an UHV annealing to 280°C [4]. However, in CIGS solar cells the heterojunction is usually made with CdS and consequently we studied the absorbers after a Cd-pre-electrolyte treatment. This enabled us to expose the surface to a high amount of Cd2+ ions without actually growing a CdS layer, which would render an investigation of the CIS surface with STM impossible.

Interestingly, the surface electronic properties are changing substantially after the Cd2+ treatment, and we observed (a) less inhomogeneities and (b) a reduction of the surface defect density, which manifested itself by a shift in the Fermi-level at the surface. Compared to the KCIS samples we do not observe distinct features at the grain boundaries anymore.

XP measurements gave important insights into the changes of the surface composition after the various treatments. We observed an Indium depletion on the Cd2+ CIS compared to the KCIS samples, which suggests that the Cd ions are substituting Indium at the surface. We compared the surface compositions to the compositions after mild sputtering with Argon ions. We found that in both cases, the surface is Cu-depleted (in agreement with most reports in literature) and most of the Cd was confined to the first few nanometers.

The PL measurements on both types of samples (KCS vs Cd2+ CIS) showed no considerable change on the bulk electronic properties. A detailed analysis of these observations will be presented and discussed.

Reference
reported that the interdiffusion of Cu and In/Ga between CIGS and Cu-Se layers is essential for the grain growth of CIGS during this Cu-poor to Cu-rich transition\textsuperscript{1-5}. However, little has been known about how the atomic structures evolve during this process.

In the present study, we use the CuInSe\textsubscript{2} (CIS) system, as it is simpler than CIGS for an initial study. Cu-Se was deposited on top of CIS, and the grain growth was directly monitored during in-situ heating in a scanning electron transmission microscope (STEM). The compositional changes were revealed simultaneously with electron energy-loss spectroscopy (EELS). The corresponding time-series STEM images and elemental maps will be presented in the conference. The results show that planar defects play an important role in grain growth. The grains with high-density planar defects tend to be consumed by the grains without planar defects, and this does not occur when there is no extra Cu-Se layer deposited on CIS. Simultaneously acquired STEM images and EELS spectrum images reveal that Cu-rich grain boundaries (GBs) between highly defected and non-defected CIS grains migrate towards the highly defected CIS grains during heating. Further EELS elemental mapping reveals Cu enrichment and In depletions at most GBs within regions having widths of more than 10 nm. Atomically resolved STEM images show a gradual phase change from a chalcopyrite CIS structure at CIS grain interiors towards an antiferroelectric Cu\textsubscript{2}Se structure at GBs, which is also evidenced by atomic-resolution EELS. In this gradual phase change, the Se sublattice stays the same, while In and Cu interdiffuse gradually without any dislocations between the Cu\textsubscript{2}Se and CIS phases. Moreover, In atoms are found at interstitial sites in Cu\textsubscript{2}Se near GBs. Density functional theory (DFT) calculations show that the diffusion barrier of In atoms from interstitial to interstitial sites in Cu\textsubscript{2}Se is very low. These results not only show that Cu diffusion at GBs assists the recrystallization of CIS, but also reveal the mechanism beneath it, which will be discussed at the conference.

conversion efficiency of 4% has been achieved for an alkali-free absorber, which is on the order of the non-doped record cell by Tiwari et al., [1]. The $V_{OC}$ was 580 mV, which lags behind the record pure-sulfide CZTS device of 683 mV, [2], and suggests that there is room for improvement.

In this work, we screen the effect of incorporating various types of new cations into the kesterite, including Ag and Ba by direct addition into the precursor ink. A comparison will be given in terms of the structure, morphology, and opto-electronic properties.

ES20.07.03
Fabrication of Band-Gap Graded CZTSSe Thin-Film Solar Cells Teoman Taskesen, Devendra Pareek, David Nowak, Timo Pfeiffelmann and Levent Güttay; University of Oldenburg, Oldenburg, Germany.

The tunability of the band-gap in kesterite absorbers by choosing different S/Se ratios offers the possibility to create a band-gap gradient throughout a single absorber layer of Cu2ZnSn(S,Se)4. This type of band-gap gradient is deeply investigated for CIGS technologies where it is commonly used for a significant enhancement of the device performance, by allowing for combination of optimized optical properties and reduction of charge carrier recombination. In this work, we present a novel method for introducing a band-gap grading via sulfuration of pure selenide Cu2ZnSnSe4 thin films by using hydrogen sulfide (H2S). The impact of various process parameters of H2S assisted sulfuration such as pressure, temperature, and duration on the properties of the resulting Cu2ZnSn(S,Se)4 absorbers are discussed. In particular, the elemental S/Se gradient throughout the sample after the process, the total content of sulphur as well as its impact on absorber band-gap and quality are investigated. Raman depth profiling confirms the formation of a grading with a relatively high sulphur concentration at the front surface which decreases towards the back side of the absorber, resulting in a front graded Cu2ZnSn(S,Se)4 absorbers. The results indicate that selenium depletion from the existing material and S-Se exchange are taking place simultaneously during the process, affecting also material properties other than the grading profile. Inaccurate selection of process parameters outside a stable range can lead to decomposition of the Cu2ZnSnSe4 layer and the formation of ZnS secondary phase at the absorber surface. Finally, the effects and advantages of the presented H2S assisted process are further discussed, including the strong kinetic nature of this process which appears to allow for a fast incorporation of a sulphur gradient.

Results on solar cell devices will be presented.

ES20.07.04
Over 13% Efficient CZTSSe and CIGS Solar Cells Processed from Non-Hydrazine Solutions Yuancai Gong, Jingjing Jiang, Shaotang Yu, Yifan Zhang, Sanping Wu, Weibo Yan and Hao Xing; Key Laboratory for Organic Electronics and Information Displays, Jiangsu National Synergetic Innovation Center for Advanced Materials (SICAM), College of Materials Science and Engineering, Nanjing University of Posts & Telecommunications, Nanjing, China.

For thin film solar cells to compete with the current market dominate silicon ones, reducing production cost is the key. Large area solution processing (to replace vacuum based deposition) to reduce fabrication cost and using earth abundant elements to lower materials cost are both effective ways to achieve this goal. Here, we report over 13% efficient copper indium gallium selenide (CIGSs) and copper indium selenide (CZTSs) solar cells respectively fabricated from DMF and DMSO molecular precursor inks. We have first used DMF as single solvent to prepare precursor solution and fabricated 10.3% efficient copper indium selenide (CISs) solar cells without any etching. We have now systematically investigated the effect of the Cu/In ratio in the precursor solution on the CISs device performance. We found that solar cell performance increases from Cu-poor (0.85) to slightly Cu-rich and then decreases for further Cu-rich condition with a peak conversion efficiency (PCE) of 12.20% achieved from the Cu/In ratio of 1.05. Further, by gallium alloying, CISs solar cell with a PCE of 13.6% has been fabricated under similar Cu-rich (Cu/In(Ga)=1.05, Ga/(In+Ga)=0.2) condition. Our results for the first time demonstrate highly efficient CIS/CIGS solar cells can be achieved from absorbers grown under Cu-rich condition. Characterization of the absorber materials and solar cell devices are investigated to understand the mechanism behind the phenomenon observed. The main issue for CZTS solar cell further development is the large open-circuit voltage deficit ($V_{oc-def}$) which could be due to large tail states, Cu-Zn antisite order-disorder, formation of deep defects and interface recombination. DMSO precursor solution has been demonstrated to be a promising approach for fabricating high performance CZTSs solar cells. Here, we have explored different approaches to understand the $V_{oc-def}$ of DMSO based CZTSSe solar cells. First, we found device $V_{oc}$ (as well as efficiency) is strongly affected by the precursor tin oxidation state (Sn4+/Sn2+) in the precursor solution. A PCE of 13.2% has been achieved from Sn4+ solution with a $V_{oc-def}$ of only 0.570 V, much lower than the current world record CZTSSe device (0.617 V), whereas the efficiency obtained from Sn2+ solution was only 7% with $V_{oc-def}$ higher than 0.600 V. The reason for the huge difference has been investigation by solution chemistry, film morphology, material property and device characterizations. Second, we have found that Ag or Ge alloying have positive effect on the $V_{oc-def}$ of DMSO solution processed CZTSSe solar cells. Our results shed new lights on suppressing the $V_{oc-def}$ and improving the efficiency of CZTSs solar cells.

Impact on Selenium Control at Growth and Annealing for Cu2ZnSnSe4 Solar Cells Hitoshi Tampo, Shinho Kim, Hajime Shibata and Shigeru Niki, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

Kesterite Cu2ZnSnSe4 (CZTSe) based materials belong to I-IV-VI4 quaternary compound semiconductor and the composition control is relatively complicated. However, the composition control is very important to obtain high efficiency solar cells. Actually, a specific composition of Cu-poor and Zn-rich composition have been used for high efficiency solar cells, while the off-stoichiometric composition results in formation of many defects. In order to overcome the problem, the several methods are introduced to relieve the off-stoichiometric effect. As mentioned above, the composition control is important however, they are mainly on cation elements, and selenium control has not been so seriously considered compared to these composition controls. One of the reasons is that the selenium control has a small effect on the composition, however selenium related defects are considered to play an important role on electrical properties. In this study, we investigate the impact on the selenium control at growth and annealing, and demonstrate high efficiency of CZTSe solar cells through the selenium control.

To obtain high quality CZTSe thin films, many researchers use two step growth method; first one is precursor deposition or low temperature compound growth, and second one is annealing. In this study, CZTSe thin films were grown by a coevaporation method at 340°C using molecular beam epitaxy equipment, and the selenium supply was controlled with the annealing condition. The annealing temperature was also conducted controlling selenium heating temperature by a quartz tube furnace with three heating zones. Although closed type annealing, at which sample is sealed in a box, is widely used, however, we used an “open type” annealing system, which has higher flexibility to control the annealing conditions, environmental species and its amount with independence from the treatment temperature, treatment pressure, carrier gas flow, and so on.

We investigated the effects of selenium supply both at the growth and annealing, and found that the efficiency gradually decreased for the higher selenium supply at the growth, on the contrary, the efficiency drastically decreased for the lower selenium supply. It was also found that the dependence of selenium supply at the annealing treatment was not so strong compared to that at the growth. The optimal efficiency was obtained with controlling annealing selenium and fixed growth selenium, and conversion efficiency (9.4% -> 10.2% -> 11.6%) improved mainly with Voc (0.401 V -> 0.406 V -> 0.419 V) and FF (0.592 -> 0.647 -> 0.687) in spite of almost constant Jsc (39.6 mA/cm2 -> 38.7 mA/cm2 -> 40.2 mA/cm2). The carrier concentration was almost identical with the conditions and the improvement is considered to be due to reduction of selenium related deep defects. The conversion efficiency of best performing cell 12.0% with Voc=0.418 V, Jsc=42.1 mA/cm2, and FF=0.683.

Effect of Alkali Post-Deposition Treatments on the Cu(In,Ga)Se₂ Surface and the Deeply Buried Cu(In,Ga)Se₂/Mo Interface Structure

Record efficiencies for Cu(In,Ga)Se₂ (CIGSe) thin-film solar cells have been reached using KF [1], RbF [2], and CsF [3,4] post-deposition treatments (PDT). The underlying mechanism for the observed performance boost have, however, not yet been completely understood. In this contribution, we present the results of hard and soft x-ray photoelectron spectroscopy studies which non-destructively probe the depth-dependent chemical and electronic properties of low-temperature processed CIGSe absorbers as a function of alkali PDT deposition rate. We find a link between Cu depletion at the absorber surface and increasing alkali content, in agreement with Ref. [5]. Depth-dependent valence band photoemission profiles indicate a shift of the valence band maximum (VBM) at the CIGSe surface away from the Fermi level with higher alkali content. It has been reported [6] that alkali elements penetrate into the absorber, especially at grain boundaries as a result of PDT. To investigate potential effects at the back contact, an absorber coated with a combined NaF/RbF/PDT was lifted off the Mo substrate; both sides were studied using hard x-ray photoemission. We detect significant quantities of Rb at the back surface of the absorber, and observe that Rb content is anticorrelated with Na on both front and back CIGSe surfaces. The Cu and Ga depletion resulting from NaF/RbF PDT is seen only at the front side of the CIGSe surface, not at the backside. Furthermore, the spectral shape of the Se and In derived shallow core level lines differs between front and back surfaces, indicating a different chemical structure. Se was found on the Mo substrate after liftoff as a result of MoSe₂ formation at the CIGSe/Mo interface. In our presentation, we will ultimately aim to link our findings to the reported efficiency increase of respective CIGSe solar cells.

A Study of the Degradation Mechanisms of Ultra-Thin CIGS Solar Cells Submitted to a Damp Heat Environment

Thierry Kohli1,2,3, Jessica de Wild1,2,3, Dilara G. Buldu1,2,4, Gizez Biran1,2,4, Guy Brummer1,2,5, Nicolas Rivar1,2, Frank Renner1,2, Marc Meurs1,2,6,7, Erfat Pouramini1,2,8 and Bart Vermeulen1,2,9 IMOMEC, University of Hasselt, Diepenbeek, Belgium; 3IMOMEC, imec, Leuven, Belgium; 4EnergyVille, Genk, Belgium; 5imec, imec, Leuven, Belgium.

On the way to achieve high efficiencies for CuIn₃₋ₓGaₓSe₂ (CIGS) thin film solar cells, alkali doping has become a necessary step. However, it is expected that a migration of the various alkali atoms over the lifetime of the cell will lead to efficiency losses [1]. Logically, ensuring the reliability of a solar cell material is a paramount step towards the commercialization of a product. Indeed, it is necessary for companies to be able to guarantee the efficiencies of the “as-sold” panels over periods of time that expand well over 20 or even 25 years. Experiments studying the reliability of the CIGS and their different components have already been performed in the past [1-4], nevertheless, the exact effects of alkali, and more generally, the precise reasons for, and effect of, the degradation, are still widely unknown.

In order to evaluate the viability of some of the most common techniques used to produce highly efficient thin-film solar cells, ultra-thin coevaporated CIGS solar cell absorber material is produced and doped with various alkali atoms (Na, K, ...). The absorber material is deposited in ultra-thin (400-500nm) layers on soda-lime glass (SLG) equipped with a Si(O,N) diffusion barrier. By reducing the amount of bulk material, the aim is to reduce the concentration of defects in the material and limit their effects as much as possible. The barrier prevents the diffusion of alkali atoms from the SLG into the CIGS and allows for a better control of the concentration of alkali atoms in the layer. Additionally, it allows for a better isolation of the effects of the different alkalis by preventing an uncontrolled mix of alkali from being present in the absorber material.

All alkalis are deposited in their fluoride form (NaF, KF, etc.) either by evaporation, prior to CIGS deposition, or by a post deposition treatment. We monitored the effects of the degradation by regular current-voltage (IV) measurements all along the 1000h experiment. These measurements showed a clear, and alkali concentration dependent, degradation of the solar cells as time increases.

Using Atom Probe Tomography (APT) on degraded as well as on undegraded (reference) cells, it was possible to show that in the absence of a potential, the alkali atom migration is minimal, and that K can be mostly found in the grain boundary region of the absorber material. Given the lack of the expected alkali migration, the main reason for the degradation of the cells seems to be the presence of water that seeps into the grain boundaries of the solar cell material, which could also be observed using APT. The possibility to reverse that degradation mechanisms involving water inclusion is currently under investigation.
Numerical electromagnetic simulations of complete solar cells have been performed for different CIGS thicknesses and various mirror materials. Simulated CIGS absorptions show good agreement with our experimental EQEs, and confirm that parasitic absorption in Mo can be avoided by using a reflective back contact. We also demonstrate the possibility to reach a short-circuit current of $J_{sc} = 36.3 \text{ mA/cm}^2$ for a 150-nm-thick CIGS absorber with a silver nanostructured mirror. Preliminary results of nanostructured back contacts fabricated by nanoinprint lithography will also be presented.

Localization and Characterization of Secondary Phases in CIGS Thin-Film Solar Cells

Sven Schönhere, Georg Voorwinden, Stefan Paetel, Erwin Lotter, Philipp Schoppe, Michelle S. Holzrichter, Udo Reislöhner, Claudia S. Schnohr and Carsten Ronning;

Institute of Solid State Physics, Friedrich Schiller University Jena, Jena, Germany; NICE Solar Energy GmbH, Schwäbisch Hall, Germany; Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg, Stuttgart, Germany.

Secondary phases in Cu(In,Ga)Se$_2$ based thin film solar cells were found at the backside of the absorber layer in contact to the back contact. Such buried secondary phases are difficult to detect, but might influence the solar cell performance. Therefore, it is desirable to develop a methodology to localize and investigate them in detail. The CIGS layer was fabricated in a co-evaporation process under special conditions. Localization and further investigations can be done by removing the absorber from the back contact or by cleaving the sample with a focused ion beam or cross-section scanning electron microscope. Energy dispersive X-ray spectroscopy (EDS) measurements reveal a varying composition of the absorber elements. However, the forced detachment of the back contact from the absorber destroys the solar cell stack and might influence the appearance of the secondary phase itself. Furthermore, investigations of the solar cell stack as a whole are no longer possible. To overcome these problems, we electrically contacted a complete solar cell inside an electron microscope and used electron-beam-induced current (EBIC) to locate buried secondary phases. In EBIC images, the secondary phases show a reduction of the current density depending on the size and the morphology of the secondary phase. Hence, the reduction of the electron-beam-induced current allows the localization of secondary phases in a reliable way without destroying the solar cell. For verification and further investigations, we prepared thin cross section lamellas via focused ion beam at the localized buried phases. Several thin lamellas of the complete solar cell stack, including the underlying substrate, were investigated via EDS with a high spatial resolution of tens of nanometers revealing compositional variations.

(Ag,Cu)(In,Ga)Se$_2$ Thin-Film Solar Cells Analyzed by Atom Probe Tomography

Hicham Aboulfadl, Jan Keller, Mathias Thuvander and Marika Edoff;

Department of Physics, Chalmers University of Technology, Göteborg, Sweden; Department of Engineering Sciences, Uppsala University, Uppsala, Sweden.

The incorporation of Ag in Cu(In,Ga)Se$_2$ (CIGSe) is understood to induce certain improvements in the opto-electronic properties of the absorber, which is reflected in enhanced conversion efficiencies [1]. Ag atoms substitute for Cu forming a pentanary (Ag$_x$Cu$_{1-x}$In$_y$Ga$_{3-y}$Se$_2$ (ACIGSe) alloy with a wider band gap compared to CIGSe absorber. The Ag alloying also allows to reduce the deposition temperatures due to the lower melting point of Ag, which as a result decreases the density of lattice defects in the absorber. Synthesizing such alloy on high strain K-rich substrates along with KF post deposition treatment displays higher device performance compared to similarly processed CIGSe devices without Ag [2]. The diffusion of alkali metals from the substrate in ACIGSe compared to CIGSe as well as the distribution of Ag in the absorbers are matters that can elucidate differences in the opto-electronic properties and therefore requires further attention.

Amongst various analytical techniques, atom probe tomography (APT) is an extremely promising tool to characterize the chemical distribution in three dimensions with sub-nm resolution [3]. APT is used in the study here as a main tool to examine local compositions within ACIGSe and the distribution of alkali metals within absorbers grown on different substrates; soda lime glass (Na-rich) and high strain point glass (K-rich), respectively. Na and K were found to segregate to different lattice defects in the absorber structures. Correlative measurements using transmission Kikuchi diffraction and APT were therefore carried out to investigate the crystallographic and chemical nature of grain boundaries and twin boundaries detected within the ACIGSe structures. Although ACGSe is a promising system for thin film solar cell technology, more research is certainly required to demonstrate if the beneficial effects observed for Ag additions are worth to pay for, considering its higher cost compared to Cu.

Studying the Light-Soaking Effect on the Absorber Layer of Cu(In,Ga)Se$_2$ Solar Cells Using Raman Analysis

Sina Soldannia Mohammad, Mason Brevig, Rouin Farschchi, Dmytro Poplavskyy and Angus Rockett;

MiaSoLe Hi-Tech Corp, Santa Clara, California, United States; Metallurgical and Materials Science, Colorado School of Mines, Golden, Colorado, United States.

Culn$_{1-x}$Ga$_x$Se$_2$ (CIGS) is a promising absorber material for high-efficiency, low-cost thin-film photovoltaics, with a significant increase in efficiency in the last 3 years. To further improve the device performance, a better understanding of the absorber layer defects is required. One puzzling behavior is the effect of light soaking (LS). CIGS solar cells exhibit metastable performance under extended duration light illumination. This has been proposed to be related to amphoteric behavior of (V$_{Ga}^{2+}$/V$_{Ga}^{3+}$) vacancies; under light illumination, the equilibrium distribution of the donor and acceptor configuration of these vacancies changes. However, this hasn’t been shown experimentally [1]. Here, we report on metastable effects using Raman analysis during light soaking. Commercial Ag-alloyed Culn$_{1-x}$Ga$_x$Se$_2$ (ACIGS) sputter-deposited samples coated with CdS, were obtained from MiaSoLe HiTech. The samples were fabricated in a production-scale roll-coater on flexible stainless-steel substrates. Na and K alkali metals were incorporated from the Mo back electrode. Current-voltage analysis of the samples under the light soaking, dark heat, and combinations of both were measured at MiaSoLe. Raman spectra were measured every 1-2 minutes over a total time of 200 minutes using continuous 532 nm laser illumination. The sample temperature was maintained at 12°C by a Peltier device mounted under the sample. The excitation depth at this wavelength is ~100nm. The laser power was set at the lowest level at which reliable data could be obtained to prevent peak shifts due to local heating. Higher laser powers produced different but variable results. The results showed time-dependent variation in the A1 (CIGS) mode at 176 cm$^{-1}$. In addition, a broad shoulder related to the ordered defect compounds such as Cu(In$_{1-x}$Ga$_x$)$_2$Se$_2$ was detected at ~155 cm$^{-1}$. After 60 min illumination, the intensity of the CIGS A1 mode dropped while the ordered defect structure peak grew. For relatively stable samples, the A1/ODC stabilized at higher values after 200 min exposure; however, unstable samples stabilized at lower ratios. This suggests re-ordering of Cu-Se bonds under illumination. We are planning to study these effects as a function of temperature to establish the kinetic rate parameters of the changes.

In-Depth Analysis of Phase Distribution in Zn(O,S) Thin Films Deposited by a Reactive Sputtering

Dae-Hyung Cho, Woo-Jung Lee, Byungha Shin and Yong-Duck Chung;

1Electronics and Telecommunications Research Institute (ETRI), Daejeon, Korea (the Republic of); 2Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Korea (the Republic of); 3Korea University of Science and Technology (UST), Daejeon, Korea (the Republic of);

Korea University of Science and Technology, Daejeon, Korea, Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg, Stuttgart, Germany.

Zn-based materials such as ZnO, ZnS, or Zn(O,S) are being widely used for optoelectronic devices, thin film transistors, and photovoltaic devices due to their wide bandgap, chemical stability, inexpensiveness, and nontoxicity. ZnO$_{1-x}$S$_x$ films especially show very interesting changes in electronic properties when the sulfur-to-oxygen composition ratio (x) is varied. With increasing x between 0 < x < 0.5, the conduction band minimum (CBM) hardly changes and the valence band maximum (VBM) moves up, while for x larger than 0.5, it is the CBM that moves up and the VBM remains nearly unchanged, which yields the bandgap bowing. A deposition method is an important issue to consider in the fabrication of the Zn(O,S) thin films with high quality, composition controllability, and industrial applicability. Among various methods of Zn(O,S) deposition, reactive sputtering is an attractive choice because it is manufacturing-friendly. However, a highly energetic plasma during the sputtering is likely to make undesired effects especially when forming very thin films.

In this study, the Zn(O,S) thin films were prepared using a single Zn target and O$_2$/Ar mixture gas. Despite careful control of the sulfur-to-oxygen composition ratio and its
gradient through the vertical direction, we found that the sulfur-to-oxygen composition ratio changed along the depth direction; the bottom layers became O-rich. Additionally, Zn(OH)2 secondary phase was observed at the bottom side of the Zn(O,S) thin films, which induced much lower VBM. The properties of the fabricated thin films and solar devices were characterized by a transmission electron microscopy, an energy dispersive spectroscopy, an X-ray photoelectron spectroscopy, and a current-voltage measurement. In this work, we present several strategies to mitigate the unwanted compositional variations and the formation of secondary phases to achieve high quality Zn(O,S) thin films with reactive sputtering. The details of these strategies will be presented.

The Overall Distribution of Rubidium and Cesium in Highly Efficient Cu(In,Ga)Se2 Solar Cells Philip Schöppel1, Sven Schönher1, Philip Jackson2, Roland Wuerz2, Wolfgang Wisniewski1, Torsten Schwarz1, Maurizio Ritzer1, Andreas Johannes1, Maximilian Zapf1, Gema Martínez-Criado1,6, Claudia S. Schnoor1 and Carsten Ronning1,2.1 Institute of Solid State Physics, Friedrich Schiller University Jena, Jena, Germany; 2Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg, Stuttgart, Germany; 3Otto Schott Institute of Materials Research, Friedrich-Schiller-University Jena, Jena, Germany; 4Max-Planck-Institut für Eisenforschung GmbH, Düsseldorf, Germany; 5European Synchrotron Radiation Facility, Grenoble, France; 6Instituto de Ciencia de Materiales de Madrid, Madrid, Spain.

Thin film solar cells based on the absorber material Cu(In,Ga)Se2 have achieved conversion efficiencies well over 22%. The recent push in record efficiencies was mainly realized by applying an alkali fluoride post deposition treatment (PDT) to the absorber. Best results were obtained for heavy alkali elements like Rb and Cs. In order to study the beneficial effect of the heavy alkali elements we investigated highly efficient Cu(In,Ga)Se2 solar cells, whose absorbers were subjected to either a RbF-PDT or a CsF-PDT. Thin cross sectional lamellas were cut out of the entire devices and analyzed via a combination of synchrotron based spatially resolved X-ray fluorescence analysis and different electron microscopy techniques. It is evident that Rb accumulates at random high-angle grain boundaries, at the p-n junction, and at the interface between the absorber and MoSe2 layer. The agglomeration of Rb at the grain boundaries is accompanied by a reduced Cu concentration and slightly increased In and Se concentrations. Furthermore, variations in the local composition of the absorber at the p-n junction indicate the formation of a secondary phase, which shows a laterally inhomogeneous distribution. In case of the CsF-PDT, we obtained similar results. Hence, the improved solar cell performance due to heavy alkali fluoride PDT can be expected to originate from a favorable modification of the p-n junction, the random high-angle grain boundaries or the back contact interface or from a combination of these effects.

ES20.07.16
Microstructure Alternation in Heterojunction Interface Engineering of CZTS Solar Cell Jiahong Huang, Kaiwen Sun, Xin Cui, Chang Yan, Martin Green and Xiaojing Hao; University of New South Wales, Sydney, New South Wales, Australia.

Kesterite Cu2ZnSnS4 (CZTS) photovoltaics have been comprehensively investigated in the past decades but are still hampered by a relatively large open circuit voltage (Voc) deficit, which is due to the non-radiative recombination within the CZTS bulk and hetero-interface region. Heterojunction interface engineering is of great importance to tackling the interface recombination problem by optimizing the band alignment between the absorber and the buffer and interface passivation. In this work, we reported a detailed characterization of the microstructure at the interface of the CZTS device with three different buffer materials using high-resolution TEM technique. It has been revealed that an ultra-thin ZnS or Zn (S, O) nanolayer can be formed at the CZTS and the buffer for the subsequent growth of ZnSnO and CZnS layers, while such feature has not been observed in the CdS buffer sample. Such ultra-thin ZnS or Zn (S, O) is found grown epitaxially at the CZTS surface with high crystallinity as the lattice mismatch between ZnS and the kesterite CZTS is negligibly small. The presence of this nano-structure between the buffer and CZTS absorber may benefit the device performance by reducing interface crystalline defects and thereby decrease the interface recombination while acting as a tunneling layer for current transport.

ES20.07.17
Crystal Structure of (In,Ga)Se2 Solid Solution Studied by XAFS Kosuke Beppu, Tetsushi Maeda and Takahiro Wada; Ryukoku University, Otsu, Japan.

Crystal structure of (In,Ga)Se2 precursor material was studied by X-ray absorption fine structure (XAFS) in order to prepare highly efficient Cu(In,Ga)Se2 (CIGS) solar cells. On the basis of the results, preparation process of high-quality CIGS thin films is discussed. The CIGS thin films were prepared by a 3-stage process. In the first stage, the initial stage consists of deposition of an (In,Ga)-Se precursor layer. In the second stage, the precursor layer is exposed to Cu and Se fluxes to form Cu-rich CIGS. In the third stage, In, Ga, and Se are added to the Cu-rich CIGS layer in order to obtain a slightly (In,Ga)-rich CIGS film. Then, the property for the first layer of (In,Ga)Se2 can affect the quality and crystal orientation of CIGS, which is finally obtained in 3-stage process. The crystal structure of InSe is hexagonal layered defect wurtzite type structure. The crystal structure of GaSe is monoclinic defect sphalerite type structure. Therefore, the crystal structure of (In,Ga)Se2 is predicted to be affected by a Ga content. In this work, we synthesized (In,Ga)Se2 and clarified their crystal structures. (In,Ga)Se2 was prepared by a mechanical method. (In,Ga)Se2 was characterized by X-ray diffraction (XRD) and XAFS. The XRD patterns of (In,Ga)Se2 were gradually changed with Ga content. The Rietveld analysis for the XRD patterns clarified the crystal structure of (In,Ga)Se2. When Ga content was more than 50 mol%, the layered defect wurtzite type structure can be obtained. When Ga content was more than 50 mol%, the layered defect wurtzite type structure can be obtained. The transition probability also showed change of the crystal structure of (In,Ga)Se2. Since an electron was easy to flow into the anti-bonding orbital due to the change of the crystal structure, the bond length varied and lattice parameter was changed.

ES20.07.18
Characterization of Defect Levels in BaSi: by DLTS and Significant Improvement of Photoreponsivity by Increasing Growth Temperature Yudai Yamashita, Takuma Satoh, Kaoru Toko and Takashii Suemasu; University of Tsukuba, Tsukuba, Japan.

Barium disilicide (BaSi2) shows great promise as a new material for thin-film solar cells. It has a suitable bandgap of 1.3 eV, large optical absorption coefficients exceeding those of CIGS,1,2 and a large minority-carrier diffusion length of about 10 µm.3,4 We achieved a conversion efficiency of 9.9% in p-BaSi2/n-Si heterojunction solar cells.3,4 We target next BaSi2 pn homojunction solar cells. To this end, high-quality BaSi2 light absorbers with low defect density (N D) are inevitable. In this work, we investigated defect levels and their values of V T in the BaSi2 layers by deep level transient spectroscopy (DLTS), and succeeded in reducing defects in BaSi2 films. In the first experiment, undoped BaSi2 absorber layers by DLTS. After thermal cleaning (TC) under UHV at 800°C, we grew a 500-nm-thick undoped BaSi2 layer by MBE using an optimized Ba/Si ratio on n-Si (111) (1×1014 cm-2) to form a heterojunction diode. The electron concentration (n) of the BaSi2 was below 1015 cm-3. The Schottky barrier height was 2×103 eV cm-3 at RT. The depletion region stretches in both sides. However, the defects on the Si substrate decrease to a value below the detection limit.4 For this reason, the detected peaks indicate defects in BaSi2. An upward facing peak caused by majority-carrier (hole) trap level (H1) was observed at approximately 126 K. The hole trap level was calculated to be approximately 0.27 eV from the valence band maximum, and N D was 1×1012 cm-3. This value is approximately 100 times smaller than that reported 5. As the DLTS signal near 125 K decreased as |R/|S| decreased and hence it approached the BaSi2/Si interface. This result shows detected defects existed in BaSi2, and their density decreased around the interface. When we changed the number of injected carriers by changing the pulse width (τp), the DLTS signal increased sharply as the τp increased from 0.1 to 10 ms, indicating the presence of point defects. First-principles calculation has revealed that Si vacancy (V Si) is most likely to occur.6 One of the calculated defect levels due to V Si is in good agreement with H1. In order to understand why the density of V Si decreases in BaSi2 close to the heterointerface, RBS measurement was carried out. The depth profiles of Ba to Si atomic ratios showed that BaSi2 was in excess of Si around the interface. This result means that Si atoms diffuse into the BaSi2 layer from the Si substrate during MBE growth and fill the Si vacancies. From this result, it is expected that promoting Si diffusion from the substrate is effective for reducing the density of BaSi2 defects. In the second experiment, in order to promote the diffusion of Si atoms from the Si substrate, we raised the substrate temperature (Tsub) during MBE growth from 580 to 650°C. In this experiment, we varied the Ba to Si deposition rate ratio (R Ba/R Si) from 0.4 to 4.7. The photoreponsivity changed drastically depending on R Ba/R Si and reached a maximum of around 2.7 A/W at 1.55 eV under the bias voltage of −1 V applied between the top and bottom electrodes when the R Ba/R Si was around 1.2. This value is more than three times larger than that reported 7, suggesting that the density of V Si was significantly suppressed.
Reducing the thickness of Cu(In,Ga)Se₂ (CIGS) absorber layers has potential to decrease its cost significantly, but has drawbacks like incomplete absorption and increased back-contact recombination, both resulting in power conversion efficiency losses. One solution is to implement a rear surface passivation layer, which has potential to reduce rear surface recombination velocity and increase rear internal reflection [1]. Alumina (Al₂O₃) is such an ideal passivation layer, but unfortunately also acts as an electron and diffusion barrier layer, and thus prevents current flow and sodium (Na) diffusion. As is discussed below, our novel approach to generate point contact openings in this passivation layer overcomes both problems at once. The proposed method is to use sodium fluoride (NaF) on top of the Al₂O₃ passivation layer, which will generate contact openings during selenization. This applied approach is industrially viable, as compared to proven methods – e.g. using nanoparticles, e-beam or nano-imprint lithography – which are too expensive, time-consuming or not applicable for larger areas. D. Ledinek et al. previously proposed using a very thin layer of Al₂O₃ rear surface passivation in combination with NaF deposition to enhance the electrical characteristics of CIGS solar cells. In their study this surface passivation is claimed to allow tunneling [2]. In our study, we prove that point contacts have been generated in this Al₂O₃ surface passivation layer. Atomic layer deposition (ALD) was used to deposit very thin Al₂O₃ layers on molybdenum (Mo) rear contact, and NaF was deposited on these layers by spin coating. Thereafter CIGS layers (>500 nm thick) were grown by single stage co-evaporation at 550°C, followed by standard solar cell process described in [3]. To detect the contact openings in the passivation layers, scanning electron microscopy (SEM) combined with energy dispersive X-ray (EDX) spectroscopy was applied. Glass/Mo/Al₂O₃/NaF characterization samples were used for this analysis, where the co-evaporation process was mimicked by using a selenization step. After the selenization, point openings in the thin Al₂O₃ passivation layers were determined by SEM, and supported by EDX measurement. To investigate the impact of Al₂O₃ thickness on passivation of the CIGS rear surface, time resolved photo-luminescence (TR-PL) measurements on finished absorber layers (capped with CdS) were used. According to these TR-PL results, a 6 nm thick passivation layer gave the highest free charge carrier lifetime and PL response in all sets of samples. This was confirmed in full solar cell devices, where a significant increase in power conversion efficiency, and gain in open-circuit voltage, current density and fill factor values was measured for the 6 nm Al₂O₃ rear passivated CIGS devices, as compared to unpassivated reference cells. Hence, it can be concluded that by using a simple, cost-effective and fast way, i.e. ALD for Al₂O₃ and spin coating for NaF, we succeeded to make point contact openings to passivate the back surface of ultra-thin CIGS solar cells. The ongoing work focuses on different aspects: (i) At present the point openings are still submicron size, now we try to make them nano-size. (ii) We also concentrate on controlling the density of the contact openings, e.g. by changing the temperature of ALD process or the molarity of NaF solution. (iii) This approach also enables us to investigate different metal oxides as passivation layers, such as H₂O₂ and TiO₂ in combination with the same contact opening approach. (iv) And finally, we are investigating this rear surface passivation approach for other absorber layer deposition/growth techniques, e.g. a 2-step sputtering + selenization method.

[1] Poncelet, O. et al. DOI: 10.1016/j.solener.2017.03.001
revealed a characteristic time scale of 200 – 260 ps for recombination. Hall effect and TRTS measurements revealed electron and hole mobilities in the range of 50 – 100 cm²/Vs and a majority carrier density of 9x10¹⁴ cm⁻³. These dynamics result in a characteristic minority carrier diffusion length of less than 200 nm, leading to incomplete carrier collection, as confirmed by a strongly decreasing external quantum efficiency at long wavelengths for a device prepared on the crystal.

Carrier dynamics and device performance strongly depend on cation composition. Near-stoichiometric compositions (Cu/(Zn+Sn) > 0.92 and Zn/Sn < 1.12) had much shorter carrier lifetimes of less than 20 ps, which lead to Jₑₑ = 16.2 mA/cm², Voc = 220 mV, and efficiency = 1.7%. Low carrier lifetime, which may be due to the high density of cluster defects related to Cu₉₋₁₀Sn₉₋₁₀ antisites, limits Jᵥ and Voc as well as efficiency. To reduce the defect concentration, Ag was used as a substitute for Cu since the covalent radius of Ag is approximately 15% larger than that of Cu and Zn. With Ag/(Ag+Cu) = 0.29, lifetime increased by more than an order of magnitude to 9 ns, with associated increase in diffusion length up to ~1 μm. Improved performance with Ag alloying had previously been observed for polycrystalline thin films, with improvements partially ascribed to larger grains and changes to the chemistry of the grain boundaries. However, the dramatically increased lifetime that we observe with Ag alloying in single crystals indicates that reductions in bulk defect densities are likely the dominant factor. Incorporating Ag into CZTSSe devices may lead to increased efficiencies. Our approach combining ultrafast spectroscopy and device measurements can lead to more detailed understanding of performance-limiting photophysical processes and can subsequently accelerate the development of even more efficient PVs.

Ultrafast Carrier Dynamics at Proton-Bombarded Cu(In,Ga)Se₂ Thin Films Measured by Optical Pump-Thz Probe Spectroscopy

Woo-Jung Lee¹, Chul Kang², Dae-Hyoung Cho¹, Gyuseok Lee¹ and Yong-Duck Chang¹; ²Electronics and Telecommunications Research Institute, Daejeon, Korea (the Republic of); ³Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of); ⁴Pohang University of Science & Technology, Pohang, Korea (the Republic of); ⁵Korea University of Science and Technology, Daejeon, Korea (the Republic of).

The photoexcited carrier dynamics in optoelectronic devices such as photovoltaic and thermoelectric devices is a major research topic over the past decades. Chalogenide-based Cu(In,Ga)Se₂ (CIGS) thin film has attracted considerable attention as a material for photovoltaic devices with high radiation tolerance in space environment. However, very little empirical work has been done until recently, related to the studies on radiation damage and photoexcited carrier dynamics with radiation exposure in CIGS thin film. In this paper, we carried out the irradiation of H⁺ ion beams with injection energy of 200 keV into CIGS thin film by varying the concentration of H⁺ ions beams dose from 10¹⁵/cm² to 10¹⁶/cm². To investigate the optical and electrical property, the carrier concentration and hall mobility were evaluated as a function of H⁺ ions beams dose. To study photoexcited carrier dynamics after ion beams bombardment, optical pump-Thz probe (OPTP) spectroscopy were measured, which is sensitive to behavior of free carriers within ultrashort time scales of ps. Contrary to pure CIGS thin film, the carrier lifetimes of ion beams-bombarded CIGS thin film were drastically decreased, which is directly related to the surface defect states induced by radiation damage. Moreover, carrier lifetimes varied with the concentration of H⁺ ions dose due to different settlements of ion beams along the depth direction into the CIGS film.

Based on carrier-recombination process, we introduce an interpretation of the photocarrier dynamics in terms of surface defect states existed in the ion beams-bombarded CIGS thin film as a function of H⁺ ion dose.

Understanding the Role of CdS/CdSe Bilayer Window in CdTe Solar Cells via Capacitance Spectroscopy

Rasha A. Awqi, Mohammed Razoqi, Deng-Bing Li, Zhaoqing Song, Robert W. Collins and Yanfa Yan; Department of Physics and Astronomy, and The Wright Center for Photovoltaics Innovation and Commercialization (PVIC), The University of Toledo, Toledo, Ohio, United States.

Over the last decades, the significant increase in short circuit current density has been considered as one of the most important factors that led to the current record efficiency CdTe solar cells. The improvement of short circuit current density is mainly achieved by incorporating Se into CdTe. The impact of Se incorporation is commonly attributed to the optimal band alignment introduced by the formation of CdSeₓ₁₋ₓTeₙ alloy. However, other possible mechanisms that may lead to the enhanced device performance, including the changes in the carrier density profile, trap state distributions in bulk and at interfaces, and barrier heights are yet to be systematically investigated.

In this work, a series of electrical characterization measurements are carried out to explore the effects of incorporating a CdSe interlayer in CdTe solar cells. Temperature dependent current density-voltage (J-V-T) measurements are performed to extract the Shockley back barrier heights for devices with different CdSe and CdS cell thicknesses. Temperature dependent capacitance–voltage (C-V-T) measurements are used to compare the charge carrier density distributions through the absorber layers. In addition, thermal admittance and impedance spectroscopy measurements are carried out to explore the defects in bulk and at interfaces, conductivity, and carrier mobilities. Combining these advanced electrical characterization techniques allows us to probe the origins of the enhanced performance in CdSeₓ₁₋ₓTeₙ solar cells. Our study would supply a better understanding of Se incorporation in CdTe absorber layers, thus providing guidelines to further improvement of CdTe solar cells.

The Impact of Band Tails on Charge Carrier Dynamics and Solar Cells

Hannes Hempel, Jose Marquez Prieto, Rainer Eichberger and Thomas Unold; Helmholtz Zentrum Berlin, Berlin, Berlin, Germany.

In many photovoltaic materials the impact of disorder and band tails is discussed controversially and it is unclear whether extended band states or localized tail states dominate charge carrier dynamics. Here, we investigate the effect of band tails on charge carrier transport and recombination and interpret it in a novel way and deduce the consequences for solar cells. To this end, we probe photoexcited charge carriers in a kesterite-semiconductor as a model system over their full life span from femtoseconds to microseconds by time-resolved terahertz spectroscopy and photoluminescence spectroscopy. We find that occupation of the band tails is strongly temperature-dependent. Above a characteristic temperature charge carrier are activated out of Urbach tail states. This mobility value is at least one order of magnitude lower than in a theoretical tail-free kesterite-semiconductor. Further, the mobility at terahertz frequencies indicates that charge carriers localize in tail states with a typical spatial extent of 11 nm. The recombination kinetics of photoexcited charge carriers can be described within the Shockley-Read-Hall model of defect assisted recombination. Unambiguous signs of an influence of band tails are not measured at room temperature, but secondary effects from the affected carrier distribution and transport are discussed. The non-radiative recombination is found to be the major bottleneck for a potential solar cell and reduces the open circuit voltage of a potential solar cell by 270 mV. However, below the characteristic temperature of 200 K charge carrier relax by multiple-trapping into the deep Urbach tail and lead to a strongly injection-dependent charge carrier distribution, transport and recombination as previously observed for amorphous semiconductors.

Voltage Loss Analysis for CZTSSe Solar Cells with Sn Content Variation

Antonio Cabas Vidiani¹, Mohammed Azzouzi², Stefan Haass¹, Jason A. Rohr², Yaroslav E. Romanyuk¹, Ayodiya N. Tiwan¹ and Jenny Nelson²; ¹Empe-Swiss Federal Laboratories of Materials Science and Technology, Zurich, Switzerland; ²Department of Physics and Centre for Plastic Electronics, Imperial College London, London, United Kingdom.

The absence of toxic and scarce elements makes kesterite (Cu(In,Ga)Se₂) a promising inorganic thin film photovoltaic technology, but its performance advancement is hindered by a substantial voltage loss. This is commonly expressed as the open circuit voltage deficit (ΔVoc,deficit = Voc – Vocₐₚ) which requires bandgap determination. The band tails that characterize kesterite absorption spectrum make bandgap evaluation inaccurate and dependent on the method, thus Voc-deficit interpretation is unreliable for proper performance comparison. It was demonstrated by Yao et al. (Phys. Rev. Appl., 4, 1 (2015)) that from the reciprocity principle and the external quantum efficiency it is possible to measure voltage losses avoiding the bandgap estimation.
of 27 at%, Voc and V_{oc,real} were the lowest of the series whereas electroluminescence quantum yield (QE_{LED}) was the highest (5.2×10^-4 %). This indicates that the lowest photovoltaic performance does not always correlate with a high non-radiative recombination in kesterite solar cells. This is also supported by temperature dependent current-density (JV-T) and capacitance-frequency (CF-T) measurements confirming the Sn variation has no appreciable influence on the defect distribution.

It is concluded that QE_{LED} obtained by means of EL and EQE measurements is a suitable indicator of non-radiative losses for compositionally complex absorbers like kesterite.

Characterization of Thin CdTe Solar Cells with a CdSeTe Front Layer
Alexandra Bothwell, Pascal Jundt, Jennifer Drayton and James Sites; Colorado State University, Fort Collins, Colorado, United States.

CdTe telluride (CdTe) photovoltaic device efficiencies show significant improvement with the incorporation of a cadmium selenium telluride (CdSeTe) alloy layer deposited between the magnesium zinc oxide (MgZnO) device emitter and CdTe absorber layers. CdSeTe/CdTe devices are fabricated by close-space sublimation with a total absorber thickness of 1.5 µm. At this thickness, both the CdSeTe and CdTe layers are fully depleted. The incorporation of the CdSeTe layer is confirmed by microscopy measurements and shows minimal grading of Se into the CdTe layer. Loss analysis calculated from optical measurements shows that the CdSeTe layer acts as the primary absorber in the CdSeTe/CdTe structure, absorbing at least 90% of the photons. Current density-voltage measurements show an increase in current density of up to 3 mA/cm² with the addition of a CdSeTe layer that is due to a band gap shift from approximately 1.5 to 1.43 eV for CdTe and CdSeTe/CdTe absorbers respectively, where band gaps are determined by quantum efficiency and spectral photoluminescence measurements. Improvement in CdSeTe/CdTe device quality compared to CdTe is reflected in spectral photoluminescence measurements which show peak intensities many times greater when Se is incorporated into the absorber. The voltage deficit, calculated as the difference between the optimal absorber band gap and the measured open circuit voltage, shows improvement with the incorporation of the CdSeTe layer. This is corroborated by improved electroluminescence intensity, which is proportional to voltage deficit. The incorporation of CdSeTe as part of the absorber layer in CdTe device structures improves device current density and voltage deficit and has therefore increased device efficiencies by 2% absolute for CdSeTe/CdTe absorbers with a total thickness less than two microns.

Flexible Cu(In,Ga)Se₂ Solar Cells for Outer Planetary Missions—Investigation Under Low Intensity Low Temperature Conditions
Collin Brown¹, Vincent Whiteside², Dnyutray Poplawskiy², Khalid Hossain³, Mangal Bhosdale¹ and Ian Sellers¹; Homer L. Dodge Department of Physics and Astronomy, The University of Oklahoma, Norman, Oklahoma, United States; ³MiaSolo Hi-Tech Corp, Santa Clara, California, United States; ²Amethyst Research Inc, Ardmore, Oklahoma, United States.

Cu(In, Ga)Se₂ (CIGS) solar cells have been studied for space applications for a number of years due to their radiation tolerance and low cost. Most early work has studied CIGS on soda lime glass, which is too bulky for space applications, and would not allow for the complex folding arrays that have been proposed for future deep space missions. Here, commercially available flexible CIGS solar cells are investigated under conditions consistent with those around the outer planets. Performance under these low temperature low intensity (LILT) conditions is critical to study, as these conditions can reveal issues not present under normal operation [1]. Current density-voltage (J-V) and external quantum efficiency (EQE) measurements under different space conditions, illumination, and bias conditions are performed to investigate the environmental effects of these deep space conditions. Of particular interest at low temperature is the behavior of the well-known Ve-Vce metastable defect [2], and its potential role in device performance under LILT conditions. Here, evidence of a photo-activated barrier is observed, which is attributed to the same defect center, although its effect on power generation at LILT conditions appears to be minimal. Additionally, proton irradiation with high fluence levels is investigated to emulate certain conditions near Jupiter. Although degradation is observed, self-healing behavior under annealing conditions is also evident. [1] D. A. Scheiman and D. B. Snyder, “Low intensity low temperature (LILT) measurements of state-of-the-art triple junction solar cells for space missions,” in 2008 33rd IEEE Photovoltaic Specialists Conference, 2008, pp. 1-6. [2] S. Lany and A. Zunger, “Light- and bias-induced metastabilities in Cu(In,Ga)Se₂ based solar cells caused by the (Ve-Vce) vacancy complex,” Journal of Applied Physics, vol. 100, no. 11, p. 113725, 2006/12/01 2006.

Real Time Spectroscopic Ellipsometry Analysis of the Structural Evolution and Optical Properties of CuInSe₂ by One and Two Stage Thermal Co-Evaporation
Dhurba R. Sapkota¹, Puja Pradhan¹, Prakash Korala¹, Adam Phillips¹, Sylvain Marsilliac², Michael Heben¹ and Robert W. Collins¹; ¹Center for Photovoltaics Innovation and Commercialization (PVIC), Department of Physics and Astronomy, University of Toledo, Toledo, Ohio, United States; ²Virginia Institute of Photovoltaics, Old Dominion University, Norfolk, Virginia, United States.

Real time spectroscopic ellipsometry (RTSE) measurements have been performed on copper indium diselenide (CuInSe₂) narrow bandgap solar cell materials. In these studies, thin film CuInSe₂ absorber structures have been deposited in one-stage and two-stage thermal co-evaporation processes on smooth c-Si wafer substrates held at temperatures in the range of 300-570 °C. Analysis of the RTSE data for one-stage CuInSe₂ yields the structural evolution and the complex dielectric functions (ε₁, ε₂) of the individual CuInSe₂ layers, the latter relevant for the elevated temperatures of deposition. In this analysis, information on the structural evolution, i.e. the surface roughness and underlying bulk layer thicknesses versus time, is obtained with monolayer-level sensitivity during thin film nucleation and coalescence. Complex dielectric functions (ε₁, ε₂) of deposited films as well as their bandgap energies and broadening parameters are obtained at different measurement temperatures applying the combination of RTSE and in situ SE measurements during sample cooling. All such deduced information on the structural and optical properties provides insights into CuInSe₂ film crystallinity and grain growth processes. In the two stage process, CuInSe₂ is obtained by depositing either In₃Se₄ or Cu₃Se₄ first, followed by exposure to either Cu₃Se₂ or In₃Se₄ evaporant, respectively. Real time SE has been applied to both stages of each CuInSe₂ deposition in order to compare the structural and optical property evolution characteristic of the two different routes for CuInSe₂ fabrication. The goal of this work is CuInSe₂ of optimum stoichiometry and grain structure obtained under RTSE monitoring and control for use as a bottom cell absorber material in tandem solar cell applications. Results correlating structural evolution and ultimate device performance will be reported.

Highly Efficient Earth-Abundant CZTSSe Solar Cell by Introducing p+-CTSSe Point Contacts
Chih-Yang Huang¹,², Cheng-Ying Chen¹,²,³,⁴, Yu-Chen Chen¹,², Jih-Shang Hwang¹, Kuei-Hsien Chen¹,² and Li-Chyong Chen¹,²,³,⁴; ¹National Taiwan University, Taiwan; ²Institute of Atomic and Molecular Science, Academia Sinica, Taipei 106, Taiwan; ³Institute of OptoElectronic Sciences, National Taiwan Ocean University, Keelung, Taiwan; ⁴Center of Atomic Initiative for New Materials, National Taiwan Ocean University, Taiwan.

Recently, Cu₂ZnSn(S,Se)₄ (CZTSSe) solar cell has attracted many attentions due to several advantages of CZTS(e) such as earth-abundant, cheap, nontoxic, high absorption coefficient (~10⁷ cm⁻¹) and tunable bandgap (1.15-1.5 eV). So far, the highest efficiency of CZTS(e) solar cell is 12.6% achieved by IBM team but its power conversion efficiency (PCE) still cannot compete with the commercial thin-film solar cells, e.g., CIGS and CdTe. There are numerous issues need to be solved to enhance the PCE (e.g., back contact losses, interfacial losses, deep defects). Especially, back contact losses cause degradation of CZTS(e) solar cell due to interface defects between CZTS(e) and MoO₃ layer [1]. The metallic precursors prior to CZTSSe sulfo-selenization, producing p+-CTSSe and ZnSe, which helps reduce interface recombination, on the bottom of the CZTSSe absorber layer. The main improvement results from increasing fill factor (FF) and short circuit current due to less recombination at back interfaces. Moreover, a 9.61% PCE (~10.6% in J-V) and Li-Chyong Chen

Effect of Combined Alkali (KF + CsF)-Post-Deposition Treatment on Cu(In,Ga)Se₂ Solar Cells

Ha Nguyen, Guy Brammertz, Chirila et. al. DOI: 10.1038/NMAT3789

We report a novel approach to generate plasmons in CIGSe thin films in the wide spectral range. In this work, a new methodology to generate plasmons in the CIGSe thin film used dual-ion beam sputtering. The valence band offset at n-type Mg₂Zn₁₋ₓSnₓO (MZ1) p-CIGSe heterojunction interface can be determined by the core-level photoemission-based method. Here, the calculation of was done by two methods: (1) considering different core level peaks of Se 3d and Mg 2p for CIGSe and MZ1, respectively, and (2) considering same core-level peaks of Zn 3d for CZTSSe and MZ1. The values of valence band onset (VBOn), as obtained by linear extrapolation of the onset of the valence band, are 2.97 and 0.54 eV, respectively. Figure 1(a) shows the core-level peaks of the MZ1/CZTSSe heterojunction. The core-level spectra of Zn 3d recorded on the MZ1/CZTSSe heterojunction is dominated by one symmetric peak, implying a uniform bonding state. Figure 1(b) shows transmission spectra using ellipsometry. Figure 1(c) shows the energy band diagram calculated using Ultra violet photoelectron spectroscopy (UPS).

CIGSe layers have recently set a new record efficiency of 22.9%, thus demonstrating a continuous improvement of this technology. Currently, the standard thickness for the CIGSe absorbers is 2-3 μm. Reduction in material consumption will help to further reduce the cost. When approaching the material reduction by reducing the absorber thickness to below 700 nm leads to increase in production quantity but, on the other hand, it considerably reduces light absorption in absorber layer causing in strongly enhanced recombination at the back contact. Here, we will focus on the optical aspect and investigate a novel means to generate broadband plasmonic generation in ultrathin CIGSe layers for enhanced absorption in solar cells.

We report a novel approach to generate plasmons in CIGSe thin films in the wide spectral range. In this work, a new methodology to generate plasmons in the CIGSe thin film used dual-ion beam sputtering (DIBS) system is reported. Sputtering of material during growth by utilizing secondary DC ion source present in the DIBS system leads to the generation of different metallic and metal oxide nanoclusters of its constituent elements. Moreover, the formation of nanoclusters and generation of plasmons are verified by electron energy loss spectra obtained by UPS analysis, FESEM, and spectroscopic ellipsometry. Additionally, calculation of valence bulk, valence surface, and particle plasmon resonance energies are performed, and indexing of each plasmon peaks with corresponding plasmon energy peak of the different nanoclusters are done. This approach offers a convenient method to produce plasmon resonance across the broad spectral range spanning 2.1-10.74 eV. Further, use of this dual ion beam sputter instigated plasmon enhanced absorbers can be a novel mean to enhance the performance of photovoltaic devices.

Alkali metal (Na, K, Rb, and Cs) incorporation or post-deposition treatment (PDT) is known to be effective in improving the conversion efficiency of Cu(In,Ga)Se₂ (CIGSe) and Cu(InGa)₅(S)₇Se₃-thin film solar cells. Among them, Cs has been known to boost Voc and Jsc in CIGSe, and the world-record cell is also based on this technique. A new world-record CIGSe efficiency of 22.9% has been achieved in the research cell of Solar Frontier K.K, by CsF-PDT. However, CsF-PDT effects have been rarely studied, and therefore, it is worth to investigate the Cs incorporation.

This study reveals CIGSe-post-deposition treatment (PDT) effects on a Cu(InGa)₅(S)₇Se₃ (CIGSe) cell in comparison with KF-PDT effects. After CIGSe growth, we performed three different alkali-PDTS (KF, CsF, and combined KF + CsF) on CIGSe thin films, and examined the material and cell properties. Both KF- and CsF-PDT CIGSe cells showed similar cell efficiency improvements (~17.5%) compared to the untreated CIGSe cell (~16%). However, the reasons for the improvement differed. The CIGSe cells with KF-PDT exhibited further reduction in the recombination at the CdS/buffer interface compared to the CsF-PDT CIGSe cell. On the other hand, the CIGSe cell with CsF-PDT exhibited further reduction in the recombination in bulk compared to the KF-PDT CIGSe cell. Therefore, the overall conversion efficiency (18.4%) due to cooperative alkali incorporation effects. This device exhibited reduced recombination at both the Cds/CIGSe interface in the space charge region (SCR) and bulk compared to all other cells. Finally, we achieved a highly efficient combined alkali-PDT CIGSe device (20.15%) by applying a MgF₂ anti-reflective coating layer.

The biggest difficulty for improving the power conversion efficiency of Cu₂ZnSn(S, Se)₄ (CZTSSe)CdS/ZnO thin film solar cells is improving the open circuit voltage (VOC). Probably leading causes of the VOC deficit in CZTSSe devices have been identified as bulk recombination, band tails, and the intertwined effects of CZTSSe/CdS band offset, interface defects, and interface recombination. In this work, we predicted the CdS buffer layer by Mg-doped ZnO (Mg₂Zn₁₋ₓSnₓO) and measure the interface of n-type Mg₂Zn₁₋ₓSnₓO (MZ1) p-CZTSSe heterojunction interface can be determined by the core-level photoemission-based method. Here, the calculation of was done by two methods: (1) considering different core level peaks of Se 3d and Mg 2p for CZTSSe and MZ1, respectively, and (2) considering same core-level peaks of Zn 3d for CZTSSe and MZ1. The values of valence band onset (VBOn), as obtained by linear extrapolation of the onset of the valence band, are 2.97 and 0.54 eV, respectively. Figure 1(a) shows the core-level peaks of the MZ1/CZTSSe heterojunction. The core-level spectra of Zn 3d recorded on the MZ1/CZTSSe heterojunction is dominated by one symmetric peak, implying a uniform bonding state. Figure 1(b) shows transmission spectra using ellipsometry. Figure 1(c) shows the energy band diagram calculated using Ultra violet photoelectron spectroscopy (UPS).
Correlated to linear behavior of I-V experimental curves as measured by four-point probe on MoS

Modeling Influence of Diffuseness on Real-Life Solar Module Performance

ES20.07.37

Improved for the sulphurised samples. The formation of stoichiometric CZTS is an important factor to use it as an absorber layer in a thin film solar cell. The Ultra-violet Cu, Zn, Sn, S in required ratio. The presence of O and C was also detected due to atmospheric contamination. It is evident from the atomic % calculation that the stoichiometry has their composition are discussed in this paper. The composition of the CZTS thin film samples were studied using X-ray photoelectron spectroscopy, which revealed the presence of Cu, Zn, Sn, S in required ratio. The presence of O and C was also detected due to atmospheric contamination. It is evident from the atomic % calculation that the stoichiometry has improved for the sulphurised samples. The formation of stoichiometric CZTS is an important factor to use it as an absorber layer in a thin film solar cell. The Ultra-violet photoelectron spectroscopy was used to study the ionization energy, electron affinity, electronic band gap of the material and the data were in relation to reported results. Thus, from the XPS results it is obvious that the sulphurised CZTS thin films can be used as absorber layer in a thin film solar cell.

Modeling Influence of Diffuseness on Real-Life Solar Module Performance

In this work, we investigate the effects of heat, light and voltage bias on the metastable behavior of CIGS solar cells through accelerated stress tests (AST) on the order of days (50 - 100 hours) in influence to the thin-film PV stabilization tests in IEC 61215-2 standards. A comprehensive analysis of devices with different alkali treatments using current-voltage (I-V), capacitance-voltage (C-V), quantum efficiency (QE), time-resolved photoluminescence (TRPL), and time-of-flight secondary ion mass spectroscopy (ToF-SIMS) to propose a preliminary mechanism for changes in device parameters with AST. Additionally, in-situ I-V characterization has been used to determine activation energies of change in $V_{oc}$ to further understand the effect of Na incorporation on the underlying mechanisms.

Three sample types were prepared at ZSW for accelerated stress testing: Type A with baseline Na, Type B with intended reduced Na with the introduction of a sputtered AlO$_x$-AlN barrier to reduce Na diffusion from the substrate and Type C with baseline Na plus a RbF post-deposition treatment. The CIGS layer was deposited by coevaporation process and the CdS buffer layer was deposited by chemical bath deposition (CBD) according to standard procedures. The buffer-window stack for Types A, B and C samples was CBD CdS followed by sputtered undoped ZnO and Al-doped ZnO layers. The cells were completed with Ni/AlNi grid contacts and the cell separation was done by mechanical scribing. Three primary stress factors considered in this study are voltage (low and high internal field), illumination (light and dark), and temperature (room temperature to 85°C). Under illumination and open-circuit (OC) conditions, the photogenerated charge carriers must recombine entirely internally, resulting in a decrease in built-in field. However, under short-
A conversion efficiency up to 20% have been recently achieved on the thin film cells using epitaxial Cu(In,Ga)Se$_2$ epi-CIGSe absorbers [1]. This high performance, large domain size and surface smoothness make the epi-CIGSe one of the excellent platforms to investigate electronic structure and effect of post deposition treatment (PDT) on it. In this study, we have studied surface potential, surface photovoltage over epi-CIGSe, band alignment at CdS/epi-CIGSe interface and effect of PF-KPT on them by Kelvin probe force microscopy, and photoemission and inverse photoemission spectroscopy.

Epi-CIGSe absorbers composed of Cu$_{n}$(In$_{0.6}$Ga$_{0.4}$Se$_{2}$ bottom- and Cu$_{n}$In$_{1-x}$Ga$_{x}$Se$_{2}$ top-layer grown on GaAs (001) substrate by molecular beam epitaxy were used as specimens. The cells using epi-CIGSe absorber and ZnO window layer of deposition of ZnO and light soaking showed a conversion efficiency of 20%. Details of preparation conditions were shown in the previous paper [1]. Surface photovoltage was determined from surface potential change induced by illumination of 685 nm light with an intensity about 10 mW/cm$^2$. CdS buffer was deposited onto the epi-CIGSe by $in$-situ evaporation. All of the measurements were performed at a pressure of low 10$^{-5}$ Pa scale.

AFM measurements reveal that surfaces of the epi-CIGSe consist of wide and atomically flat terraces and ridges with a height below few tens nm. The latter is parallel to anti-phase domain boundaries along [1 1 0] direction of the chalcopyrite phase. It is noteworthy that any edges of crystalline facets are hardly observed. Surface potential of the polycrystalline CIGSe films consists of two components and the width of each component is about 120 mV. These features are attributed to variations in crystalline planes and in surface terminations over poly-CIGSe. KF-PDT selectively suppressed the higher voltage-side component that should be attributed to anion-termination dominant facets. For the polycrystalline CIGSe films consists of two components and the width of each component is about 120 mV. These features are attributed to variations in crystalline planes and in surface terminations over poly-CIGSe. KF-PDT selectively suppressed the higher voltage-side component that should be attributed to anion-termination dominant facets.
Among the alternatives for CdS buffer layers in Cu(In,Ga)Se₂ oxidation-/reduction cycles and their reversible effect on the dipole formation on chalcopyrite surfaces, sometimes even above, CIGSe devices with a chemical bath-deposited (CBD) CdS buffer layer. Additionally, increasing the Ga/(Ga+In) (GGI) ratio allows increasing the bulk.

To evaluate the band alignment of CdS/CZTGe heterointerface, n-typed CdS buffer was deposited onto the CZTGe by thermal evaporation technique. He(I,2s) and Al(Ka) lines were used as the light source in the UPS measurements. All the bands of the CBD, UPS, IPS, and CDS depositions were performed in ultra-high vacuum condition (pressure < 10⁻⁷ Pa) without air exposure.

The UPS and IPS reveal the Fermi-levels are located near the center of the bandgap of CZTGe with x from 0 to 1. Although this hole concentration is much smaller than that (~10¹⁸ cm⁻³) in the CZTGe bulk, laser-irradiated XPS revealed that the origin of the hole deficiency near the surface is due to defects distributed closer to CZTGe surface than in the bulk, rather than Fermi-level pinning at the CZTGe surface. Moreover, we determined the conduction and valence band offset (CBO and VBO) at the CdS/CZTGe heterointerface relative to Ge composition x by using XPS, UPS, and IPS measurements by stepwise CdS deposition (e.g. CdS film thickness = 0, 3, 6, 30 nm). The CBOs decreased from -0.36 to -0.01 with increasing of x. A positive CBO indicates that the position of the conduction band minimum (CBM) of the CdS is higher than that of CZTGe, which is so-called “spike” conduction band alignment whereas the band alignment is flat in x = 1. In contrast, the VBOs remain constant and are around 1.1 eV. We revealed these CBO and VBO relative to Ge composition can be explained by the theoretical calculation. In the case of high performance CIGS heterojunction solar cells, the CBO at the Cds/CIGS heterointerface have CBOs from 0 to ~0.30 eV. Concerning it, we conclude CBOs at the CdS/CZTGe heterointerface with x from 0 to 1 are significant adequate value for the high performance solar cells in a point of electronic structure at the interface. Despite of it, cell performances of our CdS/CZTGe heterojunction solar cells drastically decreased with increasing of x over 0.2. We will discuss the relationship between band alignment of CdS/CZTGe and solar cell performances.

Among the alternatives for CdS buffer layers in Cu(In,Ga)Se₂ (CIGS)-based thin-film solar cells, In₅S₃ is a very promising candidate, leading to cell efficiencies very close to, or sometimes even above, CIGS devices with a chemical bath-deposited (CBD) CdS buffer layer. Additionally, increasing the Ga/(Ga+In) (GGI) ratio allows increasing the bulk band gap of the absorber, which in turn is expected to lead to higher open-circuit voltages. To optimize the design for both, GGI ratio and alternative buffer layer, an important prerequisite is a detailed knowledge of the electronic and chemical structure of CIGS absorber surfaces with varying GGI ratios, their interfaces with CBD-In₅S₃ buffer layers, and the chemical and electronic properties of the final film (i.e., full-thickness buffer layer). In this contribution, laboratory-based photoelectron spectroscopies (XPS, UPS, IPS), x-ray excited Auger electron spectroscopy (XAES), as well as synchrotron-based soft-x-ray emission spectroscopy (XES) are used to acquire this information. With these complementary spectroscopic methods, important insights into, e.g., elementary ratios at the surface of the investigated absorbers, intermixing processes at the interface, buffer layer growth properties, and characteristic species in the buffer layer, are gained. The results of these measurements allow us to discuss the chemical and electronic structure of the CIGS-In₅S₃/CIGS interface for different GGI’s.

An assessment of the intrinsic electronic properties of chalcopyrite surfaces is crucial to understand the characteristics of the window/absorber interface and related post-deposition treatments in chalcopyrite solar cells. However, a basic understanding of the involved processes is complicated by surface oxidation, granular inhomogeneities and grain boundaries. To gain access to the fundamental electronic properties of chalcopyrite surfaces, we focus on epitaxially grown CdSe₅S₃ (epi-CISe), which forms the energetically most favorable {112} facets upon slight Cu depletion. Scanning tunnel spectroscopy (STS) is a valuable tool in assessing whether chalcopyrite surfaces are electronically defective or passivated. Here, we carry out STS measurements on epi-CISe surfaces along with complementary surface-sensitive techniques such as X-ray, ultraviolet and inverse photoelectron spectroscopies (UPS/IPS/IPS). In this way, the local defect density is correlated with the energy level alignment and dipole effects at the surface upon various annealing and wet-chemical treatments relevant for device fabrication.

We compare the initial (as-grown) condition of epi-CISe samples (without any air exposure) to the states after oxidation in air, etching in NH₃ or KCN, as well as subsequent annealing in ultra-high vacuum (UHV). In the as-grown condition, the sample surface is found to be intrinsically passivated with a low defect level density. Based on this, a consistent determination of the surface band gap by STS and UPS/IPES reveals a value of 1.65 eV in accordance with density functional theory calculations reported earlier. Furthermore, our measurements provide evidence for the absence of any local or global surface dipole(s). These findings are in line with previous theoretical models predicting that the intrinsic dipole(s) of the polar facets in CISe are compensated by shallow surface defects. Nevertheless, our STS data do not show any spectral signatures of the corresponding defect levels, possibly due to their shallow nature. In contrast, upon oxidation in air, an overall high surface defect level density in conjunction with a considerable net-surface dipole associated with a potential drop of ~0.7 eV at the surface is observed. This surface dipole is accompanied by an upward band bending that shifts the surface Fermi level position from mid-gap (for the as-grown state) to p-type conditions. The high defect level density together with the dipole layer and the upward band bending persist even after removal of the surface oxides by wet-chemical NH₃ or KCN etching. Yet, a subsequent annealing in UHV restores the initial sample condition, as concluded from the absence of surface dipoles and passivation of surface defect levels. Our results shed new light on previous reports on lateral inhomogeneities on polycrystalline chalcopyrite surfaces, emphasizing the relevance of oxidation-induced dipole effects on chalcopyrite surfaces for the window/absorber interface design in chalcopyrite solar cells.

10:00 AM BREAK
CIGS solar cells are known to exhibit strong metastable behaviour and, in consequence, lot of experiments do not follow textbook interpretations. To name only two most basic measurements - light current voltage characteristics, and hence the parameters which determine the efficiency, as well as free carrier concentrations revealed by capacitance profiling, depend very strongly on the direction of the voltage sweep and/or the history of the sample. Therefore, sooner or later, everyone dealing with electro-optical characterization of CIGS solar cells experiences a kind of frustration, and metastable behaviour is often seen as an obstacle to understanding and progress. In this presentation we will show that, if analyzed with care, metastabilities can also serve as a valuable tool for investigation of CIGS-based devices. We will begin with a proposition of new classification of metastabilities. Then, we will critically review the theoretical models proposed to explain some of the observed phenomena with a special emphasis on their importance for the interpretation of experimental results. Finally, we will present how the analysis of metastable behaviour can shed some light on the role of sodium, potassium, and the deposition of different buffer layers.

Analysis of Recombination as a Function of Depth in Cu(In,Ga)(S,Se)2 Solar Cells
Alban Lafuente-Sampaio1, Jingdong Chen1, Shenghao Wang1, Mohamed M. Islam1, Takuya Kato1, Hiroki Sugimoto2, Katsuhito Akimoto3 and Takeaki Sakurai1; 1University of Tsukuba, Tsukuba, Japan; 2Solar Frontier, Tokyo, Japan.

A world record for Cu(In,Ga)(S,Se)2 (CIGS) efficiency of 22.9% has been achieved recently by Solar Frontier K.K. using Cesium treatment (Cs treatment). A common explanation for the high efficiency of the cells after alkali metal treatment is that processing passivates defects at the p-type CIGS absorber surface or grain boundaries. It is also known that the high performances of CIGS treated with alkali metal are linked to an increase of the open circuit voltage (VOC) [1]. However, the underlying physics of this effect has yet to be fully understood. To analyse the recombination mechanisms, we investigated the open current voltage at different excitation wavelengths and intensities of CIGS solar cells treated with potassium treatment (K-treatment). Based on the dependence of the CIGS Se absorption coefficient with wavelength, low energy radiation will penetrate deeper in the alloy than high energy one. Thus, the variations in wavelength and intensity open the possibility to study the recombination at different depths in the cells. Looking at VOC evolution, we can deduce the recombination rate of the CIGSSe as a function of the depth. The results of such experiment show that the untreated samples VOC decreased with excitation intensity and presents a dependence with the excitation wavelength, while the K treated samples does not have such a behaviour. This evidence a defect level in the absorber of the untreated sample which obstruct the collection of the carriers in the bulk. Using UCSAP-1D device modelling software, with a double grading structure, we investigated the recombination rate in the solar cell as a function of the depth. We evidence two different regions of recombination, in the bulk and in the depletion region. We show that the amount of recombination in each of the region depends both on the excitation wavelength as well as on the excitation intensity. The simulation was also done for different defect density, which shows that for a low defect density, recombination occurs only in the bulk, while for high defect density, recombination also occurs in the depletion layer. This creates a loss for the carrier collection, reducing the solar cell efficiency. The increase of the VOC in K-treated sample is then well explained by suppressing defect levels in the absorber layer.

11:15 AM ES20.09.03
Phonon Coupling and Shallow Defects in CuInS2
Alberto Lomuscio, Mohit Sood, Michele Melchiorre and Susanne Siebentritt; University of Luxembourg, Belvaux, Luxembourg.

Copper indium gallium disulfide Cu(In,Ga)S2 or CIGS is a promising absorber material for thin film solar cells due to its direct band gap energy that can be tuned from 1.5 eV (pure CIS) to 2.4 eV (pure CGS). It is suitable to make single- and multi-junction solar cells. In fact, it could be used as top cell in a tandem configuration with Si or CIGSe as bottom cell. However, Cu(In,Ga)S2-based solar cells still suffer from a low efficiency compared to their counterpart Cu(In,Ga)Se2-based solar cells, that have reached a record conversion efficiency of 22.9%. This is mainly due to a low open circuit voltage. Recently, a new fundamental breakthrough came when Hiroi et al. reached the world record efficiency of 15.5% with pure sulfide CIGS solar cell[1] and open circuit voltage up to 973 mV, using processing temperatures above those used traditionally (~550°C). Nevertheless, there is a lack of knowledge regarding the recombination processes and intrinsic defects for this chalcopyrite material. In fact, a deeper understanding is needed to better control the electronic properties, therefore to further improve the performance of devices based on this absorber material.

In this work, we present a detailed photoluminescence (PL) investigation of polycrystalline CIS thin film and we compare the results to those reported in literature. The sulfide CIS absorbers were deposited on molybdenum coated soda lime glass in a PVD system under copper excess (Cu-rich) in a single stage coevaporation using a deposition temperature of 650 °C. The secondary phase CuS was removed by KCN etching, reaching a Cu over In ratio of 1. The low temperature PL measurements were carried out with a 663 nm wavelength laser as excitation source using a liquid Helium flow cryostat. Moreover, temperature dependent admittance measurement (ADM) were carried out on both finished devices and aluminium coated absorbers to form a Schottky contact. The PL spectra recorded at 10 K are dominated by excitonic luminescence together with defect related peaks at 1.39 eV, 1.35 eV, 1.31 eV and 1.27 eV. The excitation dependent measurements over seven order of magnitude revealed that the 1.39 eV is a donor-acceptor transition (DA) with an energy shift of the peak position of 3 meV/decade. The same shift has been found for the other transitions at lower energy. The three peaks at 1.35 eV, 1.31 eV and 1.27 eV well match the Poison distribution as phonon replica of the main peak (1.39 eV) with a Huang-Rhys factor of 0.45 and a phonon energy of about 40 meV. We therefore attribute this series of peaks to a DA transition with its phonon replica. In order to get the energy position of the defects involved in the DA transition, temperature dependent PL has been performed. We found that at 90 K the luminescence clearly becomes a free to bound transition (FB), with the shallower defect ionized. From its peak position, we extracted a defect energy of 140 meV. This value is in good agreement with the activation energy of the main step of the capacitance measurements on both devices and Schottky contact.

We do show that the 140 meV defect is a bulk defect and not an interface defect as reported in some previous works. In addition, we attribute the 1.35 eV peak to the first phonon replica of the main DA transition, together with second and third one clearly visible. This is in contradiction with previous reported studies that generally explain the 1.35 eV transition as DA with a deeper donor involved, because the further phonon replica could not be detected.

maximum achievable $V_{OC}$ that a semiconductor can generate in a solar cell and it can be determined from the external photoluminescence quantum yield (EQE$_{PL}$). We evaluate the $V_{OC}$ defect by comparing the calculated QFLS to their theoretical maximum $V_{OC}$ (in the absence of non-radiative recombination). The use of quantitative PL for calculating the $V_{OC}$ defect enables the possibility to use it in bare absorbers, powders or single crystals. This allows for differentiation of non-radiative recombination losses introduced by other layers of a solar cells stack or by the presence of grain boundaries.

We use hyperspectral quantitative PL imaging to characterize several kesterite type materials in the form of thin films, powders and single crystals. One of the recent strategies tested to overcome the $V_{OC}$ deficit limitation of kesterites has been the partial replacement of Cu, Zn and Sn cations by other elements. We also analyzed the effect in the QFLS of the incorporation of several elements in kesterite-photo voltaic materials, including Li and Ge in high efficiency solar cells and Ag in CZTSe powders. We observe that the EQE$_{PL}$ increases by the incorporation of Ag and Li in CZTSSe. Based on our results we propose some recommendations to further reduce non-radiative recombination and the $V_{OC}$ deficit in kesterite solar cells by cationic substitution.

11:45 AM ES20.09.05
Composition-Dependent Charge Carrier Dynamics at Mg$_{x}$Zn$_{1-x}$O/CdTe Interface

Niraj Shrestha, Geethika K. Liyanage, Adam Phillips, Michael Heben and Randy J. Ellingson; The University of Toledo, Toledo, Ohio, United States.

Recent studies have shown that correct conduction band alignment at the emitter/absorber interface in photovoltaic devices leads to reduced interface recombination and higher device performance. Mg$_{x}$Zn$_{1-x}$O (MZO) is an interesting choice for the emitter because (1) it is a wide bandgap material that will not absorb photons and (2) the conduction band can be controlled by changing the Mg concentration. Consequently, MZO is being incorporated into CdTe devices. Unfortunately, few groups have demonstrated the improved device performance when using MZO alone. This suggests that the band alignment is not correct or new interface defects are being introduced. Here we investigate the carrier lifetime of sputtered CdTe devices using steady-state and time resolved photoluminescence spectroscopy (TRPL). Our preliminary results show that carrier lifetime increases as the bandgap of the MZO increases from 3.4 eV to 3.7 eV. We attribute the reduction of interfacial recombination to improved band bending in the CdTe as a function of better band alignment between MZO and CdTe. We will extend our study to determine if the conduction band alignment alone is responsible for reduced recombination by varying the MZO dopant density. We will show that TRPL can be a quick tool to determine if appropriate band alignment and bending have been achieved.

SESSION ES20.10: Calculation and Prediction

2:00 PM *ES20.10.01
Disorder Effects in Photovoltaic Chalcogenides and Nitrdes
Stephan Lany; National Renewable Energy Laboratory, Lakewood, Colorado, United States.

In multinary compound semiconductors, cation disorder can decisively alter the electronic properties and impact potential applications. Computationally, this problem can be addressed by a tiered approach, where we map total energies from density functional theory onto a model Hamiltonian, which can be subsequently used in Monte-Carlo simulations. The resulting disordered atomic structures are then fed back into first principle calculations for the electronic structure, yielding properties such as the band gaps and optical spectra, and the inverse participation ratio describing localization in the density of states. This presentation will review recent work on disorder effects in chalcogenides, such as Cu$_2$SnS$_3$ and Cu$_2$ZnSnS$_4$,[1] and the photovoltaic ZnSnN$_2$[2]. We will further touch upon new nitrdes of potential interest to photovoltaics, such Mg3SBN and candidates emerging from a broader nitrde search.[3]

2:30 PM ES20.10.02
Predicting Defect Formation Energies from Statistical Learning of Bulk Properties
Amit Samanta, Joel B. Varley and Vincenzo Lordi; Lawrence Livermore National Laboratory, Livermore, California, United States.

Point defects play an important role in determining a wide variety of materials properties and detailed analyses of their role often necessitates the evaluation of their formation energies and transition levels. Generally, formation of point defects involves displacing few atoms from their ideal positions meaning that defect formation is very localized process that involves very little degrees of freedom of a system. In this talk, I will illustrate how machine learning techniques can be used to predict formation energies and transition levels of native defects in III-V and II-VI semiconductors with a quantifiable uncertainty using a set of simple descriptors, like branch point energy and dangling bond energies. These descriptors can capture local neighborhood information as well as structural information and can be evaluated easily from ab initio simulations. Our analysis opens avenues for predicting the stability of defects in complex materials and alloys by training a coarse-grained model which can significantly simplify experimental design and material synthesis.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Machine Learned Defect Level Predictor for Cd-Based Chalcogenides
Arun Kumar Mamodi Kanakkithodi, Michael Davis and Maria K. Chan; Argonne National Laboratory, Argonne, Illinois, United States.

Impurities and defects in the band gap are critically important in photovoltaic (PV) materials, including thin film chalcogenides, as recombination centers, dopants, or passivants. Predicting formation energies and charge transition levels for defects in these PV materials is thus paramount; density functional theory (DFT) calculations have been widely applied for such studies. However, the requirement of large supercells and inclusion of charged states make these computations very expensive, and trends and knowledge from previous calculations are not exploited in subsequent ones. In this work, we use DFT to generate a substantial computational dataset of the formation energies and transition levels of vacancy, interstitial and substitutional point defects in Cd-based pure and alloyed chalcogenide systems (CdX, where X is O or a combination of S, Se, Te). The hybrid HSE06 functional is used for these calculations to correct for the band gap and band edge miscalculation that is characteristic of the standard PBE functional for this class of materials. We then apply machine learning techniques to extract crucial design rules and predictive models from the data, via the intermediate process of numerically representing any defect in terms of easily calculated structural and electronic properties of defect atoms, their known compounds, and using information from cheaper, lower-fidelity calculations. Using correlation analysis and regression techniques, we obtain accurate predictive models for formation energy and every relevant transition level that require only a handful of descriptors as input. These models are used to make predictions for defect energy levels in thousands of unexplored cases, such as Cd(Se,Te) which is of current interest, thus expanding our knowledge to wide areas of the chalcogenide chemical space. The machine learning strategy used here can lead to a framework for accelerated prediction of defect properties and allow efficient materials design for performance improvements in Cd-chalcogenides as well as other PV materials.

3:00 PM BREAK

SESSION ES20.11: Module Fabrication and Stability
Session Chairs: Amit Munshi and Mario Ochoa
Cadmium telluride (CdTe) solar cells have been researched for decades and through this time very few key technological step changes have been critical to its success: I. the superstrate process that forms a buried passivated junction, II. the annealing in a chlorine containing atmosphere, III. a stable copper back-contact, and IV. the introduction of selenium to grade the absorber structure. First Solar’s thin-film CdTe solar cells have been certified at 22% cell efficiency. The presentation will review our understanding of the performance limiting mechanisms and opportunities to further improve efficiency. Desirable improvements often conflict with established processes and material choices and this places significant constraints on the development of new technology components. One of these improvements, is to replace the p-type dopant in the absorber layer with a dopant from the 5th column of the periodic table. Over the last two years, First Solar has made steady progress on realizing a Group-V doping in polycrystalline CdTe and the first milestone was the consistent demonstration of greater than 10% cm² hole concentration with a flat doping profile and narrow depletion width. It has been challenging to produce the desired improved Voc with an alternative dopant and we will review evidence that may point to a direction on how to overcome the limitations.

First Solar’s leading thin-film manufacturing capabilities are in process of ramping the new utility-power optimized Series 6 module. Series 6 modules will have power ratings up to 440 Watts with an optimized design to lower installation and other balance of system cost. It will preserve First Solar existing CdTe module power density advantage superior temperature coefficient, spectra and shading response.

As CIGS PV technology has matured to production on an industrial scale, its long-term stability becomes increasingly important. The electric yield and thus the revenue of a PV system depend on both the initial conversion efficiency as well as its development over time. Increasing this long-term stability by understanding and lowering the degradation of CIGS technology is therefore a key strategy for its market success. Furthermore, increasing the long-term stability of individual solar cells allows to lowering the demands and thus the cost of barrier materials necessary for flexible CIGS modules. Literature has revealed that large differences in the stability of CIGS modules in the field have been observed. Therefore it is important to identify, predict and prevent degradation mechanisms.

An overview of degradation mechanisms occurring in CIGS solar cells and modules (observed in the laboratory and field experiments as obtained from literature) will be presented.

A first reason for the long term performance loss of CIGS solar cells and module is water ingress. Tests have shown that humidity can cause the increase of sheet resistance of the ZnO:Al front contact, while it can also deteriorate the interconnection conductivity, especially in the P2. Both effects can lead to an increased series resistance. Methods to mitigate the degradation of the ZnO:Al front contact on cell level are thicker layers, higher deposition temperatures, post deposition annealing, higher carrier concentrations and smoother underlayer substrates. The use of alternative TCOs like ITO and IO:H can also improve reliability. Moreover, the presence of humidity combined with a bias voltage can lead sodium migration, which can cause severe shunting. Strong effect of the sodium content on this degradation mechanism has been observed. Fortunately, most sources reveal that exposure to only elevated temperatures and illumination do not harm, or even improve solar cell performance.

Another degradation mechanism occurring in the field is power loss due to partial shading of CIGS modules. If one or several cells in a module are covered by e.g. bird dropping, humans, animals or trees, a reversal of the power flow can occur in the shaded area. In a module cells are connected in series, due to this series connection a current is forced through the shaded cells, resulting in a reversed power flow over the shaded cells, often referred to as negative or reversed bias. It was observed that very short shading events of seconds could lead to degradation of the modules.

Modules degraded due to partial shade show very typical symptoms, which are: Reduction of FF due to reduced Ideg/Isc ratio; Small dark spots in electroluminescence due to localized shunts corresponding with worm-like defects, visible by naked eye; Non-permanent effects were also observed: the electrical performance can either reduce and increase over time after exposure to reverse bias. This effect seems strongly dependent on the module type.

The reverse characteristics can be modified by a change in buffer layer composition and thickness, although the relation with degradation has up till now not been made.

Another degradation mechanisms that mostly has been observed in the field is Potential-Induced Degradation (PID). This is caused by the exposure of modules in the (negative) end of a string to voltages as high as 1000 V. PID has been identified on CIGS modules by a combination of electroluminescence and IV measurements. PID is also a common defect for crystalline silicon modules, where it is associated with sodium migration, mostly from the front glass. For CIGS, the sodium could originate from the substrate glass.

In the present study, standard cells of 0.5cm² of the mini-module are compared to that of small-area cells, additional characterizations (SEM, Raman, XPS, XRD) were performed and led to the following hypotheses. As all of the layers composing the devices (i.e. small cell and mini-module) were grown simultaneously, the parameters potentially explaining the observed lowered Voc/cell (mini-module) relative to that of small-area cells, additional characterizations (SEM, Raman, XPS, XRD) were performed and led to the following hypotheses. As all of the layers composing the devices (i.e. small cell and mini-module) were grown simultaneously, the parameters potentially explaining the observed lowered Voc/cell of the mini-module are reduced to that of small-area cells, additional characterizations (SEM, Raman, XPS, XRD) were performed and led to the following hypotheses. As all of the layers composing the devices (i.e. small cell and mini-module) were grown simultaneously, the parameters potentially explaining the observed lowered Voc/cell of the mini-module are reduced to that of small-area cells, additional characterizations (SEM, Raman, XPS, XRD) were performed and led to the following hypotheses. As all of the layers composing the devices (i.e. small cell and mini-module) were grown simultaneously, the parameters potentially explaining the observed lowered Voc/cell of the mini-module are.

The photovoltaic performance demonstrated here in this alternative architecture opens new routes to drastically decrease the gap observed between small-area-cells and industrial modules.

Cu(In,Ga)(S,Se)² based thin-film solar cells have recently achieved the outstanding performance of 22.9% efficiency at the laboratory scale. In contrast, the best performance of CIGS solar commercial modules does not exceed 15.5%. Such a difference is partially inherent to the actual architecture of the modules (P1, P2, P3 patterning), leading to a decreased active area, an increased series resistance as well as optical losses due to the decreased sheet resistance of the transparent conductive oxide (e.g. ZnO:Al). To overcome these limitations, we propose a modified architecture of modules where the cells are interconnected via metallic grids. This monolithic approach consists in using Ni/AlNi grids to electrically connect the rear contact of the cell N to the top window layer of the cell N+1. Independently of absorber band gap energy, this architecture allows (i) increasing the width of the cells, thereby decreasing the surface ratio of inactive area and (ii) decreasing the thickness of the ZnO:Al layer without resistive losses, thereby minimizing the optical losses.

In the present study, standard cells of 0.5cm² and alternative modules composed of 3 cells connected in series are investigated. The most impressive result concerns the FF achieved with the alternative module, which reaches the value of 81%, yielding an active area efficiency of 17.2%. The Voc of the alternative module is 2.05 V (i.e. 684 mV per cell), which is close but still lower than the Voc of the standard small-area cell (702 mV). In order to further explore the potential origins of such lowered Voc/cell (mini-module) relative to that of small-area cells, additional characterizations (SEM, Raman, XPS, XRD) were performed and led to the following hypotheses. As all of the layers composing the devices (i.e. small cell and mini-module) were grown simultaneously, the parameters potentially explaining the observed lowered Voc/cell of the mini-module are.

The photovoltaic performance demonstrated here in this alternative architecture opens new routes to drastically decrease the gap observed between small-area-cells and industrial modules.
zone. The size of the dead zone is typically in the range of ~350 um for commercial modules. The ratio between this dead zone and the small cell size is one of the factors that play a large role in the cell to module losses. The selective removal steps or scribes that are present in the monolithic interconnection can be made using laser scribing (P1, P2) or mechanical patterning (P2, P3). Laser scribing has the advantage of precision and lesser peripheral damage as compared to mechanical scribe. Industrially also laser scribing is preferred due to wear of the needle in mechanical patterning. Higher yield and smaller dead area in the interconnection make that successful laser scribing is important for improvement of the module efficiency.

In the monolithic interconnection the P1 scribe separates the metal back contact and is typically done with a laser. The P2 creates the connection between the bottom and top contact of neighboring cells and both laser as well as mechanical scribes are used. The P3 that isolates the top contact (TCO) of the cells is typically made using a mechanical scribe. Laser scribing of the P3 however is challenging because CIGS is very thermally sensitive. It has been shown that laser patterning of CIGS induces formation of conductive species. These conductive species create shunts in the scribe that are detrimental to the efficiency [1].

In this work we show the use of Raman spectroscopy for identification of shunt-free P3 scribe using a pulsed laser. Ablation of the TCO is the minimum requirement to form the P3, but removal of CIGS is an added advantage since CIGS has lateral conductivity. Melting of CIGS which leads to formation of conductive species needs to be avoided for good isolation in the P3.

Material removal by a typical laser scribing process involves rapid heating, melting and evaporation material. The thermal sensitivity of the CIGS can results in molten scribe edges, redeposition of conductive material and compositional changes within the layer next to the scribe. Different laser parameters were systematically studied for pulsed infrared laser scribing of CIGS including pulse duration, pulse overlap and laser fluency. Raman spectroscopy in conjunction with SEM, EDX and lock-in thermography was used to identify compositional changes in the area of the scribes.

In our research we have shown that Raman spectroscopy is a very suitable technique to monitor melting and shunt-free scribing in CIGS. We will explain our approach of using Raman line-scans over the laser scribe and the use of a contour plot. This approach allows for clear differentiation between shunted versus shunt-free scribes looking at the broadening of the main 177 cm⁻¹ CIGS peak and the appearance of a CIS peak at 290 cm⁻¹. Finally we show that shunt-free laser scribing of a P3 in CIGS is possible using a pulsed infrared laser.

**Using Correlative EBIC-EBSD-APT to Identify Limitations in Cu(In,Ga)Se₂ Photovoltaic Cells**

*Jens Keutgen, Oana Cojocaru-Mirédin and Mohit Raghuwanshi; RWTH Aachen University, Aachen, Germany.*

Solar cells based on Cu(In,Ga)Se₂ (CIGS) present efficiency of up to 22.9% and is highest among other thin film photovoltaics, but considering Shockley-Queisser limit (33.7%) there is still a big room for improvement. Impressively, over the years, its maximum efficiency is achieved in its polycrystalline form, even with its small grain sizes of 2 μm. Previous studies have shown an important role of all grain boundaries (GBs) 2–4 towards its output efficiency. Here using electron beam induced current (EBIC) technique we found that most of the GBs are indeed beneficial for the device, however a small percentage (15%) of GBs was found detrimental. Hence, in this work we have isolated these detrimental GBs and perform correlative EBIC-EBSD and atom probe tomography (APT) on them to identify its type, structure and composition as shown in Figure 1. These results show that detrimental GBs are mainly enriched in Cu and O and depleted in Ga. Whereas characteristics of a beneficial GB are Cu depletion, no O and no change in Ga. With sufficient statistics, we have obtained characteristics of ‘detrimental’ GBs, which could be avoided in future by variation in deposition parameters and post deposition treatments.

**Suitable Complex S-Se Graded Bandgap Profiles on Kesterite-Based Solar Cells**

*Jacob Andrade-Arvizú, Victor Izquierdo-Roca, Ignacio Becerril, Pedro Vidal-Fuentes, Maxim Guc, Yudania Sánchez, Sergio Giraldo, Zacharie Jehl, Marcel Placidí, Alejandro Pérez-Rodríguez and Edgardo Saucedo; Solar Energy Materials and Systems, Catalonia Institute for Energy Research (IREC), Sant Adrià de Besós, Spain; IN2UB, Departament d’Electrònica, Universitat de Barcelona, Barcelona, Spain.*

Graded band concepts have been shown to be a disruptive issue in order to achieve high efficiency devices in thin film chalcopyride photovoltaics. In the case of kesterite (Cu₂ZnSn(S,Se)₄ or CZTSe) in short) based solar cells, two main strategies are being explored in order to achieve bandgap grading: cationic substitution (Cu by Ag, Zn by Cd, Sn by Ge and Si) and anionic (S-Se) compositional engineering. Both the cationic and anionic substitutions are complementary as they primarily affect either the conduction (cation) or valence (anion) bands. The specific control of the anionic composition along the volume of kesterite absorbers has been found challenging due to the similar formation energy of selenide and sulfide compounds that favors S-Se solid solutions over phase segregation. This work presents the development of a novel and non-toxic reactive annealing process that allows the synthesis of CZTSe solar cells with S-Se sharp graded compositional profiles and sheds light onto the dynamics of anionic bandgap grading in kesterite solar cells. By using different sources (pure S > CH₃S > SeS > SnS, ordered by expected reactivity), testing to control perfectly the S and Se content of the final CZTSe layers and to form an S-enriched top surface. After an optimization of the annealing parameters, we demonstrate the feasibility of a graded composition CZTSe phase with high S content at the top by introducing pure S during the cooling down process of the CZTSe kesterite. Multi-wavelength depth-resolved Raman spectroscopy measurements allowed to characterize the complex graded structure and estimate the composition of the CZTSe layers. A bandgap > 1.20 eV within the depletion zone and ≤ 1.03 eV towards the back contact interface is obtained this way. These results are correlated with in-depth Auger Electron Spectroscopy (AES), Grazing Incidence X-Ray Diffraction (GIXRD) and X-ray fluorescence (XRF), confirming the possibility of achieving a complex graded anionic compositional, and therefore, graded bandgap profiles. The fabricated solar cell devices show conversion efficiencies > 9%, with a Voc deficit of 420 mV, which currently represent a promising result for non-optimized graded absorber. In summary, preliminary results in which the samples are first selenized and then, in-situ superficially sulfurized, show the possibility of creating an inverted grading profile with higher bandgap towards the surface of the absorber by using pure elemental S source. We will show that obtaining S-Se graded bandgap profiles (both at the front and back interfaces) is only possible when the S is introduced in an out-of-equilibrium state. Strategies for achieving more complex graded bandgap profiles will be discussed including effects on device performance using experimental analysis by SCAPS modeling.

**Control of the Composition of CZTSe Absorber Material and Its Influence on Solar Cell Performance**

*Teoman Taskesen, David Nowak, Vincent Steininger, Devendra Pareek, Wenjuan Chen, Jörg OHland, Ulf Mikolajczak and Levent Gümey; University of Oldenburg, Oldenburg, Germany.*

Up to date, kesterite has drawn a significant attention as an absorber material for future photovoltaic applications. Recent research aims at understanding the nature of this quaternary material and intends to improve the device efficiency further. In this work, we performed a compositional study on CZTSe kesterites grown by a two-step process. Films are processed by sputtering of precursors containing elemental Zn and alloyed CuSn layers, and an annealing procedure at 530 °C under selenium atmosphere, additionally...
placing elemental Sn within the susceptor. We distinguish two mechanisms for composition control and demonstrate their tuning for optimization of the absorber fabrication process. A direct composition control can be achieved in the classical manner by varying the sputtering duration for each layer of the stack. Another indirect control parameter is the tuning of the selenium amount: This is found to impact the final composition of the absorber by i) stabilizing the formation reaction of CZTSe, ii) hindering possible SnSe loss from the CZTSe absorber at high temperatures, and iii) reacting with the elemental Sn in the selenization chamber to SnSe, assisting for the incorporation of additional Sn into the film via SnSe, vapour. Each of these three mechanisms appears to be influenced by the amount of Se available in the chamber. Elemental analysis of the grown absorbers shows a variation of the Cu/Zn and Zn/Sn ratios in the range of 0.9:1.6 and 1.2:1.2 respectively. Solar cell results demonstrate that the studied system is highly tolerable for the compositional variations, showing device efficiencies between 9 and 11% even at significantly off-stoichiometric compositions. By fine-tuning the discussed parameters, improved solar cells were obtained reaching a $V_{OC}$ of 476 mV for pure selenium kesterite and device efficiencies around 12%.

II-IV-V$_2$ semiconductors such as ZnSnN$_2$ and ZnSiP$_2$ offer the promise of optoelectronic properties on par with the III-Vs combined with the tunability of complex multinary materials like CIGS, due to their ternary composition and ability to control cation order parameter. For example, ZnSnN$_2$ has been predicted to exhibit band gap tunability from 1.1-1.5 eV based on variation in cation disorder, which arises mainly from local violations of the octet rule, with band gap narrowing occurring when N-centered motifs deviate from their ideal 2Zn + 2Sn coordination. Other II-IV-V$_2$ materials such as ZnSiP$_2$, ZnGeP$_2$, and ZnGeN$_2$ exhibit similar phenomena. The nitride materials of this family exhibit defect tolerant behavior and are photoactive as polycrystalline thin films, while the phosphides are lattice-matched to Si, and can be grown epitaxially for tandem photovoltaic applications. We have grown thin films of several nitride and phosphide members of this family and have observed strong photoluminescence behavior, promising energy conversion properties in a photoelectrochemical configuration, and tunable carrier concentration. This talk will focus on experimental methods for synthesis and characterization of these materials (including combinatorial methods), evidence of their potential for photovoltaic applications, and calculations that provide a physical understanding of disorder and its impact on relevant properties.

Quantitative Evaluation of Metastability Mechanisms in CIGS Solar Cells Marco Nardone$^3$, Yasas Patikirige$^1$, Curtis Walkons$^4$, Shubhra Bansal$^2$, Theresa Friedlmeier$^3$, Oliver Salomon$^3$, Kyoung E. Kweon$^3$, Joel B. Varley$^1$ and Vincenzo Lordi$^3$; 1Bowling Green State University, Bowling Green, Ohio, United States; 2University of Nevada, Las Vegas, Las Vegas, Nevada, United States; 3Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg, Stuttgart, Germany; 4Materials Science, Lawrence Livermore National Laboratory, Livermore, California, United States.

Copper Indium Gallium Diselenide (CIGS) photovoltaic devices usually exhibit variations in device performance when exposed to heat, voltage bias, and/or light. The degree of such variations and their reversibility depends on fabrication processes and impurity concentrations. Typically, light soaking at elevated temperatures increases the apparent doping concentration and open circuit voltage while heating in the dark tends to reverse those gains. Although the underlying mechanism is not clear, this metastable behavior is often attributed to transitions of the copper-selenium (V$_{Cu}$-V$_{Se}$) divacancy defect between donor and acceptor states. A better understanding of metastability could improve the utility of test standards and suggest pathways to increase power conversion efficiency.

In this work, physical models of metastability are quantitatively evaluated by comparison to current density-voltage (JV) data collected in situ during light soak at various temperatures and applied bias. Our time-dependent JV data at different stress conditions provide a unique platform for testing mechanistic hypotheses. Additional insight is gained by comparing CIGS devices with either CdS or Zn(O,S) buffer layers. Metastability mechanisms based on defect kinetics associated with lattice relaxations are coupled with semiconductor device simulations to predict how JV, quantum efficiency (QE), and capacitance voltage (CV) characteristics vary with time under specific stress conditions. The evaluated defect kinetics models include the ($V_{Cu}$-$V_{Se}$) divacancy complex with the previously calculated activation energies as well as more generic models of charge-induced shallow or deep defects. $Ab-initio$ calculations are also conducted to elucidate possible chemical species and lattice relaxation parameters.

Our results suggest that the ($V_{Cu}$-$V_{Se}$) divacancy model alone does not explain much of the observed metastability data due to the low transition energy barrier from the donor to acceptor state. Calculations with the generic defect models suggest that the data can be described by the formation of shallow acceptors upon electron capture with an activation energy close to 1 eV. In some cases, the formation of deep recombination centers with similar activation energy must also be evoked to account for losses in open circuit voltage during light soak at higher temperatures. In general, these types of mechanisms are associated with phenomena such as persistent photococonductivity and self-compensation when a system is sufficiently flexible to readjust in response to a shift away from equilibrium. In the case of metastability, it appears that electron injection in CIGS causes the system to respond by creating defects that reduce the electron concentration. This work quantifies the rates and magnitudes of the response.

Part of this work was conducted under the auspices of the U.S. DOE by LLNL under Contract DE-AC52-07NA27344.

11:00 AM *ESE20.12.06
Group-V Doping Limit in Cd-Rich CdTe for High Open-Circuit Voltage Akira Nagaoka$^{1,2,4}$, Darius Kuciauskas$^3$, Kenji Yoshino$^3$, Yoshitaka Nose$^3$, Kensuke Nishikawa$^3$ and Mike Scarpulla$^3$; 1Department of Materials Science and Engineering, Kyoto University, Kyoto, Japan; 2Department of Applied Physics and Electronic Engineering, University of Miyazaki, Miyazaki, Japan; 3National Renewable Energy Laboratory (NREL), Golden, Colorado, United States; 4Department of Materials Science and Engineering, University of Utah, Salt Lake City, Utah, United States.

Both group-V element doping and Cd-rich composition are important techniques for overcoming the open-circuit voltage deficiency in CdTe photovoltaic device by improvements of both p-type doping and long minority carrier lifetime. However, group-V doping simultaneously involves the formation of AX compensating donor like defect which results in low doping activation.

We present a comprehensive experimental approach to reveal equilibrium As doping limit of a few times $10^{17}$ cm$^{-3}$ in Cd-rich CdTe by very gentle cooling process. As-doped Cd-crich CdTe single crystal with high hole concentration $> 10^{17}$ cm$^{-3}$ and long bulk lifetime $> 20$ ns can be obtained. We demonstrate CdTe photovoltaic device with high open-circuit voltage of 900 mV by As-doped Cd-rich bulk single crystal as absorbing layer. These results indicate that group-V doping and Cd-rich composition enable the improvement of optical and microstructure deficiency in CdTe photovoltaic device.

11:30 AM ES20.12.07
Effects of Alkali Metal Impurities on Metastability Mechanisms in CuInGaSe$_2$ Solar Cells Kyoung E. Kweon$^3$, Amit Samanta$^1$, Joel B. Varley$^1$, Vincenzo Lordi$^3$, Curtis Walkons$^4$, Shubhra Bansal$^2$, Marco Nardone$^3$, Yasas Patikirige$^1$, Theresa Friedlmeier$^3$ and Wolfim Hempel$^3$; 1Lawrence Livermore National Laboratory, Livermore, California, United States; 2Mechanical Engineering, University of Nevada, Las Vegas, Las Vegas, Nevada, United States; 3Physics and Astronomy, Bowling Green State University, Bowling Green, Ohio, United States; 4Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg, Stuttgart, Germany.

Cu(In,Ga)$_{2}$Se$_{3}$ (CIGS)-based solar cell has yielded the highest light-to-electrical energy conversion efficiency of all thin-film solar cells. To achieve a high conversion efficiency, incorporation of alkali metal (AM) impurities in CIGS has become critical. In addition, light induced and voltage-bias induced metastabilities could further enhance the performance of p-type CIGS by increasing hole concentration. However, the relationship between AM impurities and positive light/voltage-bias induced metastabilities is not well understood and remains largely explored. However, it has been experimentally observed that a large amount of AM impurities segregate at grain boundaries and the absorber/buffer interface, but they can diffuse into the grain depending on the growth conditions or over long aging times. Therefore, analysis of AM impurities both in the grain and at the grain boundaries are important to elucidate their role on metastabilities.

In this work, we performed first principles calculations with a hybrid functional to explore effects of AM impurities on electronic properties of CuInSe$_2$ (CIS), particularly on light-induced metastabilities. First, we calculated binding interaction between AM and divacancy complexes ($V_{Cu}$-$V_{Se}$), which has been speculated to exhibit metastable properties in
CIGS. We found that formation of \( (\text{V}_{\text{Cu}}-\text{AM}_{\text{Cu}}) \) complexes, in which AM is located at the \( \text{V}_{\text{Cu}} \) site, is energetically favorable. The binding energy of the \( (\text{V}_{\text{Cu}}-\text{AM}_{\text{Cu}}) \) complexes with respect to the \( (\text{V}_{\text{Cu}}-\text{F}_{\text{Cu}}) \) and \( \text{AM}_{\text{Cu}} \) increases in order of increasing atomic size of AM (Na < K < Rb). Similar to the \( (\text{V}_{\text{Cu}}-\text{F}_{\text{Cu}}) \) complex, the \( (\text{V}_{\text{Cu}}-\text{AM}_{\text{Cu}}) \) complexes also have different donor and acceptor configurations, and conversion between these two stable configurations can occur by overcoming energy barriers accompanied by accepting electrons/relieving holes. Our calculations predict that the required energy for the forward reaction (donor to acceptor conversion) is 0.16, 0.42, and 0.60 eV eV for the \( (\text{V}_{\text{Cu}}-\text{Na}_{\text{Cu}}) \), \( (\text{V}_{\text{Cu}}-\text{K}_{\text{Cu}}) \), and \( (\text{V}_{\text{Cu}}-\text{Rb}_{\text{Cu}}) \), respectively, which is larger than 0.05 eV for the \( (\text{V}_{\text{Cu}}-\text{F}_{\text{Cu}}) \). This suggests that formation of the metastable acceptor configuration would be largely suppressed for the \( (\text{V}_{\text{Cu}}-\text{AM}_{\text{Cu}}) \) complexes with heavier AM.

Second, we examined geometries, energetics, and electronic structures of \( \text{AM}_{\text{Cu}} \) and its associated defect complexes at grain boundaries. Among many possible grain boundaries, we constructed \( \{112\} \) twin boundaries (TB), which are commonly observed in CIGS. Three different \( \{112\} \) twin boundaries were found with different Se local coordination environment at the boundary; for the most stable TB, all Se atoms at the TB are regularly coordinated with 2 Cu and 2 In, while for the least stable TB, Se atoms at the TB are coordinated with either 3 Cu and 1 In or 1 Cu and 3 In. Our calculations demonstrate that the formation energy of \( \text{AM}_{\text{Cu}} \) decreases at all three TB considered in this work with respect to that in the bulk, while the amount of decrease is larger for the TB containing more irregularly coordinated Se atoms at the boundary. Also, we found that heavier AM has stronger tendency (Na < K < Rb) to segregate at the grain boundaries, which agree well with the experimental observations demonstrating that K or Rb locates at the grain boundaries by kicking out Na at the grain boundaries. Furthermore, \( \text{AM}_{\text{Cu}} \) interaction with other point defects and defect complexes will be discussed to understand more comprehensive effects of AM impurities at the grain boundaries.

11:45 AM ES20.12.08
Microscopic Effects of Light-Soaking for Cu(In,Ga)Se2 Solar Cells
Alexandra Nikolaeva1, Maximilian Krause1, Wolfram Witte2, Dimitrios Hariskos2 and Daniel Abou-Ras2; Helmholtz-Zentrum Berlin, Berlin, Germany; *Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg (ZSW), Stuttgart, Germany.

Light-induced enhancement of the performance as a result of an increase of the open-circuit voltage and fill factor is widely observed in Cu(In,Ga)Se2 (CIGS) solar cells with Zn-compound buffer layers [1,2]. However, the reason for the improved efficiency is still under discussion. The present study was conducted in order to investigate the microscopic effects of light-soaking (LS) in Cu(In,Ga)Se2 solar cells with solution-grown CdS and Zn(O,S) buffer layers. Electron-beam induced current (EBIC) measurements were carried out before and after the LS under AM 1.5G illumination, as well as after keeping samples in the dark. In addition, cathodoluminescence and energy-dispersive X-ray spectrometry analyses were performed in order to gain insight into possible effects on the local radiative recombination and the elemental distribution. By evaluating EBIC profiles extracted perpendicular to the p-n junction, values for the widths of the space-charge regions, which are (roughly) proportional to \( \text{N}_{\text{v,0}} \) [3], and for the diffusion lengths of minority charge carriers were determined [4]. It is revealed that for solar cells with both, CdS/CIGS and Zn(O,S)/CIGS heterojunctions, the diffusion length increases significantly already after 30 min LS treatment. The doping density slightly increases during the LS process. In addition, the influence of electron-beam irradiation and heat-light soaking was investigated.

High Performance Triboelectric Nanogenerators for Continuous Self-Powered Electronics

Prof. Baik will first introduce the fabrication of triboelectric nanogenerators with high-output as well as the preparation of the triboelectric active materials. This will be followed by a review of the physical and chemical understanding for the mechanism to generate the high-output in terms of energy conversion efficiency. Prof. Baik will also survey the potential applications for the self-powered systems such as IOT sensors, filters etc.

10:00 AM BREAK

Triboelectric Nanogenerators for Internet of Things

This part will introduce the development of IoT and requirements of energy harvesting. Then, we will review the progress of materials, performance of triboelectric nanogenerators and other energy harvesters. Lastly, the demonstrations of TENGs for IoT Applications will be investigated with latest research achievements. The trend of IoT, TENGs and energy harvester technology will be discussed.

11:15 AM

Implantable and Wearable Self-Powered Medical Electronics

This part will first demonstrate the first in vivo mechanical energy harvester and devices. We will then show a pacemaker prototype for controlling the frequency of heartbeat for the first time. Finally, Prof. Li will demonstrate other applications as real-time acquisition and wireless transmission of self-powered cardiac monitoring data. These works are concentrated on live-powered implantable medical devices.

1:30 PM

Piezotronic Effect for Efficient (Photo)Electrochemical and Catalyst Applications

This part will first discuss the fundamental principles of applying the piezotronic effect in engineering the interfacial band structure. Practical systems that implement the piezotronic enhancement will also be discussed. At last, Prof. Wang will show that piezoelectric potential can raise the energy of electrons at the surface of piezoelectric material (or electrode) to such a level that is sufficient to drive proton reduction reactions within its immediate vicinity.

2:15 PM

Piezotronics for 2D Materials

This part will first elaborate on the fundamental physics and material science of the piezotronic effect in 2D materials, which serve as the basis for understanding and utilizing the interfacial and charge carrier engineering in 2D piezotronics. Prof. Wu will then discuss the latest progress in the fundamental exploration and technological advances in 2D materials piezotronics. Finally, Prof. Wu will provide a perspective of this rapidly-advancing field.

3:00 PM BREAK

3:30 PM

Piezo-Phototronics of 3rd Generation Semiconductor

This part will first introduce the framework of the piezo-phototronic effects in III-Nitrides quantum well. Furthermore, Prof. Hu shall survey the carrier dynamic process in piezo-phototronic effects with the transit piezophototronic model and the time-resolved photoluminescence. Finally, Prof. Hu will discuss the applications of piezo-phototronic effect on III-Nitrides visible light communications, micro LEDs and solar cells.

4:15 PM

Principle and Luminescence Application of Piezo-Photonics

This part will first introduce physical mechanisms of piezo-photonics. Some host materials and metal-ion activators will be described for demonstrating piezo-photonic effect. Prof. Hao will then provide a unified profile and recent prototypical demonstrations of light-emission triggered by various mechanical stimuli. Finally, Prof. Hao will discuss the challenges and perspectives of this research field.

* Invited Paper
Piezoelectricity, a phenomenon known for centuries, is an effect that about the production of electrical potential in a substance as the pressure on it changes. For wurtzite structures such as ZnO, GaN, InN and ZnS, due to the polarization of ions in a crystal that has non-central symmetry, a piezoelectric potential (piezopotential) is created in the crystal by applying a stress. The effect of piezopotential to the transport behavior of charge carriers is significant due to their multiple functionalities of piezoelectricity, semiconductor and photon excitation. By utilizing the advantages offered by these properties, a few new fields have been created. Electronics fabricated by using inner-crystal piezopotential as a "gate" voltage to tune/control the charge transport behavior is named piezotronics, with applications in strain/force/pressure triggered/controlled electronic devices, sensors and logic units. This effect was also extended to 2D materials such as MoS$_2$. Piezo-phototronic effect is a result of three-way coupling among piezoelectricity, photonic excitation and semiconductor transport, which allows tuning and controlling of electro-optical processes by strain induced piezopotential. The objective of this talk is to introduce the fundamentals of piezotronics and piezo-phototronics and to give an updated progress about their applications in energy science (LED, solar) and sensors (photodetector and human-CMOS interfacing).

Sustainable Power Generation from Multifunctional Triboelectric Nanogenerators Sang-Woo Kim; Sangkyunkwan University, Suwon, Korea (the Republic of).

Energy harvesting systems based on triboelectric nanomaterials are in great demand, as they can provide routes for the development of self-powered devices which are highly flexible, stretchable, mechanically durable, and can be used in a wide range of applications. Our recent research interest mainly focuses on the fabrication of high-performance triboelectric nanogenerators (TENGs) based on various kinds of nanomaterials. Flexible TENGs exhibit good performances and are easy to integrate which make it the perfect candidate for many applications, and therefore crucial to develop. In this presentation, I firstly introduce the fundamentals and possible device applications of TENGs, including their basic operation modes. Then the different improvement parameters will be discussed. As main topics, I will present a couple of recent achievements regarding highly stretchable transparent flexible TENGs, textile-based wearable TENGs, highly robust and efficient TENGs with multifunctional materials, etc. The recent research and design efforts for enhancing power generation performance of TENGs to realize self powering of portable and wearable sensors and electronics will also be discussed in this talk. Finally I am going to introduce a graphene triboelectronic touch sensor which is based on coplanar coupling of a single electrode mode TENG (S-TENG) and a graphene FET. When any object (e.g. human finger) comes into contact with friction layer of the S-TENG, the charges are produced due to well-known triboelectric effect. The triboelectric charges act as a gate bias to the graphene FET and modulates its current transport. The triboelectric sensors have displayed a sensitivity of ~2 % kPa$^{-1}$, a limit of detection <1 kPa, and a response time of ~30 ms. Furthermore, the devices can effectively detect touch stimuli from both bare and gloved fingers which can be a limitation with capacitive touch screens.

Theoretical Potential for Low Energy Consumption Phase Change Memory Utilizing Electrostatically-Induced Structural Phase Transitions in 2D Materials Evan Reed, Daniel A. Rehn, Yao Li and Eric Pop; Stanford University, Stanford, California, United States.

Structural phase-change materials are of great importance for applications in information storage devices. Thermally driven structural phase transitions are employed in phase-change memory to achieve lower programming voltages and potentially lower energy consumption than mainstream nonvolatile memory technologies. However, the waste heat generated by such thermal mechanisms is often not optimized and could present a limiting factor to widespread use. The potential for electrostatically driven structural phase transitions has recently been predicted and subsequently reported in some two-dimensional materials, providing an athermal mechanism to dynamically control properties of these materials in a nonvolatile fashion while achieving potentially lower energy consumption. In this work, we employ DFT-based calculations to make theoretical comparisons of the energy required to drive electrostatically-induced and thermally-induced phase transitions. Determining theoretical limits in monolayer MoTe$_2$ and thin films of Ge$_2$Sb$_2$Te$_5$, we find that the energy consumption per unit volume of the electrostatically driven phase transition in monolayer MoTe$_2$ at room temperature is 9% of the adiabatic lower limit of the thermally driven phase transition in Ge$_2$Sb$_2$Te$_5$. Furthermore, experimentally reported phase change energy consumption of Ge$_2$Sb$_2$Te$_5$ is 100–10,000 times larger than the adiabatic lower limit due to waste heat flow out of the material, leaving the possibility for energy consumption in monolayer MoTe$_2$ at room temperature of 9% of the adiabatic lower limit of the thermally driven phase transition in Ge$_2$Sb$_2$Te$_5$. Furthermore, experimentally reported phase change energy consumption of Ge$_2$Sb$_2$Te$_5$ is 100–10,000 times larger than the adiabatic lower limit due to waste heat flow out of the material, leaving the possibility for energy consumption in monolayer MoTe$_2$-based devices to be orders of magnitude smaller than Ge$_2$Sb$_2$Te$_5$-based devices.
Multifunctional ZnO and BaTiO3 Based Electro-Active Thin Films

Walker Tuff1, Yuyuant Xie2, Saquib Ahmed3 and Sankha Banerjee1; Mechanical Engineering, California State University, Fresno, Fresno, California, United States; Mechanical Engineering, Buffalo State College, Fresno, California, United States.

Electrical impedance spectroscopy (EIS) has been recognized as a powerful diagnostic tool for its extraordinary sensitivity. It has been widely used in evaluating electrical properties of materials and their interfaces with surface-modified techniques. Typically, EIS test applies a harmonic voltage perturbation to the target, then measures the response current, which can yield invaluable information of material electrical properties and structures as so-called impedance spectroscopy. In practical, impedance spectroscopy measurement on a multifunctional piezoelectric composite material is conducted through probing two electrodes at specific point or surface, while the specification of probing sites is generally arbitrary. The following work deals with the impedance tomography based characterization of ZnO/ZnO nanowire epoxy-BaTiO3 thin films with a variation in ZnO volume fraction from 1-10%. Impedance tomography data will also be used for generating dependent and independent data sets towards data analytics based optimization of surface properties and development of fabrication-process-property relationships. The surface micro-structure and topography will analyzed using scanning electron microscopy and profilometry. The piezoelectric and piezoelectric properties of these composites will also be characterized.

2:00 PM *ES21.02.03
Piezotronic/Piezophototronic Based Sensors and Applications

Junyi Zhai1, 2; Beijing Institute of Nanoenergy and Nanosystems, CAS, Beijing, China; Center on Nanoenergy Research, Guangxi University, Nanning, China.

Multifunctional micro/nano devices and systems are of important applications in smart electronics for health care, human-machine interfacing, infrastructure monitoring and security. In recent years, piezophototronic effect is developed fast since it offers a new method to improve/tune the optoelectronic properties dramatically. The key characteristic of the piezophototronic/phototronic effect is that the carrier generation, transport, separation and/or recombination at the heterojunction/interface can be tuned by modulating the piezopotential created and further tuned by externally applied strain. Piezophototronic effect can enhance the sensitivity of photodetector dramatically. Here, we show a self-powered GaN flexible film-based metal-semiconductor-metal (MSM) UV photoswitch. The asymmetric MSM structure was designed to suppress carrier recombination and enhance carrier transport. At self-powered condition (no external bias voltage), its UV on/off ratio reaches up to 4.67*104 with high reliability of on/off switching response. Also its UV detection shows an excellent sensitivity (1.78*107 cm²V-1W-1). In particular, strain modulation can improve the UV on/off ratio (~154%) by piezo-phototronic effect. Besides photosensitive conversion and electroluminescence, photoluminescence can be tuned by piezoelectric effect as well. Here we have developed a new method of pressure modulation by using pressure/stress induced piezoelectric effect to tune PL intensity of InGaN/GaN MQW under small strain (0–0.15 %). Such modulation effect is distinct, linear and ultrafast. Based upon it, an all optical pressure sensor array by the piezophototronic effect has been developed to measure dynamic pressure distribution without the need of electricity. Beyond the limitations of optical connection, our all-optical device offers a novel and suitable way for large-area, high-uniform, high resolution, ultrahigh speed pressure/strain distribution sensing. When combine piezotronic effect with magnetostriction, multi-field couplings can be realized. For example, magneto-optics and electro-optics, magneto-electrics and magneto-mechanics, piezotronics and piezophototronics, which could be of interest for fabricating functional devices in the fields of energy conversion, magnetic/optical imaging, high-density optical communication and information storage, smart sensing, and so on.

2:45 PM ES21.02.04
Piezo-Phototronic Effect in GaN Based Optoelectronic Devices

Weiguo Hu; Beijing Institute of Nanoenergy and Nanosystems, Beijing, China.

As the third-generation semiconductors, III-Nitrides exhibits great potentials in the solid-state lighting, display, power device, photovoltaics and so on. The piezoelectric property is the great difference between III-Nitrides and previous semiconductors (Silicon, Germanium, etc.). Prof. Wang pointed out that the piezo-potential can be used as a gate to tune/control the carrier generation, transport, separation and/or recombination via external strain, and thus tuning the device performances [1].

This report focuses on piezophototronic effects in III-Nitrides. Firstly, in the framework of the quantum perturbation theory and constitutive equations, we proposed a self-consistent model to study the piezo-phototronic effects in quantum structures [2,3]. This model matches well with the optical excitation in InGaN/GaN quantum well under the various external stress field. Furthermore, we studied the carrier dynamic process in piezophototronic effects with the transit piezo-phototronic model and the time-resolved photoluminescence for the first time. The piezoelectric field was partly “canceled”, which increased the overlap of wavefunctions to decrease the carrier decay time. Thus, the maximum speed of a single chip was increased from 54 MHz up to 117 MHz in a blue LED chip under 0.14% compressive strain. Finally, the piezo-phototronic effect was used to effectively improve the conversion efficiency of InGaN/GaN quantum well and compensated the thermal degradation in high power InGaN/GaN micro-strip LED arrays [4,5].

These researches deepen our understanding on carrier’s excitation and transportation under external strain filed, and exhibits important applications in communication, lighting and energy collections.

Reference

3:00 PM BREAK
Piezotronics is a promising new class of semiconductor-devices that offer important implications for the realization of flexible nano-electronic, nano-sensor, and microelectromechanical (MEMS) applications. However, reproducibility in both synthesis and sensitivity has been a materials challenge for achieving wide-scale adaptation of these applications. We present a novel method for the synthesis and study of the piezoelectric effect of single-crystalline zinc oxide (ZnO) nanosheets (NS). Here we show reliable synthesis of free-standing two-dimensional (2D) nanometer thick ZnO achieved using Ionic Layer Epitaxy (ILE). In this method, a highly-packed surfactant monolayer guides crystal evolution underneath the ionized headgroups at the air-water interface. Using dynamic contact electrification force microscopy (DC–EFM) we measure the piezo response coefficient ($d_{33}$) of our as-synthesized NSs in the nanometer scale from 1 to 3 nm. The $d_{33}$ was found in the range of 10-60 pm/V. The thickness-related piezoelectric responses were studied as well. Comparing to reported piezo response values of bulk ZnO, the piezo response of our ZnO NSs offer significant implications for next-generation nanomaterials as building blocks for piezotronics.

**Stretchable and Wearable Triboelectric Nanogenerators for Human Machine Interface**

**Pooi See Lee**; School of Materials Science and Engineering, Nanyang Technological University, Singapore, Singapore.

Harvesting energy from our environment or biomechanical motion requires the development of mechanical energy harvesting devices that are compliant to curvilinear surfaces or wearable on human body. Triboelectric nanogenerators (TENGs) generate electricity by triboelectrification and electrostatic induction from ambient energy that are ubiquitous and constantly available. Wearable TENGs based on textiles are attractive options as it can be incorporated onto garments and versatile for high portability. We developed two kinds of textile-TENGs, one for harvesting energy from water flow and another for harvesting biomechanical energy from human motion. An all-fabric-based dual-mode device harvests both the electrostatic energy and mechanical energy of water, achieving the maximum instantaneous output power density of 0.30 W m$^{-2}$. To generate energy from subtle biomechanical motion, an all-textile nanogenerator utilizing HCOEPNs encapsulated black phosphorus was presented with considerably high output (~250–880 V, ~0.48–1.1 mA cm$^{-2}$) with a small force (~5 N) and low frequency (~4 Hz), which can power small electronic gadgets. On the other hand, ionic based materials can be utilized to generate signal from touch and decode environmental changes. Based on the ionic conductive nanomaterials as building blocks for piezotronics.

**Self-Powered Motion Sensors and Monitoring Systems Based on Triboelectric Nanogenerator**

**Qingliang Liao**, Zheng Zhang, Zhuo Kang and Yue Zhang; University of Science and Technology Beijing, Beijing, China.

The advances in industry and information technology promote the development of internet of things and sensor technology. Self-powered systems based on energy harvesting technologies have been given significant attention with the increasing concern over energy crisis. Triboelectric nanogenorator (TENG) provides a novel mechanical energy harvesting technology and also can be used in the field of self-powered electronics. In this work, several kinds of self-powered electronics and system based on TENG were developed. Firstly, self-powered biomechanical motion sensors based on TENG were designed. Four kinds of TENGs with different structures were designed and the detecting properties of the fabricated biomechanical motion sensors were investigated. In order to meet the demands of actual application, the hybrid energy systems based on TENG were developed. A self-cleaning and self-charging power system based on an amphiphobic hydraulic TENG was constructed. A high-efficiency portable air filter enhanced by triboelectric effect was fabricated. These works represent a significant step for electronics and systems with superiorities of self-powered, high efficiency and low cost.

**Large-Area Solution-Grown Two-Dimensional Tellurene for Smart, Ubiquitous Electronics**

**Yixiu Wang**, Gang Qiu, Ruxing Wang, Peide P. Ye and Wenzhuo Wu; Purdue University, West Lafayette, Indiana, United States.

The reliable production of two-dimensional (2D) crystals are essential for exploring new science and implementing novel technologies in the 2D limit. However, ongoing efforts are limited by the vague potential in scaling-up, restrictions in growth substrates and conditions, small sizes and/or instability of synthesized materials. Here we report the fabrication of large-area, high-quality 2D tellurene by a substrate-free solution process. The crystals exhibit process-tunable thicknesses from a monolayer to tens of nanometers, and lateral sizes up to 100 nm. The chiral structure of tellurene gives rise to strong in-plane anisotropic properties and giant thickness-dependent shifts in Raman vibrational modes, unseen in 2D layered materials. The tellurene transistors can exhibit air-stable performance at room temperature for over two months, with on/off ratios on the order of $10^2$ and field-effect mobility ~700 cm$^2$/Vs. More strikingly, with scaled channel length and integration with high-k dielectrics, the record-high on-state current density of 1.06 A/mm is demonstrated, surpassing all state-of-the-art 2D-based transistors. Our versatile solution process allows access to a broad range of characterization and application of tellurene as a new 2D semiconductor for high-performance, energy-efficient electronics in future ubiquitous applications.

**8:15 AM ES21.04.02**

**Conformal Piezoelectric Energy Harvesting and Storage from Motions of Internal Organs**

**Canan Dagdeviren**; Media Lab, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Implantable medical devices have made a major impact in improving healthcare. In recent years, these devices have increasingly become active rather than passive – for example, cardiac pacemakers are those of the active type. A key challenge for these active systems is their need for an internal electrical power source. A downside of present active systems is the limitation of their internal batteries, which are rigid, bulky and must be changed frequently, thus requiring recurring surgical procedures, with associated complication risks and additional healthcare costs. One compelling solution would be to employ energy harvesting as a means of recharging or completely replacing batteries for active implantable medical devices. Energy harvesting — through chemical reactions, heat extraction, blood flow, and natural mechanical movements of organs — could help address energy depletion issues in implantable devices. However, most energy harvesting units being considered today are like conventional batteries, in that they also rely on rigid electronics and subcomponents, and therefore, are incapable of providing intimate mechanical contact with soft tissue.
We have developed a new class of biocompatible piezoelectric mechanical energy harvesters (PZT MEHs) that are soft and flexible, with extremely low bending stiffness, allowing them to conform to and laminate on the heart as well as on other soft tissues. These devices are the first-of-its-kind flexible generators that convert mechanical energy from internal organ movements into electric energy to power medical devices. We designed and fabricated the entire device, and performed *in vitro* and *in vivo* tests, and analyzed the data to show that it is a feasible new invention. The co-integrated collection of such energy-harvesting elements with rectifiers and microbatteries provides an entire flexible system, capable of viable integration with the beating heart via medical sutures and operation with efficiencies of ~2%.

This conformal mechanical energy harvesters can yield significant amounts of electrical power from motions of internal organs, up to and exceeding levels relevant for practical use in implants. Under the rhythmic contraction of the heart muscle, the device bends and relaxes, enabling to supply enough trickle charge — a steady stream of charging current at low rate — to satisfy the needs of a pacemaker. Thus, this technology could extend the battery life of implanted medical devices or even eliminate the need of battery replacement that altogether would spare patients from repeated operations and the risk of surgical complications. Another potential application of this technology is in powering heart monitors/sensors worn epidemically on skin.

Fibre-Based Triboelectric Generators for Smart Textiles Using Surface-Modified Electrospun Polymer Fibres
Tommaso Busolo1, Daniel Ur1, Sung Kyun Kim2, Piotr Szewczyk1, Mateusz Marzec1, Andrzej Bernasik1, Urszula Stachewicz1 and Sohini Kar-Narayan2; 1Faculty of Metals Engineering and Industrial Computer Science, AGH University of Science and Technology, Krakow, Poland; 2Department of Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom; 3Academic Centre for Materials and Nanotechnology, AGH University of Science and Technology, Krakow, Poland.

Wearable healthcare devices and point-of-care diagnostics are essential tools to provide affordable healthcare globally and to deliver personalised medicine. These devices are able to remotely monitor patient health in real time, thus improving diseases management and reducing medical cost. Furthermore, the physiological data collected can be used by a machine learning software to provide personalised treatments.

One of the biggest challenges that wearable technology faces is power supply[1]. In this context, triboelectric generators are promising as they rely on motion-generated surface charge transfer between materials with different electron affinities to convert mechanical energy, for example from body movements, into useful electricity. Fibre-based triboelectric generators are therefore particularly promising for wearable applications as they can harvest the kinetic energy from body motion and be seamlessly integrated into “smart” textiles at the same time. Current fibre-based triboelectric generators are limited by low power output. Two of the most effective methods to improve this are increasing surface area and altering the surface chemistry of the material. Higher surface area allows for higher charge transfer density, while tailored surface charge properties improve the charge transfer mechanisms. Electrospinning can be used to effectively tailor the surface chemistry of fibres by alternating voltage polarities in a single-step manufacturing process[2]. In our work, we have enhanced the triboelectric performance of poly(methyl methacrylate) and polyvinylidene fluoride by engineering both its surface area (due to the fibre geometry) as well as the surface chemistry (by controlling the polarity of applied voltage during electrospinning). Scanning electron microscopy and electrical measurements were used to study the effect of surface area enhancement. X-ray photoelectron spectroscopy and Kelvin probe force microscopy have demonstrated that the improvement in triboelectric output is correlated to molecular reorientation on the fibre surface caused by the applied voltage during electrospinning. The suitability of surface-modified electrospun fibres as high-performance materials for fibre-based triboelectric generators is demonstrated in this work, along with applications in intelligent textiles.

Triboelectric Technology Based Sensors for Human-Machine Interaction
Chenguo Hu; Chongqing University, Chongqing, China.

A sensing system is the core in human machine interaction (HMI), which connects the human being and machine with understanding the human instruction or senses. In this presentation, I will introduce the sensors based on triboelectric nanogenerator (TENG) technology, including an eye motion triggered self-powered mechanosensational communication system (1), a self-powered auditory sensor for social robotics and hearing aids (2), a quantization rotation sensing and gesture control of a robot joint (3), and a self-powered 2D barcode recognition system for personal identification. This work expresses notable advantages of using TENG technology to build a new generation of sensing systems for meeting the challenges in HMI.

Developing Energy Storage Devices for Nanogenerators as Small-Power Energy Harvesters
Xianmiao Lu; Beijing Institute of Nanoenergy & Nanosystems, Beijing, China.

Increasing demands for self-powered portable electronics and remote sensors have put forward imperative request on small power harvesting devices such as triboelectric nanogenerators that can collect environmental/ambient energy. Due to the intermittent nature of these power sources, energy storage for such devices is of significant importance for continuous power supply. When charged at low and intermittent power, energy storage devices such as supercapacitors or batteries need to handle pulse energy input and have minimal leakage current. However, research on energy storage devices with low self-discharge and high charging efficiency for small and pulse electric currents has not been paid enough attention. In this presentation, I will discuss our recent efforts in developing supercapacitors with suppressed self-discharge/improved frequency response that are suitable for small power harvesting applications.

For electric double layer capacitors (EDLCs), self-discharge has been an inevitable issue that causes decay of cell voltage and loss of stored energy. Due to self-discharge, applications of supercapacitors for long-term energy storage or collecting environmental energy harvested by small power devices have been severely limited. There are three main self-discharge processes for EDLCs, including i) charge diffusion and redistribution, ii) faradaic reactions, and iii) ohmic leakage. To alleviate this issue, we introduced an additive to the electrolyte to suppress the self-discharge of EDLCs. When the EDLCs are charged, the electric field in the double layers near the electrode surface induces much enhanced fluid viscosity. As a result, the diffusion of ions and redox species in the electrolyte can be impeded and the self-discharge rate can be reduced. We have demonstrated the decay rate of open circuit potential and leakage current can be reduced by more than 80%. Simulation results confirmed the reduced contribution of both diffusion of ions and faradaic reactions to the overall self-discharge. Furthermore, when the EDLCs were employed for storing energy harvested by a triboelectric nanogenerator (TENG) that has a characteristic of pulsed output current, much enhanced charging efficiency was attained. In another effort, we employed a low-cost charging material for the preparation of supercapacitors with high frequency response for pulsed charging. The high-frequency supercapacitors exhibited excellent frequency response with a phase angle of ~80° at 120 Hz. When the supercapacitors were employed for storing energy generated by a rotating TENG with pulsed output at frequencies ranging from 450 to 1350 Hz, the energy utilization efficiency was improved by more than 20% compared to conventional activated carbon based supercapacitors.

9:45 AM BREAK
The reliable production of atomically-thin crystals is essential for exploring new science and implementing novel technologies in the 2D limit. In this talk, I will discuss our recent discovery of a new 2-D material, tellurene, synthesized by a substrate-free solution process. The tellurene crystals exhibit process-tunable thicknesses from a monolayer to tens of nanometers, and lateral sizes ~ 100 µm. Our prototypical tellurene transistor device, which is air-stable, shows an excellent all-around figure of merits compared to existing 2D materials. We further carry out the first experimental exploration of piezotronic effect in tellurene and systematically investigate the piezotronic transport properties. The fundamental understanding of piezotronic coupling in tellurene is expected to provide insights for the development of 2-D material piezotronics, leading to the realization of “smarter” electronics for a multitude of emerging technologies, e.g., wearable electronics, soft robotics, medical prosthetics, and human-machine interface.

Printing Two-Dimensional Piezoelectric Layers Using Liquid Metal Reaction Media
Nitu Syed1, Torben Daeneke2, Ali Zavabeti2 and Kourosh Kalantar-zadeh2; 1School of Chemical Engineering, University of New South Wales, Kensington, New South Wales, Australia; 2School of Engineering, RMIT University, Melbourne, Victoria, Australia.

The recent exploration of two dimensional (2D) planes as piezoelectric structures has accelerated. Mechanical displacements, such as vibration, bending and stretching, are ubiquitously present in the ambient environment and 2D structures may facilitate their sensing and the harvesting of their kinetic energy to power miniaturised devices based on such piezoelectric materials. Piezoelectric measurements using 2D materials, including their lateral strength and high crystallinity along the planes, large surface area to mass ratios and compatibility with surface fabrication processes, provide the concept of 2D piezoelectric with great prospect for future industries. Field of 2D piezoelectric materials can benefit from the emergence of crystals featuring high piezoelectric coefficients such as gallium phosphide (GaPO4). This 2D material is an archetypal piezoelectric with wide-ranging industrial applications. However, it does not naturally crystallise in a stratified structure and hence cannot be exfoliated using any of the conventional methods. Here we present a low temperature liquid metal 2D printing and synthesis strategy. Interfacial oxide layer of liquid gallium is exfoliated and surface-printed, followed by the vapour phase reaction between the gallium oxide sheet and phosphoric acid. The method gives access to large-area, uniform 2D GaPO4 nanosheets of unit cell thickness (~1.1 nm), while featuring wafer scale lateral dimensions. The unit cell thick nanosheet presents a large effective out-of-plane piezoelectric coefficient of nearly 8 pm/V. The developed liquid metal based process is also suitable for the synthesis of free-standing 2D GaPO4 nanosheets over micron sized cavities. The presented low temperature process is compatible with a variety of electronic device fabrication procedures, providing a facile route for the development of 2D piezoelectric devices for sensing and energy harvesting.

method was used to fabricate PVDF, PVDF-barium titanate (PVDF-BT), PVDF-graphene, and PVDF-BT-graphene fibers. The volume fractions of BT and graphene were varied from 0.01 to 0.10, and a loom was used to weave the fibers into a fabric for testing. The properties of the textiles were measured before and after exposure to a contactless corona-discharge plasma to determine if additional pooling enhanced the performance of the fabrics. The piezoelectric strain coefficient, $d_{33}$, of the fabrics was measured using a piezometer at a frequency of 110 Hz. The impedance, resistance, conductance, and capacitance were measured using an impedance analyzer over frequency ranges of 20 Hz to 200 Hz and 20 Hz to 10 MHz. The geometric parameters of the textiles were also calculated to measure the resistivity, conductivity, and dielectric constant. The surface morphology of the textiles was analyzed with the aid of a scanning electron microscope.

SESSION ES21.06: Nanogenerators and Piezotronics I
Session Chairs: Christian Falconi and Rusen Yang

PCC North, 100 Level, Room 132 C

1:30 PM ES21.06.01
Piezo-Phototronic Effect Enhanced Photoelectrocatalysis Linlin Li; Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, Beijing, China.

TiO$_2$ is a well-known photocatalyst used for water splitting, pollutant removal, antibacterial application, etc. How to increase the efficiency by overcoming their limitation including fast recombination of photoexcited carriers, limited light utilization are still great challenge. In this talk, I will introduce our recent research progresses in piezo-phototronic effect enhanced photodynamic bacteria killing wound healing, and photoelectrocatalysis. For the first time, the tribo-layer of TENGs have been fabricated via dispersing the lead-free piezoelectric materials to increase the output performances, the fundamental mechanism of which is to enhance the triboelectric effect of materials mainly ferroelectric polymers. PVDF/PTFE based TENG. The enhancement in the performance of the TENG has been correlated with the changes in the properties of PVDF. We believe that this work will provide a simple yet effective way of enhancing the triboelectric effect of materials mainly ferroelectric polymers.

Structure Design and Enhancing the Performance by Dielectric Modulation of TENG for Harvesting the Blue Energy Yi Xi; Chongqing University, Chongqing, China.

Piezoelectric nanogenerator (TENG) has been considered to be a more effective technology to harvest various types of mechanic vibration energies such as wind energy, water energy in the blue energy and so on. Considering the vast energy from the blue oceans, harvesting of the water energy has attracted huge attention. There are two major types of "mechanical" water energy, water wave energy in random direction and water flow kinetic energy. Moreover, surface charge density of tribo-layer is the most key-point parameter for developing high performance TENG. Most of the previous works were focus on the surface structural/chemical modification, nevertheless the internal space of the tribo-layer and its mechanism exploration were less investigated. Herein, internal space charge zones are built through embedding ravines and gullies cross-cross gold layers in near-surface of tribo-layer, which leads to the high output performance of TENG. At the same time, the tribo-layer of TENGs have been fabricated via dispersing the lead-free piezoelectric materials to increase the output performances, the fundamental mechanism of the TENG has been discussed from the perspectives of dielectric modulation.

2:00 PM ES21.06.03
Unidirectionally Polarized Diphénylalanine Nanotube Based Piezoelectric Energy Generator Ju Hyuck Lee$^{1,2}$; *Energy Science and Engineering, Daegu Gyeongbuk Institute of Science and Technology, Daegu, Korea (the Republic of); *Bioengineering, University of California, Berkeley, Berkeley, California, United States.

Piezoelectricity is defined as the interconversion between mechanical and electrical energy induced by charge redistribution and separation when mechanical or electrical stimuli are applied to materials that do not have inversion symmetry. Although various conventional inorganic piezoelectric materials exhibit strong piezoelectric property, these materials often require substances that are harmful to the environment / human body or harmful to the environment during the fabrication process. Many natural biomaterials (eg, amino acid, peptide, protein, and virus) that can be synthesized in an environmentally friendly manner have been found to have piezoelectric properties and it is comparable to conventional piezoelectric materials. Recently, self-assembled diphénylalanine (FF) nanotubes have been reported to have strong piezoelectric properties comparable to conventional piezoelectric materials. However, the difficulty of fabricating unidirectionally polarized FF nanotubes that can convert mechanical forces into electrical energy has been a major impediment to the realization of high power bio-piezoelectric devices. Here, we develop a novel fabrication process to synthesize large-scale aligned and unipolarized FF nanotubes. We use a meniscus-driven self-assembly process which is environmental friendly process. By controlling the thermodynamic and kinetic parameters of fabrication process, we synthesized FF nanostructures ranging from vesicles to aligned peptide nanotubes. The resulting horizontally aligned FF nanotubes have unidirectional polarization. Furthermore, this synthesis process allows us to easily scale-up to form large-area coatings that we use to develop piezoelectric energy generator.

2:15 PM ES21.06.04
Enhanced Triboelectric Effect in PVDF—Changing Its Surface Roughness, Polarizability and Hydrophobicity Huidrom Hemojit Singh and Neeraj Khare; Indian Institute of Technology Delhi, Delhi, India.

With the advancement in technology and the urgent need for clean energy sources, triboelectric nanogenerator also known in short as TENG starts gaining lots of attention in recent years. TENG works on the principle of contact electrification, in which when two different materials come into contact charges are generated on the surface of the materials.$^{[1-3]}$ The amount of charges generated depend on various parameters, like surface roughness, work function, polarizability and hydrophobicity of the materials. $^{[4-6]}$

In the present work, we have modified surface roughness, hydrophobicity and polarizability of polyvinylidene fluoride (PVDF) by incorporating hydrothermally synthesized ZnO nanorods into PVDF. The changes in the above properties of PVDF lead to the enhanced triboelectric effect of PVDF. The films were prepared using a simple drop casting method, and no surface treatment or complex film synthesis techniques were not employed. TENGs fabricated by coupling ZnO-PVDF film with polytetrafluoroethylene (PTFE) showed a much enhanced triboelectric output of voltage of ~119 V and short circuit current of ~1.6 μA. The instantaneous output power is 65.6% more as compared to PVDF/PTFE based TENG. The enhancement in the performance of the TENG has been correlated with the changes in the properties of PVDF. We believe that this work will provide a simple yet effective way of enhancing the triboelectric effect of materials mainly ferroelectric polymers.

References
for the fabrication of high-quality ferroelectric devices and imply its role in a next-generation production of sensors, energy harvesters, and microelectromechanical systems.

Capacitors. The capacitors consist of lanthanum nickelate (LNO) electrodes and lead zirconium titanate (PZT) ferroelectric layer. To prepare the inks we first synthesized sol-gel precursor solutions and adjusted their physical properties by the addition of ethanolamine and ethylene glycol. The solvent composition was selected on the basis of our previous work to suppress the coffee stain formation of dried structures [A. Matavz et al., Appl. Phys. Lett. 113, 012904, 2018]. One of the most demanding issues in multilayer inkjet printing is the control over the wetting behavior throughout the fabrication process. To achieve this, we employed a few-nanometer-thick polymeric layer, which redefines the surface properties after each deposition step and ensures the repeatability during the fabrication of LNO/PZT/LNO stacks. The polymeric layer decomposes during annealing and does not influence the performance of capacitors.

Among them, a triboelectric nanogenerator (TENG), which is one of energy-harvesting devices, has been extensively investigated owing to several advantages such as cost-effectiveness, structural simplicity, wide material selection, and high conversion efficiency. Despite these attractive advantages, it remains a challenge to achieve a high output performance while preserving both the transparency and the flexibility because of the opaque and less flexible metal. Therefore, the triboelectric potential could be used to control the electrical transport in semiconductors. On the basis, several triboelectric functional devices have been developed including tribotronic smart skin, tactile sensing array and tuning diode, which has demonstrated triboelectricity-controlled electronics and established the active mechanosensation for external environment. In addition, the triboelectric power management strategy is also reviewed, in which the triboelectricity can be managed by electronics in reverse action. With the implantation of triboelectric power management module, the harvested triboelectricity by various kinds of human kinetic and environmental mechanical energy could be effectively managed as a power source for self-powered systems. According to the research prospects for interactions between triboelectricity and semiconductor, tribotronics is expected for significant impacts and potential applications in MEMS/NEMS; flexible electronics, robotics, wireless sensor network, and Internet of Things.

Flexible and Controllable Piezo-Phototronic Pressure Mapping Sensor Matrix by ZnO NW/p-Polymer LED Array Rongrong Bao and Caofeng Pan; Chinese Academy of Sciences, Beijing, China.

Flexible and Controllable Piezo-Phototronic Pressure Mapping Sensor Matrix by ZnO NW/p-Polymer LED Array. Functional tactile sensing device is mandatory for next-generation robotics and human-machine interfaces since the emulation of touching requires large-scale pressure sensor arrays with high-spatial resolution, high-sensitivity, and fast-response[11]. Some tactile sensors fabricated with organic transistors or micro-structured rubber layer pressure sensor arrays have been reported[12], whose working mechanism is based on changes in capacitance or resistance. Our group have demonstrated pressure sensor array base on piezotronic and piezo-phototronic effects. A spatial resolution of 120 µm was achieved for piezotronic pressure sensor array and an ultra-high resolution of 2.7 µm was derived from piezo-phototronic pressure sensor array using ZnO nanowire (NW)-p-GaN LEDs array[13]. These devices provide stable, fast response, as well as parallel-reading detections of spatial pressure distributions. However, the lacking of flexibility with a rigid sapphire substrate prevents the NW-LEDs array device from applications as smart skin; and the pressure measuring range of the device is in a relatively high pressure region. Therefore, a flexible pressure mapping system with moderate spatial-resolution become necessary and may find numerous potential applications in human-machine interfaces.

Organic/inorganic hybridized LEDs are drawing tremendous attentions because of their high flexibility. Among them, n-ZnO and p-poly(3,4-ethylenedioxythiophene)-poly(styrene sulfonate (PEDOT:PSS) hybridized inorganic/organic LED has aroused great technological and scientific interests due to the excellent optoelectronic properties of ZnO and the high flexibility, low-cost, easy fabrication, potential for large area deposition and commercial availability of PEDOT:PSS. Here, we demonstrate a flexible LED array composed of PEDOT:PSS and patterned ZnO NWs for mapping spatial pressure distributions. By utilizing strain-induced negative piezoelectric polarization charges presented at local interface of the p-n junction, piezo-phototronic effect has been applied to modify the band structure through reducing the barrier height for hole injections from PEDOT:PSS side, and thus facilitate the recombination between electrons and holes in ZnO side for enhancement of light emitting intensity. Therefore, the pressure distribution is obtained by parallel-reading the illumination intensities of LED pressure sensor array. The spatial resolution is achieved as high as 7 µm by fabricating ZnO nanowires on flexible substrate. By

**ES21.07.01 Piezo-Phototronic Effect Enhanced Performance of the Flexible Microwave Detectors**

Qianqian Du, Shuming Zhu, Jiandong Ye, Kun Tang, Youdou Zheng and Shulin Gu, Nanjing University, Nanjing, China.

Owing to the large surface to volume ratio and tunable surface morphologies, photodetectors based on low-dimensional nanostructures exhibit superior performance, thus many efforts have been made to optimize the photodetector devices [1]. Zinc oxide (ZnO) with the advantages of being flexible and fast and having high resolution in stress/pressure sensor applications, high chemical stability and outstanding optical properties in optoelectronics applications, has attracted significant attention in recent years[2]. In this study, the ZnO microwires were fabricated by a simple one-step chemical vapor deposition (CVD) method. We demonstrated photodetectors based ZnO microwires modified with NiO on a rigid SiO\textsubscript{2} substrate and the other on flexible polyethylene terephthalate (PET), respectively. We also investigated the electronic property of the devices with stress and light in detail. The results indicated that The piezo-phototopict effect can effectively enhance the performance of ZnO photodetector.

**ES21.07.02 High-Performance Piezoelectric Nanogenerators Based on Composite Thin Films**

Su Yeon Lee, Eun Jung Lee, Sunho Jeong and Youngmin Choi; KRIST, Daejeon, Korea (the Republic of).

Energy harvesting that can scavenge various kinds of mechanical energy from several different sources has attracted great attention. In particular, a flexible energy-harvesting device consisting of piezoelectric materials has been studied and is regarded as a power source for flexible and wearable electronic devices because the piezoelectric elements can effectively convert to electrical energy from mechanical energy. Recently, many researchers have attempted to achieve highly efficient energy-harvesting devices using several fabrication methods. However, there are still the challenge problems with flexible piezoelectric nanogenerators. Here we report the flexible piezoelectric nanogenerators (PNGs) based on composite thin films comprising amine-functionalized lead zirconate titanate (PZT) nanoparticles (PZT-NH\textsubscript{3} NPs) and a thermoplastic triblock copolymer. Without additional dispersants, the uniform distribution of PZT-NH\textsubscript{3} NPs in the polymer composite improves the piezoelectric power generation compared to that of a PNG device using pristine PZT NPs. This unique composite behavior allows the PZT-NH\textsubscript{3} NP-based flexible PNG to exhibit a high output voltage of 65 V and current of 1.6 μA without time-dependent degradation. This alternating energy from the PNG can be used to charge a capacitor and operate light-emitting diodes through a full bridge rectifier. Furthermore, the proposed PNG is demonstrated as a promising energy harvester for potential applications in self-powered systems.

**ES21.07.03 Enhanced Piezoelectric Nanogenerator Performance by Point Defect Control of MoS\textsubscript{2}**

Sang A Han\textsuperscript{,1,2}, Ka-Young Park\textsuperscript{3} and Jung Ho Kim\textsuperscript{1}; University of Wollongong, Wollongong, Alabama, United States; Sungkyunkwan University, Suwon, Korea (the Republic of); Sejong University, Seoul, Korea (the Republic of).

The piezoelectric characteristics of two-dimensional materials are of great interest for high-performance piezoelectric potential applications. The CVD-based large-area monolayer MoS\textsubscript{2} is essential for practical applications. However, the CVD-based MoS\textsubscript{2} has the intrinsic defect of sulfur vacancies during the growth process, and these defects play an important role in screening the piezoelectric potential. So only small piezoelectric potential induced power output has been observed from the CVD-grown MoS\textsubscript{2}. Here we demonstrate a high performance piezoelectric nanogenerator using CVD-based monolayer MoS\textsubscript{2} nanosheet by an additional sulfur treatment process during the MoS\textsubscript{2} growth process. The measured piezoelectric coefficient (d\textsubscript{31}) of the CVD-grown large-area monolayer MoS\textsubscript{2} nanosheet is 3.73 pm V\textsuperscript{-1} using lateral PFM methods, and it generates a peak power density of 0.73 pW, which is 10 times higher than that of the pristine monolayer MoS\textsubscript{2} nanosheet.

**ES21.07.04 Nylon 11-MoS\textsubscript{2} Composite Layer with High Performance for Triboelectric Nanogenerator**

Minj Kim, Sol Lee, Anh Cao Viet, Daehoon Park and Junghyo Nah; Chungnam National University, Daejeon, Korea (the Republic of).

Triboelectric nanogenerators(TENGs) have gained much attention thanks to their relatively high output power through scavenging vibrating resources that exist in our living environment. To date, a number of approaches, such as surface patterning, dielectric permittivity modulation, chemical functionalization, have been introduced to enhance output performance of the TENGs. However, the TENG’s output performance has still been limited due to relatively low output current density on the triboelectric frictional surfaces. Therefore, simple and effective methods are necessary to boost the output current density of the TENG, which further extend the performance limit of the TENGs.
In this report, we adopted the composite structure consisting of MoS$_2$ flakes and ferroelectric Nylon 11 polymer to improve output current density. Here, ferroelectric Nylon 11 provides a knob to adjust surface triboelectric charge density by surface polarization. In addition, MoS$_2$ provides the trap states to further increase charge density in the composite structure. Using these two knobs, the output charge density was greatly improved in comparison to the TENG without the MoS$_2$ particles. Specifically, 5-fold higher current density was obtained by using the polarized MoS$_2$-Nylon 11 composite layer compared with the device fabricated only with non-polarized Nylon 11. Consequently, the maximum output power density of $-40$ mW/cm$^2$ was achieved in our work. The approach introduced here provides simple strategy to effectively extend the output performance limit of TENGs.

**Role of Indium Zinc Oxide-Based Interfacial Layer for High Performance Triboelectric Nanogenerators**  
Dahoon Park, Kyung Soo Han, Sol Lee and Junghyo Nah;  
Chungnam National University, Daejeon, Korea (the Republic of).

Triboelectric nanogenerators (TENGs), which can effectively convert various mechanical stimuli to electricity by using a relatively simple device structure and cost-efficient, are considered as a promising candidate for coping with gradually increasing energy demands. To date, various research efforts have been reported to enhance the output performance of TENGs, which have greatly improved their output performance. However, triboelectric output performance enhancement is still hindered by its relatively low output current compared to its output voltage. Thus, further study is necessary to boost the output current density to further extend the performance limit of the TENG.  

In this work, we report the output performance enhancement method by inserting an indium zinc oxide (IZO) layer under polydimethylsiloxane (PDMS). Specifically, the 0.5 M IZO solution was prepared by spin-coating on stainless steel sheet, followed by curing and annealing processes. Next, IZO layer is buried by spin-coated PDMS. The TENG with a buried layer is relatively unaffected by surface wear-out. Furthermore, its output enhancement is considerably enhanced. The role of IZO layer is two folds: electron discharge from interface states at the IZO-PDMS interface and electron supply from the IZO layer by energy band bending during contact-separation motion. Consequently, the output performance of the TENG with an IZO layer is remarkably improved by adopting the IZO layer, generating an output power density of $-25$ mW/cm$^2$. Especially, about 9-fold increase of output current was observed in TENG with an IZO layer due to additional electron supplying effect by n-type semiconductor IZO. The approach presented here is a simple method for boosting the performance of TENGs and effectively alleviating their susceptibility to friction surface wear-out.

This research is supported by Korea Ministry of Environment(MOE) as Advanced Technology Program for Environmental Industry Program.

**ES21.07.06**

**A Novel Multi-Functional Self-Powered Pressure Sensor with Hierarchical Wrinkle Structure**  
Liming Miao, Hang Guo, Ji Wan, Haobing Wang, Xiaoliang Cheng and Haixia Zhang;  
Peking University, Beijing, China.

**Novelty:** This paper reports a novel multi-function self-powered pressure sensor with hierarchical wrinkle structure which is thin and flexible. Due to the sensitive hierarchical wrinkle structure, the sensor shows the sensitivity of 2.0 kPa$^{-1}$ and the excellent response performance of 0.15 ms (rise time) and 0.7 ms (relaxation time). In addition, the surface charges deriving from the contact of PDMS and ITO on the wrinkle structure enable the sensor to be a generator and differentiate various mechanical stimuli.

**Background:** With the development of electronic skins and wearable devices, flexible sensors based on capacitive effect due to its stability, are now concerned about by more and more people. One of the most of them require multi-features and complicated fabrication because of the complex designed dielectric layer. PDMS wrinkle structure fabricated by C$_4$F$_8$ plasma treating has been applied to triboelectric nanogenerator (TENG) and has the advantage of simple fabrication. However, the sensor with monolayer wrinkle structure shows low sensitivity. Here, we introduce hierarchical PDMS wrinkle structure into the capacitive effect pressure sensor to improve the performance of the sensor and meanwhile integrate the feature of energy harvesting.

**Fabrication Process:** The vacuum degassed mixture of PDMS base and cross-linker is spin coated on the indium tin oxide (ITO) coated polyethylene terephthalate (PET) film. Then heat the thin PDMS/ITO/PET film at 100 degree celsius for 45 seconds. Next implement a C$_4$F$_8$ plasma treatment for 1000 seconds, after which the heat the film till the curing of the thin PDMS layer. Finally, cover the wrinkle-structured film with another ITO/PET film. The thickness and area of the sensor are about 260 μm and 6.25 cm$^2$, respectively.  

**Working principle:** As a capacitive effect sensor, the ITO layers work as two conductive electrodes and the dual-scale wrinkle structure, the thin PDMS layer and the air work as dielectric layer. While as a generator, the PDMS and ITO work as charges generation surface and the air between the wrinkle gap enables PDMS layer and ITO layer to contact and separate. The hierarchical wrinkle structure manages differentiating normal pressure and bending.

**Experimental Results:** Since extending C$_4$F$_8$ plasma treating time to 1000s can produce hierarchical wrinkle structure on the PDMS surface, the sensitivity in the relatively low pressure regime (0-500 Pa) can get an obvious promotion from 0.5 kPa$^{-1}$ (50s plasma treating), 1.0 kPa$^{-1}$ (500s plasma treating) to 2.0 kPa$^{-1}$ (1000s plasma treating). Moreover, in the relatively high pressure regime (more than 1500 Pa), the sensitivity of the sensor gets a slight promotion from 0.1 kPa$^{-1}$ (50s & 500s plasma treating time) to 0.2 kPa$^{-1}$ (1000s plasma treating time). Moreover, the response performance is excellent with the release-time is 0.7 ms and the rise-time is even only 0.15 ms. When pressure is applied, the small wrinkle firstly works and then sense the pressure quickly and sensitively by forming deformation, thus the sensitivity of the pressure sensor in the relatively low pressure regime can be highly enhanced and the response time is extremely short. When the pressure is applied extremely high, the big wrinkle begins to work and shows a sensitivity of 0.2kPa$^{-1}$ once bigger than that of a PDMS plate. As a TENG, the output voltage of the sensor under bending stimuli is about 300 mV, while that of the sensor under pressure stimuli is only about 75 V. The output current of the former is about 3μA, while the latter is about 17 μA. The wave pattern under pressure stimuli is more sharp than that under bending stimuli. The reason for the feature of mechanical stimuli differentiation of the device can be attributed to the hierarchical wrinkle structure. The two forces can make hierarchical wrinkles contact with the PET/ITO with different deformation which leads to different contact area thus results in output voltage and current.

**Helicene-Based Polymers** Joshua C. Sevlar and Ruel McKenzie; Polymer Engineering, University of Akron, Akron, Ohio, United States.

**Helicenes** are a unique group of helically configured aromatic compounds which have been shown to possess potentially useful properties. Pertinent to this proposed research, helicenes have been shown both computationally and experimentally to be piezoelectric. It is the intent of this research to show how to utilize functionalized helicenes as monomers in the backbone of existing polymer systems. In this way, a new multi-functional class of polymers will be developed which possess the inherent properties of helicenes. These molecules derive their piezoelectric properties from the inherent strain in the molecule originating from their helical shape. This is unlike existing piezoelectric polymers such as poly-(vinylidene fluoride) (PVDF) whose piezoelectric properties originate from interaction between dipoles in the polymer structure. This research will begin with the synthesis of a diol-functionalized, nine-ringed helicene for application in a proof-of-concept polyester system. Initial characterization of this polymer will provide insight the as-synthesized properties of this novel polymer, and later optimization of piezoelectric properties will show the presence and extent of the functional activity of the polymer. The capability of these molecules to be adapted for use in various polymer chemistries give this new class of polymers potential for use in applications where material properties have previously limited the versatility of piezoelectric polymers.

**Localized Plasmon-Stimulated Triboelectric Nanogenerator**  
Gi Hyeon Han;  
MSE, UNIST, Ulsan, Korea (the Republic of).

We report for increase the surface charge density of the TENG using a surface plasma resonance. Resonant energy transfer (RET) generates electron–hole pairs in the thin PDMS layer and the air work as dielectric layer. While as a generator, the PDMS and ITO work as charges generation surface and the air between the wrinkle gap enables PDMS layer and ITO layer to contact and separate. The hierarchical wrinkle structure manages differentiating normal pressure and bending.

**Experimental Results:** Since extending C$_4$F$_8$ plasma treating time to 1000s can produce hierarchical wrinkle structure on the PDMS surface, the sensitivity in the relatively low pressure regime (0-500 Pa) can get an obvious promotion from 0.5 kPa$^{-1}$ (50s plasma treating), 1.0 kPa$^{-1}$ (500s plasma treating) to 2.0 kPa$^{-1}$ (1000s plasma treating). Moreover, in the relatively high pressure regime (more than 1500 Pa), the sensitivity of the sensor gets a slight promotion from 0.1 kPa$^{-1}$ (50s & 500s plasma treating time) to 0.2 kPa$^{-1}$ (1000s plasma treating time). Moreover, the response performance is excellent with the release-time is 0.7 ms and the rise-time is even only 0.15 ms. When pressure is applied, the small wrinkle firstly works and then sense the pressure quickly and sensitively by forming deformation, thus the sensitivity of the pressure sensor in the relatively low pressure regime can be highly enhanced and the response time is extremely short. When the pressure is applied extremely high, the big wrinkle begins to work and shows a sensitivity of 0.2kPa$^{-1}$ once bigger than that of a PDMS plate. As a TENG, the output voltage of the sensor under bending stimuli is about 300 mV, while that of the sensor under pressure stimuli is only about 75 V. **Tunable Tribolectric Dual-Gate Logic Devices Based on 2D MoS$_2$ and Black Phosphorus**  
Guoyun Gao$^{1,2}$,  
1Beijing Institute of Nanoenergy and Nanosystems, Beijing, China;  
2University of Chinese Academy of Science, Beijing, China.

With the Moore’s law hitting the bottleneck of scaling-down in size (below 10nm), personalized and multifunctional electronics with an integration of two-dimensional (2D) materials and self-powering technology emerges as a new direction of scientific research. Triboelectric nanogenerators (TENGs) that efficiently convert mechanical energy into...
electric power have great potential in self-powered smart systems and modulating semiconductor devices. As the basic components in integrated circuit, logic circuits based on 2D materials transistors have a promising potential. Here, we report a tunable tritobronic dual-gate logic device based on MoS2-FET, black phosphorus FET and a sliding mode TENG. Triboelectric potential produced from the sliding mode TENG under an external displacement can efficiently drive the complementary transistors and logic devices without applying a gate voltage. The high-s top gate dielectrics contributes to the increase of the effective capacitance of the device, leading to high performance tritobronic transistors with on/off ratio exceeding 10^4 and cutoff current below 1 pA/μm, which are the best ever obtained. Tunable electron behaviors of the logic device are also achieved according to different displacements of TENG coupled to the bottom gate, including tunable gains (improved to be ~13.8) and power consumptions (~1 nW). This work offers a low-power-consuming, active and a general approach to modulate semiconductor devices and logic circuits based on 2D materials with TENG, which can be used in micro-electromechanical systems, human–machine interfacing, data processing and transmission.

An Ambitious Triboelectric Nanogenerator for Multi-Environmental Smart Monitoring
Zening Zhao1, Fangfang Gao1, Qingliang Liao1, Zheng Zhang1, Zhuo Kang1 and Yue Zhang1, 2; 1State Key Laboratory for Advanced Metals and Materials, School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China; 2Beijing Municipal Key Laboratory of Advanced Energy Materials and Technologies, University of Science and Technology Beijing, Beijing, China.

With the advancement of human science and technology and the improvement of living standards, more people begin to put forward higher requirements for environmental conditions. Traditional and non-intelligent monitoring devices are gradually being replaced by intelligent, self-driven, simple in structure, and low-cost environmental monitoring systems, such as triboelectric nanogenerators. We report a triboelectric nanogenerator based on a tumbler structure, which adapts to the complex environment of amphibious, moisture and repeated impact, and can simultaneously collect water and wind energy in any direction and low frequency. A single device can achieve an output voltage to 140V and short-circuit current to 0.5μA. It can not only monitor wave height and wave frequency on the ocean, but also a wide range of wind speeds, even a breeze on land. Moreover, swimming pool water quality can be detected through the residual chlorine index. The advantage lies in adapting to the amphibious environment and reflecting on low frequency and irregular disturbances, with good prospect applications in the environmental monitoring field.

ES21.07.11
High Voltage Output Contact-Separation Mode Triboelectric Nanogenerators Based on Commercial-Available Polymers
Micky Wong; Hong Kong Polytechnic Univ, Hong Kong, Hong Kong.

As a sustainable power source, triboelectric nanogenerators (TENGs) have attracted extensive attention from both academia and industry to solve the growing energy crisis. Herein, a high voltage output contact-separation mode triboelectric nanogenerator is demonstrated by using commercial-available polyurethane foam and ebonite as triboelectric materials, which presents flexibility, durability and reliability, simultaneously. The dependence of electric outputs on the different parameters of the TENGs, including triboelectric affinity, gap distance between frictional layers, and the dimension of devices, has been systematically investigated. The optimized device can generate an open-circuit voltage of above 1000 V and a short-circuit current of above 100 μA. The TENG can operate continuously for 500 k cycles under large pressuring force with stable output performance. Meanwhile it can harvest mechanical energy from various human motions, such as stepping and tapping. Arising from its reliable high voltage output, the device can be utilized as a self-powered spark plug. This study provides a feasible method for developing power sources in simple fabrication and low-cost way. The work was supported by the grant of Research Grants Council of Hong Kong.

ES21.07.12
Vibration Based Piezoelectric-Electromagnetic Hybrid Energy Harvester for Autonomous Sensor Systems
Chong Yun Kang1,2, Inki Jung1,2 and Jaehoon Choi1,2; 1Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2KU-KIST Graduate School of Converging Science and Technology, Korea University, Seoul, Korea (the Republic of).

With the advent of the IoT era, the demand for sensors has increased significantly. We note that these sensor systems can communicate with each other over wireless networks in the IoT era. Especially, in particular sites where access to power is difficult, batteries have been installed as power source for wireless sensor systems. However, these batteries have a limited lifetime and require periodic replacement. So, various energy harvesting technologies have received research attention to realize an autonomous wireless sensor network by replacing the batteries. Due to relatively low power generation capability and energy conversion efficiency, however, these harvesting technologies have been applied only to limited applications.

In order to address these issues, here, we design and demonstrate a piezoelectric/electromagnetic hybrid energy harvester that can generate significant amount of electricity at vibration environments(Fig 1). Oval-like configuration using two curved piezoelectric energy harvesters based on MFC(Macro-fiber composite) piezoelectric material induces large displacement of a permanent magnet installed at the end of the top surface which allows efficient power generation both piezoelectric and electromagnetic energy harvesters. Compared to output average power (1.09 mW) of cantilever type piezoelectric energy harvester, piezoelectric part of Oval-shaped harvester shows about two times higher output average power (2.58 mW) at 0.5 g and 60 Hz vibration due to its enhanced vibration characteristics. Also, we provide the resonance frequency tuning guidelines and the optimization strategies of the Oval-shaped hybrid energy harvester using Finite Element Analysis (FEA) and mechanical equivalent system. The hybrid energy harvester contains two magnets facing same polarity on both side of Oval-shaped monolith. This configuration improves the spring constant of Oval-shaped harvester, reducing the damping ratio, efficiently. With two magnets, the Oval-shaped hybrid energy harvester with MFC achieves up to 1.03 mm displacement at 60 Hz and 0.5 g vibration conditions. Also, considerable improvement of output power is observed at both piezoelectric and electromagnetic parts. The output average power of piezoelectric part and electromagnetic part are 7.66 mW (239.4 μW/cm^2) and 0.60 mW (18.8 μW/cm^2), respectively. Total hybrid output power is 8.26 mW which is sufficient power for operating commercialized Bluetooth module (5 mW), continuously. This milliwatt-scale (~mW) hybrid energy harvester provides us the opportunity to realize autonomous sensor system to come in the near future.

ES21.07.13
Tuning the Photoluminescence of Aggregation-Induced Emission Luminogens via Magnetostrictive Stress and Piezoelectric Strain
Li Chen1, 2, 3; Hong Kong Polytechnic Univ, Kowloon, Hong Kong; 1School of Physical Science and Technology, Guangxi University, Nan Ning, China; 2Guangxi Institute of Nanoenergy, Nan Ning, China.

Many aggregation-induced emission (AIE) luminogens exhibit mechanochromic effect through grinding the luminogen powdery. The AIE luminogens undergo bright-dark switching between crystalline and amorphous states. However, a relatively high pressure is required to trigger the phase transfer. Meanwhile, the color manipulation cannot be realized in an in situ and reversible manner, which limits some of their applications. Smart materials including piezoelectrics and magnetostricrion materials provide the opportunities to couple external field to the AIE materials and realize more flexible controllable AIE. In this work, magnetic alloy nanoparticles iron cobalt nickel and piezoelectric poly(vinylidene fluoride) (PVDF) have been utilized to tune two kinds of aggregation-induced emission luminogens. Precise control over the emission intensity of luminogens under the external applied magnetic field or electric field has been demonstrated. The AIE has been decreased with the magnetostricative stress increasing, which is contributed to the looser molecular structure of AIE luminogens under the stimulating of a time-varying magnetic field. While, the piezoelectric strain induced an enhancement of emission intensity under electric field, which originates from the contact of PVDF lattice constant and restriction of intramolecular rotations of AIE luminogens. Thus, these results are expected to enrich the understanding of the luminescence process of AIE luminogens and promise more flexibility of AIE luminogens for the magnetic-optical and optoelectronic applications.

Growth and Characterization of Spatially-Ordered PZT Nanostructures by Glancing Angle Pulsed Laser Deposition
Domingo Mateo-Feliciano, Derick DeTelleml, Pritish Mukherjee and Sarahh Wittamichi; University of South Florida, Tampa, Florida, United States.

Lead Zirconium Titanate (PZT) is one of the most widely used piezoelectric materials due to its high piezoelectric constant, great piezoelectric response, operating temperature relative to other used piezoelectrics and is one of the industry standard materials in DRAMS and MEMs due to its ferroelectric properties. In addition, PZT is of great interest in piezotronics applications but achieving spatially ordered arrays are a challenge for device construction. This paper presents the characteristics of hexagonal closed-pack PZT nanocolumns grown by a Glancing Angle Pulsed Laser Deposition (GAPLD) technique on a template silicon (Si) substrates. The substrate is patterned with a self-assembled monolayer of Silica Nanospheres (SNs) of sphere sizes of 3.5 μm, 1.18 μm, 850 nm, 500 nm, 250 nm and 150 nm in diameter by Langmuir-Blodgett technique. Subsequently, PZT was deposited by GAPLD technique at an oblique angle to the substrate to promote ballistic shadowing. In this study, we pursued an investigation of the columnar angle’s
relationship with the deposition angle, and its effect on the crystallinity of the PZT nanostructured films. Results pertaining to the morphology, structure, and composition investigated for varying template sizes by SEM, EDS, AFM, and XRD will be presented.

**Mechanically Stable ZnO Hexagonal Nanopyramids Array for High Performance Piezoelectric Applications**

Jeongmin Lim and Alfredo A. Martinez-Morales
College of Engineering, Center for Environmental Research and Technology, University of California, Riverside, Riverside, California, United States; Materials Science and Engineering Program, University of California, Riverside, Riverside, California, United States.

Mechanical force-driven power generation can be achieved by the utilization of piezoelectric materials that produce electricity in response to external mechanical stress. Diverse piezoelectric crystal structures such as perovskite and wurtzite have been studied for piezoelectric nanogenerator applications. In particular, ZnO is extensively researched due to its semiconducting properties, along with its directional preferential crystal growth nature. The piezoelectric materials of ZnO have been demonstrated mostly through the bending stress of one-dimensional nanostructures such as nanowires. The utilization of ZnO in piezoelectric applications can be significantly improved by using the piezoelectric operation mode δ33, via the structural engineering (morphology) of crystalline ZnO from one-dimensional to pyramidal nanostructures.

In this work, our modified CVD synthesis technique is applied to synthesize the mechanically stable and highly piezoelectric ZnO hexagonal nanopyramids array. The superior mechanical stability was achieved through the morphology engineering of ZnO as a step-wise pyramidal structure. The single crystal pyramidal ZnO was grown in vertically-aligned pyramidal structures by controlling the supply of Zn vapor precursor during synthesis. The piezoelectric performance was measured by piezoelectric force microscopy under the highest piezoelectric operation mode δ33. The piezoelectric performance was improved by increasing the crystallinity and reducing planar and point crystal defects, as confirmed by transmission electron microscopy and X-ray diffraction analysis. The mechanical, optical, and physical characteristics of synthesized ZnO nanopyramids were characterized by piezoelectric force microscopy, photoluminescence spectroscopy, and Raman spectroscopy.

**ES21.07.16**

**Ultrasensitive Triboelectric Nanogenerator for Weak Ambient Energy**

Zhizhen Zhao; Key Lab. for the Physics and Chemistry of Nanodevices, Peking University, Beijing, China.

Higher requirements have been put forward for self-powered systems operated with weak energy in the environment. Sensitivity, efficiency and power management design of the energy harvesting module play key roles on the sustainability of the system. In this work, we present an ultrasensitive triboelectric nanogenerator (TENG) with Cu coated fluorinated ethylene propylene films stacked in a unipolar manner and suspended by springs. Triboelectricitization and electrostatic induction take place between every adjacent film surfaces, during which transferred charges are increased by at least 50%, leading to an increased efficiency. Also, the reduced framework weight makes soft spring can be adopted for greatly improved sensitivity. Depending on the investigation of mechanical motion in the system, TENG’s energy harvesting efficiency is boosted by bringing down the moment of inertia. The linear region characteristic of an n-type junction field-effect transistor is utilized for a low-loss power management design with greatly reduced power consumption and start-up time for superior weak energy harvesting applications. Ultrasensitive and high efficient energy harvester with low-loss power management demonstrated in this work promises an outlook for an effective approach to achieve more powerful and more sustainable self-powered systems working with comprehensive ambient weak mechanical energy fitted in diverse application circumstances.

**Piezoelectric Effect Tuning on ZnO Microwire WGM Lasing**

Junfeng Lu, Caofeng Pan and Zhong Lin Wang; Beijing Institute of Nanoenergy and Nanosystems, Beijing, China.

Piezoelectric force microscopy, photoluminescence spectroscopy, and Raman spectroscopy.

Laser has higher applications in science and technology, from medical to manufacture and to defense. An important characteristic of a laser is its wavelength and width of wavelengths. Wavelength tunable nanolasers are promising for multifunctional applications in all-optical integrated nanodevices, optical communication, optical sensing technology and spectroscopy analysis. However, most of the methods for tuning the lasing modes are lack of a dynamical tenability, that is, the ability to reversibly modulate the stimulated emission in a pre-prepared single micro/nanodevice.

In this work, a novel method for a dynamic tuning on coherent light emission wavelengths of single ZnO microcavity has been proposed. Owing to the dominant role occupied by the piezoelectric polarization effect in the wurtzite-structure ZnO microwre, the effective dielectric constant (or refraction index) of the gain media is modulated towards an increasing trend by applying a tensile strain, resulting in a shift of the strain-mediated whispering-gallery mode (WGM) lasing at room temperature. Due to the narrow linewidth in the lasing mode, the strain-dependent spectral resolution is improved by an order of magnitude, making it feasible for achieving high-precision, ultra-sensitive and non-contact stress sensing. Our results have an important impact on laser modulation, optical communication and optical sensing technology.

**Biodegradable Triboelectric Nanogenerator for Biomedical Devices**

Qiang Zheng and Zhou Li; Chinese Academy of Sciences, Beijing, China.

Over the last 60 years, implantable electronic systems and devices have undergone a significant transformation, becoming a valuable biomedical tool for monitoring, measuring and soliciting physiological responses in vivo. Where in vivo sensing or stimulation is required for a short period of time, degradable implantable electronic devices can provide a solution to overcome inflammation and infections associated with long-term implant utilization. Moreover, subsequent surgical removal of these devices can be avoided which will diminish the pain and cost to the patient. Currently, fabricating a complex high-performing electronic system from entirely biodegradable, non-toxic set of electronic materials is of growing interests. However, a reliable electrical power source that suitable for those transient implantable electronic devices still has not been experimentally investigated previously.

We demonstrated a set of materials, manufacturing schemes, device components for a biodegradable triboelectric nanogenerator (BD-TENG) which can harvesting mechanical energy in vivo and physically disappeared at prescribed times without any adverse long-term effects.

Tunable electrical output capabilities and degradation features were achieved by fabricated BD-TENG using different materials. When applying BD-TENG to power two complementary micro-grating electrodes, DC pulsed electrical field was generated and the neural cell growth was successfully orientated, showing its feasibility for in-vivo neuron repairing.

Our work demonstrates a significant potential of BD-TENG as a power source for transient implantable medical devices.
Laser Diodes Due to Piezo-Photonic Effect
Redefinition the Quasi-Fermi Energy Levels Separation of Electrons and Holes Inside and Outside Quantum Wells of GaN Based Multi-Quantum-Well Semiconductor

photocurrent and also provide a potential way to optimize the performance of self-powered PDs. The phototronic effect on the transient and steady-state photocurrent are revealed based on the bandgap diagrams. The results may help us to further clarify the mechanism of the pyro-electric effect relative to that obtained from the steady-state signal. The relative persistent secondary pyroelectric effect weakens the height of Schottky barrier, leading to a reduction of the electric potential distribution during device operation. The MENG sensor exhibited a stable open circuit voltage of 10.2 V at a 30.8 kPa pressure and a calculated sensitivity of 331 mV/kPa. The stability testing result showed that the device has only ~ 5% attenuation after 10,000 cycles of repeated testing at 30.8 kPa pressure. Furthermore, it was found that the MENG sensor responds not only to a dynamic force but also a static force. Finally, a sensor array consisting of nine MENG sensor elements was fabricated. The testing results from the sensor array also revealed that a single touch of the sensor element can immediately light up an LED light at the corresponding position. This device holds great promise for use in future tactile sensors and artificial skin applications.

A Monocharged Electret Nanogenerator-Based Self-Powered Device for Pressure and Tactile Sensor Applications Shaobo Gong, Jinxi Zhang, Chenchen Wang and Kaijiang Ren; Beijing Institute of NANOenergy and Nanosystems, Beijing, China.

This study reports a self-powered pressure sensor based on a monocharged electret nanogenerator (MENG). The sensor exhibits great advantages in terms of high reliability, ease of fabrication, and relatively high sensitivity. The working mechanism of the MENG sensor was studied by both theoretical derivations and finite element analyses to determine the electric potential distribution during device operation. The MENG sensor exhibited a stable open circuit voltage of 10.2 V at a 30.8 kPa pressure and a calculated sensitivity of 331 mV/kPa. The stability testing result showed that the device has only ~ 5% attenuation after 10,000 cycles of repeated testing at 30.8 kPa pressure. Furthermore, it was found that the MENG sensor responds not only to a dynamic force but also a static force. Finally, a sensor array consisting of nine MENG sensor elements was fabricated. The testing results from the sensor array also revealed that a single touch of the sensor element can immediately light up an LED light at the corresponding position. This device holds great promise for use in future tactile sensors and artificial skin applications.

Integrated Rotating Triboelectric Nanogenerator with Wireless Energy Delivery for Smart Home Yang Jie¹, Jinjing Ma², Yandong Chen¹, Ning Wang², Zhong Lin Wang² and Xia Cao³; Beijing Institute of NANOenergy and Nanosystems, Chinese Academy of Sciences, Beijing, China; University of Science and Technology Beijing, Beijing, China.

Both energy harvesting and power delivery are the key technology for self-powered systems, so the organic integration of two technologies can improve the performance. Herein, we develop an integrated rotating triboelectric nanogenerator (TENG) based on Maxwell’s displacement current to collect ambient rotational energy for wireless energy delivery (WED). To avoid the defects of continuing friction, a new disconnect-type TENG with the simple structure of four sectors is designed. By matching with the collectors at the vertical height of 2 cm, the output of WED has the rectified current and voltage of ~3 μA and ~17 V. And small mobile electronics can be powered without wires due to the maximum value of ~22 mW m⁻². Besides, a contact-type TENG is integrated with the disconnect-type TENG to improve the efficiency and adaptation. The mobile phone and digital camera can be charged by the contact-type TENG with an electrical output of ~2 mA and ~110 V. This work shows a new prototype of hybrid TENG with WED, which makes it feasible and convenient for the electric power supply in smart home.

Effective Wound Healing Enabled by Wearable Triboelectric Nanogenerator Yin Long, Hao Wei, Jun Li, Guang Yao, Weibo Cai, Angela L. Gibson and Xudong Wang; University of Wisconsin-Madison, Madison, Wisconsin, United States.

Non-healing skin wounds affect more than 6.5 million people in the United States, and result in enormous health care expenditures and long-term physical and mental suffering. Most of current strategies, including wound debridement, compression bandaging, wound dressing, hyperbaric oxygen therapy, negative pressure therapy, and ultrasonography, are passive treatments and rarely participate in controlling endogenous cell behaviors. Electrical stimulation (ES), which imitates the natural wound healing mechanism of the endogenous electric field to facilitate skin growth, is an attractive adjunct to wound care and has a potential to treat many different types of acute and chronic skin wounds with minimal adverse effects and good simplicity to apply.

The recent innovation of triboelectric nanogenerator (TENG) opened a new route for generating periodic biphasic electric pulses by locally converting mechanical displacements, such as body or muscle motions. This exceptional capability makes TENG a unique candidate for producing electrical stimulations that is self-sustainable and biologically responsive. Besides, TENGs could be made flexible with reasonably high output power density and energy conversion efficiency. Here we report an efficient electrical bandage for accelerated skin wound healing. On the bandage, an alternating discrete electric field is generated by a wearable nanogenerator by converting mechanical displacement from skin movements into electricity. Rat studies demonstrated rapid closure of a full-thickness rectangular skin wound within 3 days as compared to 12 days of usual contraction-based healing processes in rodents. From in vitro studies, the accelerated skin wound healing was attributed to the electric field-facilitated fibroblast migration, proliferation and transdifferentiation. This self-powered electric-dressing modality could lead to a new and facile therapeutic strategy for non-healing skin wounds treatment.

Comprehensive Pyro-Phototronic Effect Enhanced Ultraviolet Detector with ZnO/Ag Schottky Junction Laijun Zhu and Zhong Lin Wang; Chinese Academy of Sciences, Beijing, China.

As a coupling effect of pyroelectric and photoelectric effect, pyro-phototronic effect has demonstrated an excellent tuning role for fast response p-n junction photodetectors (PDs). Here, a comprehensive pyro-phototronic effect is utilized to design and fabricate a self-powered and flexible ultraviolet PD based on the ZnO/Ag Schottky junction. By using the primary pyroelectric effect, the maximal transient photocurrent sensitivity of the self-powered PDs can reach up to 1.25 mA W⁻¹ for 325 nm illumination, which is improved by 1465% relative to that obtained from the steady-state signal. The relative persistent secondary pyroelectric effect weakens the height of Schottky barrier, leading to a reduction of the steady-state photocurrent with an increase in the power density. When the power density is large enough, the steady-state photocurrent turns into a reverse direction. The corresponding tuning mechanisms of the comprehensive pyro-phototronic effect on transient and steady-state photocurrent are revealed based on the bandgap diagrams. The results may help us to further clarify the mechanism of the pyro-phototronic effect on the photocurrent and also provide a potential way to optimize the performance of self-powered PDs.

Redefinition the Quasi-Fermi Energy Levels Separation of Electrons and Holes Inside and Outside Quantum Wells of GaN Based Multi-Quantum-Well Semiconductor Laser Diodes Due to Piezo-Phototronic Effect Dinge Li¹, Lifeng Feng², Wei Yang¹, Xiaodong Hu¹ and Cundu Wang²; Chinese Academy of Sciences, Beijing, China; Tianjin University, Tianjin, China; Peking University, Beijing, China.

Both accurate experiments and a self-consistent theoretical simulation using the near-ABC or ab initio method have uncovered the anomalous changes in the junction voltage (Vj) of GaN-based lasers. Here, further accurate emission spectrum characteristics and band-gap simulation of a GaN based laser diodes (LDs) confirmed that previous researchers may have been confused the junction voltage (Vj) of LDs and the separation in the two Fermi levels of electrons and holes in the active region divided by the electronic charge. For the multiple-quantum wells (MQWs), there are obvious differences between them due to piezo-photonic effect. For the ideal GaN-based LDs, despite the increase in junction voltage, physical quantities including the separation between the two Fermi levels of electrons and holes in the MQW region, the optical net gain, the carrier concentration have remained unchanged beyond the threshold region after an unpredictable sharp increase in the threshold region.

Efficient Piezocatalytic Activity Driven by the Piezoelectric Effect of BaTiO₃ Nanowires Jue Wang, Ni Qin and Dinghua Bao; Sun Yat-Sen University, Guangzhou, China.

Recently, a novel catalysis technology, which named piezocatalysis, has received significant attention due to independence of light irradiation. Here, we report the new advances in the piezocatalysis of BaTiO₃ and further investigate the relationship between piezoelectric potential and piezocatalysis. In this work, we successfully synthesized...
BaTiO$_3$ nanowires and nanoparticles by a two-step hydrothermal method. It was found that the BaTiO$_3$ nanowires exhibit effectively enhanced piezocatalytic activity under ultrasonic vibration compared with the BaTiO$_3$ nanoparticle. To explore the origin of the excellent piezocatalysis performance of BaTiO$_3$ nanowires, the distribution of piezoelectric potential in these nanomaterials was simulated by the finite element method (FEM) with the aid of COMSOL multiphysics software package. On the basis of the piezoelectric potential analysis by FEM simulation, the enhanced piezocatalytic activity of the BaTiO$_3$ nanowires can be attributed to the larger piezoelectric potential along the polar axis. A relatively larger piezoelectric potential of the catalyst surface can induce a greater shift of conduction band and valence band, resulting in easier and faster immigration of the electrons and holes, during reacting with dissolved oxygen and hydroxyl to form superoxide radicals and hydroxyl radicals. Furthermore, we demonstrate that the intrinsic charge carriers (not piezoelectric charges) in piezoelectric crystallites play the role of charge transfer in the catalysis process through regulating the concentration of charge carriers in catalyst. This study provides further understanding piezocatalysis of piezoelectric nano-materials as well as insights on the relationship between piezoelectric potential and piezocatalysis.

ES21.07.27
Multimodal Enhancement of Luminescent Light Harvester And Triboelectric Touch Sensor via P(VDF-TrFE) Hong Joon Yoon and Sang-Woo Kim; Sungkyunkwan University, Suwon, Korea (the Republic of).

Display technology has not only presented information traditionall but also multifunctional capability, flexibility, lightness and slimmness design are desired attributes for being adopted by artificial intelligent (AI) to interact with consumers. In this regard, ferroelectric poly(vinylidenefluoride-co-trifluoroethylene) (PVDF-TrFE) is of great interest as potentially applicable for display power saving material with having mechanical stability, transparency, and electrically controllable polarization. Here, we report the experimental study of a luminescent light harvesting property of CdSe QD embedded P(VDF-TrFE) nanocomposite, whereas the concentration of QD is not as much high as to interfere presenting information in visual. In agreement with theoretical calculation, the converted power from luminescent light guided to the c-Si solar cell is enhanced by 42% based on the quantum-confined Stark effect (QCSE) owing to ferroelectric polarization of P(VDF-TrFE). The resulting nanocomposite shows enhanced mechanical sensitivity (~40%) by aligned dipole moment of P(VDF-TrFE) upon mechanical contact. This nanocomposite material may potentially be applicable as multimodal display element not only enable to power itself but also detect given mechanical touch.

ES21.07.28
Butylated Melamine Formaldehyde and CaCu$_2$TiO$_4$: Particles Based Composite Dielectric Layer for High Output Performance Triboelectric Nanogenerators Jinwo Kim and Sang-Woo Kim; Sungkyunkwan University, Suwon, Korea (the Republic of).

Triboelectric nanogenerators (TENGs) offer a promising approach for mechanical energy harvesting, but an effective strategy for enhancing the output performance is a crucial requirement. Though many studies have been performed to maximize the triboelectric effect on the surface of dielectric materials, studies for improving electrostatic induction phenomenon inside the dielectric materials have not yet been conducted. Here, we propose a high output performance TENG with a composite of butylated melamine formaldehyde (BMF) matrix and the high dielectric constant particles of CaCu$_2$TiO$_4$ (CCTO) as an excellent dielectric layer for enhancing the electrostatic induction phenomenon. The high dielectric constant CCTO particles result into a strong polarization of the dielectric materials under the triboelectric field. As a consequence, the charge induction in the bottom electrode is enhanced thereby increasing the triboelectric output power. A rotation-type freestanding mode TENG based on BMF-CCTO 1wt% composite has produced an RMS voltage and a current density (268 V and 25.8 mA/m$^2$) which is about 3 times higher than that (113.2 V and 8.7 mA/m$^2$) of the TENG based on pure BMF. The strategy of incorporating the high dielectric constant CCTO particles is completely general and can be applied to any polymer matrix in order to enhance the output performance of TENGs.

In Situ TEM Investigation of Stress-Induced Recoverable Charged Domain Walls in Barium Titanate Qianwei Huang$^{1}$, Zibin Chen$^{1}$, Feifei Wang$^{2}$, Yu-Wing Mai$^{3}$, Simon Ringer$^{4}$, Haosu Luo$^{5}$ and Xiaozhou Liao$^{6}$; $^{1}$The University of Sydney, Sydney, New South Wales, Australia; $^{2}$Shanghai Normal University, Shanghai, China; $^{3}$Shanghai Institute of Ceramics, Chinese Academy of Sciences, Shanghai, China.

Domain walls in ferroelectric materials act as functionalized interfaces. The atomic structures in domain wall areas have a significant impact on the properties of the domain walls. Both theoretical simulations and experimental measurements demonstrated that dense charged domain walls (CDWs) can effectively enhance the piezoelectric response of ferroelectrics. Usually CDWs do not steadily exist due to the high electrostatic energy. In some cases, the formation of CDWs can be realized via electrical bias. However, applying an electric field to ferroelectrics could induce current leakage. In this presentation, we demonstrate that CDWs can be created via mechanical stress, which effectively avoids the potential problem of current leakage.

Here, an in-situ straining transmission electron microscopy technique was used to explore the structural evolution of ferroelectric domains introduced by mechanical stressing. Barium titanate micro-pillars were prepared using the focused ion beam technique. Mechanical loading was applied along a <100> direction. A high density of fine nanoscale domain walls formed when a pillar was compressed. Electron diffraction patterns of pillars with and without mechanical loading confirmed that all the newly created domain walls were CDWs. The original domain structure was restored with the full retraction of the external stress. The mechanism of the stress-induced evolution of domain wall structures will be discussed in detail. Our discovery is very important for the investigation of electromechanical properties of ferroelectrics.

Piezoelectric Acoustic Sensor Based on Two-Dimensional MoS$_2$ Hyoung Taek Kim, Ahrum Sohn, Jae Hwan Jung and Sang-Woo Kim; School of Advanced Material Science and Engineering, Sungkyunkwan University, Suwon, Korea (the Republic of).

Experimental studies on the physical properties of two-dimensional (2D) materials have grown exponentially since 2D materials offer unique advantages for use in such next-generation devices. Various semiconducting 2D materials have been studied, including transition metal dichalcogenides (TMDs) such as molybdenum disulfide (MoS$_2$), molybdenum diselenide (MoSe$_2$) and tungsten diselenide (WSe$_2$), which are likely to bring breakthroughs in future electronic and optoelectronic devices. The physical properties of 2D MoS$_2$ nanosheets have been actively explored particularly as a result of their possible integration in both nano/microelectromechanical devices and energy harvesting devices. Monolayer MoS$_2$ has a direct band gap and high mobility and it has been used to successfully fabricate field-effect transistors so it has emerged as an interesting complement to graphene in various semiconductor applications. In addition it is expected that piezoelectric properties of 2D layered materials are very useful to realize high sensitive, high impact resistive, self-powered sensor. However, studies on the suspended model of 2D MoS$_2$ have been done mainly on studies on the measurement method or photosensitivity, and studies using the piezoelectric characteristics of suspended MoS$_2$ have not been actively done. Here we report a new way to use 2D MoS$_2$ for high sensitive 2D piezoelectric acoustic sensor. The acoustic sensor fabricated by using suspended structure of MoS$_2$ which generate piezoelectric output potential due to vibration transmitted by sound. We have achieved high sensitivity and high impact resistance by using single layer or several layers of MoS$_2$, and by using piezoelectric properties of MoS$_2$, we have produced an acoustic sensor that does not require standby power. This study demonstrates a new way of studying 2D MoS$_2$-research and acoustic sensors by developing a high-sensitivity and high-durability acoustic sensor using suspended MoS$_2$.

Direct Current Generator Based on Microdischarge via Accumulation of Triboelectric Charge in Atmospheric Condition Minki Kang, Hong Joon Yoon and Sang-Woo Kim; School of Advanced Materials Science and Engineering, Sungkyunkwan University, Suwon, Korea (the Republic of).

A Triboelectric generator (TEG) is one of the most promising energy harvesters for powering electronics or sensors, conversing abundant kinetic energy to electrical energy. TEG generates displacement current according to triboelectric surface charge and electrostatic induction by periodic motion. Fundamentally, the surface charge density on triboelectric layer greatly affects to output performance of TEG and there have been numerous intensive studies to increase surface charge density. The surface charge density has been increased dramatically using advanced materials such as nanocomposite, ferroelectric materials or fluorinated materials. However, high surface charge density induces the microdischarge generation and upper configuration of available surface charge density in certain TEG mode becomes new challenge for next-generation high performance TEG. Here, we propose direct current generator based on microdischarge via accumulation of triboelectric charge in atmospheric condition. Microdischarge based direct current generator TEG (MD-TEG) employs in-plane configuration of each layer, electrode layer, rotor and segment layer. Also there is gap of sub-millimeter scale between electrode and rotor. These structural characteristics enable accumulation of huge amount of triboelectric charge in atmospheric condition and efficient charge-conveying those who are essential for high
output performance. Based on the novel working mechanism and structural characteristics of CSTEG, we found out that it can generate maximum output current of 12.2 mA/m² in RMS value under 1000 rpm.

**Multi-Functional Robust Reduced Graphene Oxide–Poly(vinylidene fluoride-trifluoroethylene) Flexible Nanocomposite Thin Film for Efficient Green Energy Harvesting**

Ritamay Bhunia and Ashish Garg; Indian Institute of Technology-Kanpur, Kanpur, India.

Nowadays, energy is an essential factor to sustain in our day-to-day life. The adverse effect of the mostly used energy sources fossil fuels are driving the researchers towards the alternative renewable energy research. Nanogenerators (NGs) have brought revolution in the energy harvesting research field. Modern civilization is using wireless smart nanodevices which are potentially used in sensing, monitoring of environmental state, industry, medical sciences, defense. Proliferation of using these electronic devices has raised a demand of fabrication of self-powered devices to replace battery. As ignited by the invention of piezoelectric nanogenerators (PE-NGs) in 2006[1], people are trying to harnessing electrical energy from various mechanical energies worldwide for self-powering devices at cost-effective ways. Different strategies were followed to boost up the output power level of the PE-NGs with different piezoelectric materials and various novel structures. In 2012, another more efficient and flexible, robust, low cost fabricated device named triboelectric nanogenerator (TE-NG) for harvesting energy was demonstrated by Z. L. Wang and his group.[2] So, till then these two devices have got more attention due to suitable power density, durability, flexibility, cheap device fabrication, wide material choice and outstanding adaptability to green energy sources.[3] Considering this scenario, there is urgent need for an acceptable material which can serve high output power densities with reliable time duration and can mold on any curve surface at low-cost.

Through this present work, a multi-functional eco-friendly flexible material has been presented which can be used as efficient energy harvester from ambient mechanical energies as well as ferroelectric memory device (Fe-RAM) material. We fabricated both flexible PE-NG and TE-NG of area 4x4 cm² made of reduced graphene oxide–Poly(vinylidene fluoride-trifluoroethylene) nanocomposite thin films (6-7 mm) processed through low-cost sol-gel way. Self-alignment of reduced graphene oxide (rGO) in the composite depends on different phenomena like p-p interaction between carbonyl, carboxyl functional groups of basal planes of rGO and P(VDF-TrFE), van der waals force between the nearest rGO sheets, excluded volume interaction, steric hindrance.[4] These interactions broke the centro-symmetry of rGO and piezoelectric property was induced in rGO, which further enhanced the ferroelectric, piezoelectric properties in polymer nanocomposite.[5] Due to the presence of negative functional groups attached with planes of rGO nano-flakes, it also improved the composite as a negative triboelectric material and the TE-NG performance. This was further confirmed measuring surface potential after inclusion of rGO in P(VDF-TrFE) through KPFM technique. Thus, this composite can serve as an efficient multi-functional material for energy harvesting and memory application. Piezo Force Microscopy (PFM) showed formation of more ferroelectric domains in case of composite than pristine P(VDF-TrFE). Remnant polarization (P_r) and dielectric constant increased 13.3 % and 150% from 7.18 mC/cm² and 14 of pristine polymer, respectively due to the space charge formation between interface of insulating polymer and slightly conducting rGO sheets. The highest piezoelectric co-efficient (d_33) was observed -80.19 pC/N in case of an optimum rGO concentration in polymer matrix, where the value for pristine polymer was -41.37 pC/N. The average PE-NG output voltage (V_max) made of polymer composite was measured 62 V (maximum 75 V) attaching the device on a wall of small rotary pump for 30 minutes continuously, while virgin polymer films showed 1.1 V. An average 190 V V_max was recorded from TE-NG of highest rGO content polymer nanocomposite. The maximum output power densities through 1 MW load resistance of PE-NG and PE-NG devices were 222 and 32 mW/cm². We were able to glow 20 LEDs in parallel directly by just 3 fingers tapping using TE-NG.

**ES21.07.33**

**Flexible PVDF Nanocomposite Films for Enhanced Piezoelectric Effect**

Neeraj Khare and Huidrom Hemojit Singh; Indian Institute of Technology Delhi, Hauz Khas, India.

The number of electronic devices used in our daily life has been increasing tremendously since the last decades. Several devices require only few milli-watt power. Piezoelectric nanogenerators based on the flexible piezoelectric polymers mainly Polyvinylidene fluoride (PVDF) is a path-breaking device that can power these small-scale electronic devices directly [1-2]. Although the intrinsic piezoelectric property of PVDF is low, many methods have been employed to enhance the piezoelectric property like thermal treatment, mechanical stretching and electrical poling [3]. In the present work, we will compare the performance of piezoelectric nanogenerator fabricated using various PVDF nanocomposite films. We have achieved enhanced piezoelectric property of PVDF just by adding nanostructures such as ZnO, NaNbO_3, BaTiO_3 without any further heat, electrical or mechanical treatment. XRD, polarization-electric field (P-E) measurement, Fourier transform infrared spectroscopy (FTIR) measurements have been performed, and the reason behind this enhancement in the piezoelectric property has been analyzed and discussed. We have compared the enhancement by adding a different amount of nanofillers of different shapes, and this gives a brief idea of choosing the appropriate nanofillers for enhancing the piezoelectric property of PVDF. Comparison of the performance of these nanogenerators fabricated from PVDF nanocomposites will be presented.

**Deep-Trap Dominated Sustainable Mechanoluminescence from Layered Perovskite SrSnO_3:Sm^3+ Dong Tu** and Chao-Nan Xu; 1Wuhan University, Wuhan, China; 2National Institute of Advanced Industrial Science and Technology, Tsu, Japan.

Mechanoluminescence (ML) from purely inorganic materials is basically triggered by a pre-UV-irradiation process, which largely limits its practical applications. Here, by designing a pinning-trap structure, a novel sustainable ML is developed from Ruddlesden–Popper perovskite SrSnO_3:Sm^3+ even without the pre-UV-irradiation process. This ML of SrSnO_3:Sm^3+ could keep stable and maintain a certain intensity even extending the wait time to 50 h. ML mechanism is also investigated by analysis of trap structure through the thermoluminescence method. A thermoluminescence peak at 420 K showed no attenuation after 50 h waiting time, which could be ascribed to a high-density pinning trap, result in the increase in the ML intensity and ML intensity maintenance ratio.

**Triboelectric Nanogenerator Networks Integrated with Power Management Module for Water Wave Energy Harvesting**

Tao Jiang, Xi Liang, Guoxu Liu; Chi Zhang; Zhong Lin Wang; Georgia Institute of Technology, Atlanta, Georgia, United States.

Ocean waves are one of the most promising renewable energy sources for large-scale applications. Recently, triboelectric nanogenerator (TENG) network has been demonstrated to effectively harvest water wave energy possibly toward large-scale blue energy. However, the absence of effective power management severely restricts the practicability of TENGs. In this work, a hexagonal TENG network consisting of spherical TENG units based on spring-assisted multilayered structure, integrated with a power management module (PMM), was constructed for harvesting water wave energy. The output performance of the TENG network was determined by wind wave frequencies and amplitudes, as well as the wave type. Moreover, with the implemented PMM, the TENG network could output a steady and continuous direct current (DC) voltage on the load resistance, and the stored energy was dramatically improved by up to 96 times for charging a capacitor. The TENG network integrated with the PMM was also applied to effectively power a digital thermometer and a wireless transmitter. The thermometer can constantly measure the water temperature with the water wave motions, and the transmitter can send signals for alarming once every 10 s. This study extends the application of the power management module in the water wave energy harvesting.

**Piezotronic Magnetoelectric Sensors for Biomedical Diagnostics**

Mona M. Mintken, Sören Kaps, Yogendra K. Mishra, Jürgen Carstensen and Rainer Adelung; Kiel University, Kiel, Germany.

Advanced medical diagnostics tools like magnetoencephalography (MEG) and magnetocardiography (MCG) require sensors that can detect low frequency magnetic fields of very...
small amplitudes in the nano- to sub-picotesla range. Superconducting quantum interference device (SQUID) sensors, which are state of the art in these applications, have several drawbacks including the need of cooling, operation in sheltered chambers and high cost. Magnetoelastic (ME) sensors are currently developed as a promising alternative. The working principle of ME composite sensors relies on a magnetostrictive layer, which translates the change in magnetic field into mechanical deformation. It is mechanically coupled to a piezoelectric layer to convert the mechanical strain into electric voltage.

The piezotronic effect can be employed for realizing the ME sensor signal to improve the limit of detection (LoD), which is the smallest measurable magnetic field normalized to an equivalent noise bandwidth of 1 Hz. One of the two electrodes attached to the piezoelectric component of the sensor is chosen to be a material which forms a Schottky type contact with the piezoelectric material, while the second electrode forms an Ohmic contact. The electric field generated in the piezoelectric material when it is deformed changes the charge carrier transport characteristics across the Schottky contact drastically. This effect replaces an external amplifier for the sensor signal (in this case a piezotronic current), leading to lower noise and reduced power consumption compared to conventional voltage read-out.

Two kinds of ME sensors have been investigated here: one is a cleanroom-fabricated MEMS cantilever type sensor that consists of magnetostrictive FeCoSiB and piezoelectric AlN. The other sensor type consists of a single crystalline ZnO needle mounted on a piece of magnetostrictive foil. The variation of parameters such as doping, defects and stress in the material and geometry, contact configuration, electric and magnetic bias fields and read-out process of the sensor setup leads to a deeper understanding of the piezotronic effect and is expected to increase the performance of various ME sensor types.

In the present work, we have analyzed the time signal of the ME sensors to further understand the noise sources and reduce the noise floor of the sensor system by customized digital signal processing.

High Sensitive Self-Powered Triboelectric Auditory Sensor for Social Robotics and Hearing Aid Hengyu Guo1,2,3,1, Xiaojie Pu2, Chenguo Hu1 and Zhong Lin Wang1,2,3; Georgia Institute of Technology, Atlanta, Georgia, United States; ‘Chongqing University, Chongqing, China; ‘Beijing Institute of Nanoenergy & Nanosystems, Beijing, China.

The auditory system is the most efficient and straightforward communication strategy for connecting the human beings and robots in the upcoming artificial intelligent (AI) era. Here, we design a self-powered triboelectric auditory sensor (TAS) for constructing a new electronic auditory system and further applying as the architecture of external hearing aid in intelligent robotic applications. Based on the unique working mechanism of newly developed triboelectric nanogenerator (TENG) technology, the TAS shows ultra-high sensitivity (110 mV/µB). TAS with the broadband response from 100 to 5000 Hz is achieved by designing the annular or sectorial inner-boundary architecture with systematical optimization. Incorporating with intelligent robotic devices, TAS demonstrates a capability of high-quality music recording and accurate voice recognition for realizing intelligent human-robot interaction. Furthermore, the fascinating feature of TAS with tunable resonant frequency can be achieved by adjusting the geometric design of inner-boundary architecture, which can be used to amplify a specific sound wave naturally. Based on this unique property, we propose a new type of hearing aid with TENG technic, which can simplify the signal processing circuit and reduce the power consuming. This work expresses significant advantages of using TENG technology to build a new generation of auditory systems for meeting the challenges in social robotics.

ES21.07.38

Self-Powered Multifunctional Motion Sensor Enabled by Magnetic Regulated Triboelectric Nanogenerator Zhiyi Wu, Wenbo Ding, Yejing Dai and Zhong Lin Wang; Georgia Institute of Technology, Atlanta, Georgia, United States.

With the fast development of Internet of Things, the requirements of system miniaturization and integration have accelerated research on multifunctional sensors. Based on the triboelectric nanogenerator, a self-powered multifunctional motion sensor (MFMS) is proposed in this work, which is capable of detecting the motion parameters, including direction, speed, and acceleration of linear and rotary motions simultaneously. The MFMS consists of a triboelectric nanogenerator (TENG) module, a magnetic regulation module, and an acrylic shell. The TENG module is formed by placing a free-standing magnetic disk (MD) on a polytetrafluoroethylene (PTFE) plate with six copper electrodes. The movement of the MD causes the MD to slide on the PTFE plate and hence excites the electrodes to produce voltage output. The carefully designed six copper electrodes (an inner circle electrode, an outer circle electrode, and four arc electrodes between them) can distinguish eight directions of movement with the acceleration and determine the rotational speed and direction as well. Besides, the magnetic regulation module is applied here by fixing a magnetic cylinder (MC) in the shell, right under the center of the PTFE plate. Due to the magnetic attraction applied by the MC, the MD will automatically return to the center to prepare for the next round of detection, which makes the proposed sensor more robust and more applicable in practice.

ES21.07.39

Ultrasensitive and Highly Selective Self-Powered Room Temperature NO2 Detection Enabled by Triboelectric Nanogenerator Yuanjie Su, Guangzhong Xie, Huiling Tai, Xiaosong Du and Yadong Jiang; University of Electronic Science and Technology of China, Chengdu, China.

With increasing vehicle ownership and environment pollution, the release of nitrogen dioxide (NO2) and its derivatives have considerably posed a threat to human health and public security. By far, various approaches have been applied to develop a reliable, accurate and sensitive approach for NO2 detection, including field effect transistor (FET), surface acoustic wave (SAW), bulk acoustic wave (BAW), resistance, quartz crystal microbalance (QCM). However, all of these sensing techniques are demanded for a power supply which undoubtedly renders incredible high cost and complexity. In addition, considering the tremendous number and wide distribution of gas sensor networks, it is unrealistic to continuously sustain the availability of the external power source and replace the battery for each device especially in wilderness and extreme environment. Therefore, a simple, robust and low-cost gas sensor operated by scavenging ambient energy is desperately desired.

In this work, a triboelectric nanogenerator (TENG) driven self-powered gas sensor has been developed for room temperature nitrogen dioxide (NO2) detection under UV illumination (365 nm). Powered by TENG, the concentration of NO2 can be spontaneously detected via chemoresistive gas sensor based on Zinc Oxide-Reduced graphene oxide (ZnO-RGO) hybrid films, where the voltage drop across the interdigital electrodes (IDEs) has a proportional relationship with NO2 concentration. The self-powered triboelectric gas sensor (TGS) comprised by ZnO-RGO composite films exhibit superior response (~16.8) and sensitivity as well as selectivity that for pure ZnO film. With respect to selectivity, the response of ZnO-RGO composite film based TGS to NO2 was at least 49-fold higher than those for other gases. Furthermore, through a signal processing circuit, a self-powered NO2 gas alert system was developed for real-time monitoring the ambient NO2 concentration. This work not only promotes the applicability of TENGs as self-powered sensors but also pushes forwards the active sensing network node for environmental monitoring by harvesting ambient energy.

Piezotronic Effect In 1D Solid of Elemental Tellurium Nanobelt for Smart Adaptive Electronics Shengjie Gao1,2, Yixiu Wang1,2 and Wenzhuo Wu1,2; Purdue University, West Lafayette, Indiana, United States; 1Flex Laboratory, West Lafayette, Indiana, United States.

Emerging technologies in wearable systems demand that functional devices can adaptively interact with the human body, where mechanical stimuli are ubiquitous and abundant. However, the electrical manipulation of charge carriers underpins the operations of state-of-the-art devices, and the effective control of interfacial energetics for charge carriers by the dynamic mechanical stimuli is still a relatively unexplored degree of freedom for semiconductor nanodevices. Piezotronic effect in nanostructured piezoelectric semiconductors offers exciting opportunities in addressing the above challenges. Here we report the first experimental exploration of piezotronic effect in 1D solid of p-type tellurium nanobelt and systematically investigate the strain-gated charge carriers transport properties. The strain-induced polarization charges at the [1010] surfaces of Te nanobelt can modulate the electronic transport through the interfacial effect on the Schottky contacts and the volumetric effect on the conducting channel. The competing phenomenon between interfacial
and volumetric effects has been studied for the first time in piezotronics. Our research allows the access to a broad range of characterization and application of Te nanomaterials for piezotronics and could guide the future study of piezotronic effect in other materials. This progress in piezotronics, together with emerging methods for deterministic production and assembly of nanomaterials, leads to compelling opportunities for research from basic studies of piezoelectricity and semiconductor properties in functional nanomaterials to the development of “smarter” electronics and optoelectronics.

ES21.07.41
Engineered and Laser Processed Chitosan Biopolymers for Sustainable and Biodegradable Triboelectric Power Generation Ruoxing Wang and Wenzhuo Wu; Purdue University, West Lafayette, Indiana, United States.

Triboelectric nanogenerator (TENG) is regarded as a promising technology to replace traditional power source by converting mechanical energy to electricity. However, most TENGs are made from materials that are not biocompatible, which limits their applications in biomedical and implanted applications. Here we report for the first time the development of low-cost, biodegradable and flexible triboelectric nanogenerators based on chitosan, which is one of the most abundant biopolymers on earth and can be derived from the shells of shrimp or other sea crustaceans. Tunable electrical outputs were achieved by either mixing the chitosan with other natural materials such as starch and lignin or through laser processing. The chitosan-based TENGs present efficient energy conversion performance and the optimized chitosan-based power source can be used for water purification by taking advantage of the electrostatic attraction effect and chelation with contaminants in the water. The new class of TENGs derived from natural materials may pave the way towards the economically viable production of flexible TENGs for self-powered nanosystems in biomedical and environmental applications.

ES21.07.42
Solution-Synthesized Chiral Piezoelectric Selenium Nanowires for Wearable Self-Powered Human-Integrated Monitoring Min Wu, Yixiu Wang, Shengjie Gao, Ruoxing Wang and Wenzhuo Wu; Purdue University, West Lafayette, Indiana, United States.

Smart sensing devices with high stretchability and self-powered characteristics are essential in future generation wearable human-integrated applications. Here we report for the first time scalable synthesis and integration of selenium (Se) nanowires into wearable piezoelectric devices, and explore the feasibility of such devices for self-powered sensing applications, e.g., physiological monitoring. The ultrathin device can be conformably worn onto the human body, effectively converting the imperceptible time-variant mechanical vibration from human body into distinguishable electrical signals, e.g., gesture, vocal movement, and radial artery pulse, through straining the piezoelectric Se nanowires. Our results suggest the potential of solution-synthesized Se nanowire a new class of piezoelectric nanomaterial for self-powered biomedical devices, and opens doors to new technologies in energy, electronics, and sensor applications.

ES21.07.43
Nanocomposites Electret with Unique Surface Potential Self-Recovery Characteristics for Harvesting Mechanical Energy in Extreme Environment Huayang Li and Guang Zhu; University of Nottingham Ningbo China, Ningbo, China.

Developing the electrets that can withstand harsh environments are playing an important role in harvesting mechanical energy in extreme cases. Here we report a new nanocomposites electret material that exhibit efficient self-recovery of the surface potential after water dipping. The surface charge density can reach 0.5 mC/m² and the surface potential can recover to 90% of its initial value in 60 mins after fishing out. The electret nanogenerator based on this electret can effectivly harvest mechanical energy and the high output power is 54 mW. Moreover, the electric output can self-recover by 90% in 10 mins without any other friction cycles. With a power management circuit, the electret-nanogenerator-based power-supplying system can used to power a wireless emitter. Given the self-recovery property of this new electret and the electret nanogenerator, this study broadens new perspectives for promoting the wearable devices in extreme environments.

ES21.07.44
Mapping Pressure with Flexible and High-Resolution p-GaN/n-ZnO Nanowires Arrays by Piezo-Phototronic Effect Yiyou Peng and Caofeng Pan; Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, Beijing, China.

Simulating human tactile sensing through high-resolution electronics is a significant and challenging topic in the field of artificial intelligence. Compared with the senses of sight, smell, hearing, and taste, touch remains stubbornly difficult to mimic, which needs the development of large-sized pressure sensor arrays possessing high-spatial resolution, high-sensitivity, fast-response [1, 2]. The rapidly developing flexible LED arrays can be employed as a strain sensor to indicate the pressure distribution through different light emission intensities [3, 4]. GaN, as an ideal semiconductor material for short-wavelength optoelectronics, has long been a grand challenge to be used for flexible light-emitting devices due to the rigid epitaxial substrate.

In our work, we fabricated a flexible and high-resolution p-GaN/n-ZnO nanowires heterostructure light-emitting diode (LED) arrays, the light emission of which is enhanced by piezo-phototronic effect. Specifically speaking, a flexible p-GaN film/n-ZnO nanowires light-emitting diode (LED)-based pressure sensor array, with the merits of flexibility, high resolution, fast response, good transparency, stability, and lightweight, is fabricated through laser lift-off (LLO) process and used to acquire the two-dimensional pressure distribution mapping by reading the illumination intensities from all LED pixels parrelally. The intensity of each pixel composed by a GaN/ZnO nanowire heterostructure LED can be enhanced by the local compressive strain based on piezo-phototonic effect. A high spatial resolution of 2.6 um, a fast response time of 180 ms and a relatively wide measurement region were obtained, and the sensor array can still function well after 4000 bending circles.

The approach is scientifically novel to combine the advantages of high resolution and fast response in regard to rigid GaN substrate LED and flexibility of organic LED, which may be more easily applied in highly intelligent and flourishing human-machine interfaces and make an important step in flexible photonic integration technology, with potential application prospects in smart skin, touch panel technology, biomedicine science, and optical MEMS.

ES21.07.45
Strain Modulation Band Alignment of Monolayer MoS2/ZnO Nanorod Mixed-Dimensional Heterostructure Arrays for Efficient Charge Transfer Baishan Liu1,2, Qingliang Liao1, Zhao Kang1 and Yue Zhang1,2; 1State Key Laboratory for Advanced Metals and Materials, School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China; 2Beijing municipal key Laboratory for advanced Energy Materials and Technologies, University of Science and Technology Beijing, Beijing, China.

The isolation of extraordinary two-dimensional (2D) semiconductors has inspired worldwide efforts to form van der Waals heterostructures for promoting electronic and optoelectronic applications. Due to the ultra-strength of 2D materials, strain engineering offers a new strategy for tailoring properties of heterostructures. However, this approach requires a stable method to apply strain and an understanding of strain effects on the band alignment of heterostructures. Here, we construct periodic-strained monolayer MoS2/ZnO heterostructure via nanoindentation from tailored ZnO nanopatterns. Sufficient comparison of photoluminescence (PL) measurements clearly verifies that strain can efficiently tune the band gap of MoS2 and enhance charge transfer efficiency from MoS2 to ZnO. Eventually, we demonstrate that enhanced charge transfer efficiency is attributed to strain modulation on the band alignment of MoS2/ZnO. These findings highlight strain engineering for optimizing the band alignment of heterostructure and potentially pave the way to design integrated optoelectronics or photovoltaics with novel functions.

ES21.07.46
Networks of High Performance Triboelectric Nanogenerators Based on Liquid-Solid Interface Contact Electrification for Harvesting Low-Frequency Blue Energy Juan Tai and Caofeng Pan; Beijing Institute of Nanoenergy and Nanosystems, Beijing, China.

Energy crisis has become one of world's most serious challenges, as the rapid growth of the total energy consumption. The renewable energies have been intensively explored and converted into electricity to ensure the sustainable development. The inexhaustible blue energy from the ocean is independent of season, circadian rhythm and weather. At the same time, triboelectric nanogenerators (TENGs) are considered as one of the most promising approaches for harvesting blue energy. Previously, most of the blue-energy-harvesting TENGs are based on the friction between solids, but the contact / friction area is only a tiny portion of the total surface due to the roughness of the surface and the inefficient contact condition.
In this work, a network of liquid-solid-contact triboelectric nanogenerator (LS TENG) is fabricated to efficiently harvest the huge quantities of blue energy from ocean. Due to the sufficient contact condition of the liquid solid interface, the energy output per cycle of LS TENG is about 48.7 times bigger than that of the solid-solid-contact triboelectric nanogenerator (SS TENG) with same area. The buoy LS TENG can generate several sequential damping signals just by one pulse of triggering, demonstrating the maximum utilization of the vibration energy. This characteristic merit renders it available for the buoy LS TENG to collect the low-frequency current efficiently. The output current, transferred charge and the output voltage of the network of 18 LS TENGs are 290 µA, 16725 nC and 300 V.

Additionally, the buoy LS TENGs could harvest large quantities of energy, including surface wave energy and submarine current energy, to power portable electric devices or navigation systems. In this work, the electricity generated from the LS TENGs is stored in the capacitor to drive a wireless SOS radio frequency (RF) transmitter for ocean emergencies. This work provides a more efficient method of capturing the blue energy and expands its applications.

Reference:
with smaller width and the mode positions can be modulated dynamically. The relationship between the corresponding applied strain and the tunable refractive index is analyzed in depth and discussed systematically. This method will open new horizons in understanding and utilizing the piezoelectric properties of lead halide perovskites.

ES21.07.50
An Ultralight, Self-Powered and Self-Adaptive Motion Sensor for Perceptual Layer Application in Internet of Things Xuan Zhao, Xiaochen Xun, Fangfang Gao, Qingliang Liao and Yue Zhang; University of Science and Technology, Beijing, China.

In the Internet of things (IoT), motion sensor in the perceptual layer is at the forefront of the information collection, which plays a crucial role in the IoT. However, with a large number of commercial applications, several problems of motion sensor limit the development of IoT such as poor portability, poor environmental adaptability, and high energy consumption, etc. In this work, an ultralight, self-powered and self-adaptive motion sensor (UMS) is reported. Total mass of the UMS is less than 20 mg. Zero energy consumption of the UMS is achieved by the coupling of triboelectricity and electrostatic induction. Moreover, the UMS shows satisfactory self-adaptive performance of both temperature and humidity, less-sensitive to temperature in surroundings, from 5 degrees Celsius to 60 degrees Celsius, and ambient humidity under 90% RH. Furthermore, sensing signals triggered by different motion behaviors, such as grasping, walking, stooping and so on, can be distinguished by the processor clearly, which can be applied to motion recognition and machine control. This work presents a novel UMS with characteristics of portability, energy conservation and environmental friendliness. The UMS shows broad prospect in perceptual layer application in IoT.

ES21.07.51
Ultrafast, Sunlight-Triggerable Transient Energy Harvester and Sensors Based on Triboelectric Nanogenerator Using Acid-Sensitive Poly(phthalaldehyde) Changsheng Wu, Jiun Jiang, Hengyu Guo, Paul Kohl and Zhong Lin Wang; Georgia Institute of Technology, Atlanta, Georgia, United States.

Transient electronics that can degrade under certain circumstances have great potential in biomedical and military applications. Depending on constituting materials, the transient purpose can be achieved either through material dissolution or depolymerization. Material demploymization can be achieved through variable stimuli, such as humidity, temperature, chemical, or light. Meanwhile, triboelectric nanogenerator (TENG), an emerging mechanical energy harvesting technology that has great flexibility in material choices, is promising in offering transient power sources. Pioneering efforts have been made on biodegradable TENGs using biodegradable polymers such as polyglycolic acid and poly(lactic acid) for implantable power sources. However, these TENGs only offer solution-based degradation and have limited application in non-biological scenarios. In this work, we developed the first TENG whose degradation can be triggered simply by sunlight and completed in a short time span. Its main substrate was made of the acid-sensitive poly[(phthalaldehyde) (PPHA), a photo-acid generator (PAG) called tetraakis(hexafluoro-2,5-dioxo-1,4-pentanone)diborane, and a sensitizer called anthracene. The sensitizer was used to absorb and transfer the energy of UVA light (365 nm) to PAG via photo-induced electron transfer, while the latter generates protons to trigger the depolymerization of PPHA. The triboelectric properties of this PPHA-based material were studied, which suggested that it locates at the more positive side in the triboelectric series than nylon. Transient TENG-based biomechanical energy harvester and tactile sensors were successfully demonstrated by embedding silver nanowires into the PPHA-based films. Therefore, this work not only broadens the applicability of TENG as transient power sources, but also expands the use of functional polymers towards advanced energy and sensing applications.

Piezoelectric Gated Interfacial Charge Modulation in WSe2-ZnO Mixed-Dimensional Van Der Waals Heterostructures for Ultrasensitive Flexible Photodetectors Jun Li, Zheng Zhang, Qingliang Liao, Zhiuo Kang and Yue Zhang; Beijing Municipal Key Laboratory for Advanced Energy Materials and Technologies, University of Science and Technology, Beijing, China; School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China; State Key Laboratory for Advanced Metals and Materials, School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China.

Van der Waals (vdWs) heterostructures based on atomically thin 2D materials have led to a new age in next-generation flexible optoelectronics, due to their excellent bending strength, absence of bond fracture and atomic reconstruction under strain.[1] Furthermore, gate-tunability of van der Waals (vdWs) material is crucial for modulating performance of vdWs optoelectronics. [2] However, the conventional electrostatic gating has met severe challenges in flexible optoelectronics owing to in-plane cracking and slippage of gate electrode under strain. So far, most of the reported flexible photodetector based on 2D materials suffer from low sensing performance. Here, we propose a distinctive strain-gating method to achieve high performance flexible photodetector by combining the strong light-material interaction in 2D WS2 and excellent piezoelectric property of 1D ZnO. The photodetector shows a good photovoltaic response under a defined white light illumination intensity of 0.667 mW/cm2 by a halogen lamp. By modulating with strain-induced piezopolarization charges in ZnO, short-circuit current of photodetector was enhanced by 2 times under a tensile strain of 0.87%. Under photoconductive mode, the photocurrent was improved to 320 pA, and responsivity up to 0.394 A/W. Enhancement of the sensing performance is attributed to local energy-band tilting at the piezo-modulated WSe2-ZnO interface. In particular, these piezopolarization charges lead to increase of built-in electric field in heterojunction and accelerate the separation of photo-excited electron-hole pairs, which ultimately promotes the photoresponsivity of the device. Our work provides a new strategy to achieve interaction between vdWs interface and strain stimuli, which may broaden applications of functional vdWs heterostructure for next-generation visible detecting or imaging.

Super-Stretchable and Mechanically-Durable Triboelectric Nanogenerators for Deformable and Wearable Energy Sources and Self-Powered Electronic Skins Ying-Chih Lai1,2,3, Changsheng Wu1,2,3, Zheng Zhang4, Qingliang Liao2 and Yue Zhang1; 1Department of Materials Science and Engineering, National Chung Hsing University, Taichung City, Taiwan; 2Research Center for Sustainable Energy and Nanotechnology, National Chung Hsing University, Taichung City, Taiwan; 3Innovation and Development Center of Sustainable Agriculture, National Chung Hsing University, Taichung City, Taiwan.

Wearable and stretchable electronic devices have attracted great interest because they cannot only extend the application scope of electronic systems but also provide compliant user experience. Driving those devices inevitably need power sources. However, conventional batteries suffer from not only heavy weight and bulky volume but also limited capacity and lifetime, handicapping the progress and practical uses of those emerging devices. In this present, super-stretchable and mechanically-durable triboelectric nanogenerators (SD-TENGs) will be demonstrated by using composed of intrinsic stretchable components. The newly-designed SD-TENGs can generate electricity from contact capacity and lifetime, handicapping the progress and practical uses of those emerging devices. In this work, we developed the first TENG whose degradation can be triggered simply by sunlight and completed in a short time span. Its main substrate was made of the acid-sensitive poly(phthalaldehyde) (PPHA). The sensitizer was used to absorb and transfer the energy of UVA light (365 nm) to PAG via photo-induced electron transfer, while the latter generates protons to trigger the depolymerization of PPHA. The triboelectric properties of this PPHA-based material were studied, which suggested that it locates at the more positive side in the triboelectric series than nylon. Transient TENG-based biomechanical energy harvester and tactile sensors were successfully demonstrated by embedding silver nanowires into the PPHA-based films. Therefore, this work not only broadens the applicability of TENG as transient power sources, but also expands the use of functional polymers towards advanced energy and sensing applications.

Harsh-Environmental-Resistant Triboelectric Nanogenerator Baodong Chen; Beijing Institute of NANOenergy and Nanosystems, Beijing, China.

We report a device suitable for harsh environmental applications based on the wear-resistant triboelectric material. The working modes of the harsh-environmental TENG (heTENG) was composed of freestanding mode and single electrode mode that enables both harvesting sliding/vibration energy and self-powered vibrational sensing. For the first
time, the TENG possessing wear resistance, withstanding high temperature and high hardness is achieved by employing micro-nano composite for triboelectric materials. It is demonstrated to be directly used as a key supporting part, such as automobile's brake pads. In addition, it is found that the heTENG outputs 221 V, 27.9 μA/cm² and 33.4 μC/cm². Furthermore, since the heTENG is vibration-sensitive, the automobile's self-powered smart braking (SP-SB) system and sensor network are developed successfully which can automatically provide exact early-warning signal, such as a reminding of the brake's replacement, vehicle overweight, and tire pressure variation. Our work shows a new strategy to enhanced the performance of triboelectric materials, making it applicable to harsh environment, and also provides new opportunities for sliding/vibration energy harvesting and self-powered vibrational sensing, as well as potential applications in autonomous vehicles and industrial brakes.

**Silicon-Based Spintronics—Experimental and Theoretical Validation of Spin Manipulation in Silicon**  
Paul Lou, Sun Ken, Pengfei Wang, and Dongfeng Diao; 1 Key Laboratory of Education Ministry for Modern Design and Rotor-Bearing System, Xi'an Jiaotong University, Xi'an, China; 1 Institute of Nanosurface Science and Engineering (INSE), Guangdong Provincial Key Laboratory of Micro/Nano Optomechantronics Engineering, Shenzhen University, Shenzhen, China.

As a revolutionary energy harvesting technology, triboelectric nanogenerator (TENG) has attracted the worldwide attention for its distinguished properties and wide application as self-powered sensors since it was invented. A common challenge for sliding-mode TENG was surface friction induced materials abrasion and electrical output performance degradation in mechanical energy harvesting under long-term continuous work. Clarify the effect of friction force on the electrical output performance of sliding-mode TENG not only can improve its output performance but also provide a guideline in the structure design of TENG. In this work, a series of experiments were designed and conducted to reveal the effects of the friction force on the electrical output performance of three kinds of sliding-mode TENG, namely, metal-dielectric, semiconductor-dielectric and dielectric-dielectric. The results showed that the short-circuit output current and the open-circuit voltage of the metal-dielectric sliding-mode TENG increased with the increase of sliding friction force. More importantly, we found that with an excitation induced by friction force the short-circuit output current of the metal-dielectric sliding-mode TENG showed an inverse tendency compared with the short-circuit output current under a changeless friction force. In addition, it was found that a wave friction force has great benefit in enhancing the electrical output performance of metal-dielectric sliding-mode TENG. These findings not only reveal the effect of friction force on the electrical output performance of sliding-mode TENG but also provide a guideline for designing and optimizing the structure of TENG to efficiently harvesting mechanical energy.

**Friction Force Effect on the Electrical Output Performance of Sliding-Mode Triboelectric Nanogenerator** Weiqiang Zhang, Kun Sun, Pengfei Wang, and Dongfeng Diao; 1 Key Laboratory of Education Ministry for Modern Design and Rotor-Bearing System, Xi'an Jiaotong University, Xi'an, China; 2 Institute of Nanosurface Science and Engineering (INSE), Guangdong Provincial Key Laboratory of Micro/Nano Optomechantronics Engineering, Shenzhen University, Shenzhen, China.

High-power devices, such as ultrasonic motors, underwater acoustic transducers and piezoelectric transformers, require piezoelectric ceramics with low dielectric loss tan δ, high mechanical quality factor Q_m (low mechanical loss), and simultaneously large piezoelectric constant d33 and electromechanical coupling factor k_p [1]. Many ternary and quaternary piezoelectric ceramics, such as Pb(Mg_{1/3}Nb_{2/3})O_3-Pb(Zr,Ti)O_3, Pb(M_{1/3}Nb_{2/3})O_3-Pb(Zn_{1/3}Nb_{2/3})O_3-Pb(Zr,Ti)O_3, etc. [2, 3] have been synthesized and modified by MnO, CoO, etc. to satisfy these requirements. However, it is still difficult to improve piezoelectric properties and reduce dielectric loss simultaneously. Herein we report our research work on the FeO_3 doped Pb(M_{1/3}Nb_{2/3})O_3-Pb(Zn_{1/3}Nb_{2/3})O_3-Pb(Zr,Ti)O_3 (PMnS-PZN-PZT) high-power piezoelectric ceramics. These ceramics possess a single-phase perovskite structure, and the addition of FeO_3 helps to acquire a dense morphology. FeO_3 doping also tailors the phase structure of the PMnS-PZN-PZT ceramics. Ceramics with FeO_3 content of 0.45 wt% exhibit a relatively large piezoelectric responses and extremely low losses, showing that the ceramics is suitable for the high-power applications. The electric field dependence of dielectric and piezoelectric properties in subswitching field range, and the effect of temperature on the nonlinearity of dielectric property are also investigated. The results show that the dielectric and piezoelectric constants gradually increase with the increase of electric field level. Rayleigh analysis reveals the contribution from lossless reversible domain wall motion to the high-field nonlinear dielectric and piezoelectric properties [4]. This behavior is associated with the orderly distribution of defect pinning centers, and is thought to be responsible for the low losses of the ceramics. At elevated temperatures, the mobility of the oxygen vacancies increases, so that the distributions of the defect pinning centers are gradually randomized, which consequently lead to the enhancement of high-field nonlinearity.

**Piezoelectricity and Ferroelectricity in 2D Layered Materials for Electronic Devices** Xi Yuan, Hung-Liu Chan and Jianhua Hao; The Hong Kong Polytechnic University, Hong Kong, China.

Recently, piezoelectricity in 2D van der Waals (vdW) materials has attracted great interest owing to promising unique applications in nanoscale electromechanical systems, ultrasensitive sensors, high-precision actuators, piezotronics and piezo-piezotronics. Monolayer transition metal dichalcogenide MoS_2 with intrinsic in-plane piezoelectricity has been extensively addressed in recent years, which has great potential applications. However, the vertical piezoelectric response of MoS_2 is theoretically absent due to the inversion symmetry. Here, we report out-of-plane piezoelectricity and ferroelectricity in 2D layered material InSbSe_2. Specially, the piezoelectricity based on the InSbSe_2 is not limited by edge effect and layer-dependence. Moreover, the out-of-plane ferroelectricity in InSbSe_2 is also investigated by piezoresponse force microscope, which can retain the ferroelectric behaviour down to 6 nm. This work opens the door to explore ferroelectricity and piezoelectricity to the family of 2D layered materials which will create novel functionalities of both materials and atomic-scale electronic devices. The work was supported by the grant from Research Grants Council of Hong Kong (GRF No. PolyU 153033/17P).
Electrochemical techniques have been extensively applied to treat heavy metal pollution in our daily life. Considering the energy crisis in modern times, a self-sufficient power source that coupled with chemical processes for maximizing recycling efficiency of heavy metal ions using the least electricity, is a promising alternative for the simultaneous energy saving and environmental governance. Here we investigated the effects of constant current and impulse current on hexavalent chromium (Cr(VI)) removal. Compared with constant current, impulse current with higher frequency (10 Hz) can enhance the removal efficiency of Cr(VI) under the equal electric charges. Meanwhile, the removing efficiency Cr(VI) can be further improved by optimizing the on-off ratio of pulses. Based on the analysis, a pulsed direct-current output based on triboelectric nanogenerator (TENG) is obtained through designing pulse current waveforms. With only the electrical energy extracted from mechanical motions by the TENG, heavy metal pollutant such as Cr(VI) can be sufficiently and continuously removed.

Fiber-Based Hybrid Energy Conversion Systems Bao Yang, Wei Zeng, Song Chen, Jian Song, ShiRui Liu, Shaping Lin, Lisha Zhang and Xiaoming Tao; Institute of Textiles & Clothing, The Hong Kong Polytechnic University, Kowloon, Hong Kong.

Wearable systems integrated with fiber-based electronic and photonic devices are soft, ubiquitous, flexible, stretchable, light, permeable, having the most favorite features of human-friendliness. It is extremely desirable to replace rechargeable batteries or prolong their life by harvesting energy from ambient or our body for the wearable systems to work for us anywhere at any time.

In this paper, our recent progress is presented on a number of issues of fiber-based hybrid energy conversion systems. Theoretical models for the fiber-based piezoelectric, triboelectric and their hybrid generators are proposed and verified to predict the output performance of the devices in terms of materials, device structure, harvesting circuits and operating conditions. The interaction between the cascaded PENG and TENG units in a hybrid nanogenerator and its effect on output are disclosed. Furthermore, the theoretical upper limits of output from contact-mode FTENG are revealed and verified experimentally by considering the electric breakdown due to field-induced- emission and gas- ionization. In addition, an experimental platform developed is reported for reliable triboelectric charge measurement of highly deformable and porous materials like fabrics. An extended triboelectric series is described by us including twenty-one types of commercial and new fibers. On the other hand, fiber-based flexible thermoelectric energy conversion devices are being developed. The materials, fabrication processes and characterization are discussed. The study sheds light on the scope and focus for further improvement of the devices. Based upon the findings, we have made significant enhancements of the performance.

Self-Powered Electronic Medical Devices Zhou Li; Beijing Institute of Nanoenergy and Nanosystem,CAS, Beijing, China.

Recently, piezoelectric nanogenerator (PENG) and triboelectric nanogenerator (TENG) have attracted much attention and been considered as another potential solution for harvesting mechanical energy. With its high output performance, outstanding biocompatibility and low cost, nanogenerator (NG) has been studied for powering implantable medical electronic devices.

Here, we demonstrated an in vivo biomechanical-energy harvesting using a NG. An implantable triboelectric nanogenerator (iTENG) in a living animal has been developed to harvest energy from its periodic breathing. The energy generated from breathing and body moving was used to power a prototype pacemaker and a low-level laser cure (SPLC) system, respectively. It was found that the self-powered system could regulate the heart rate of a rat and significantly accelerated the mouse embryonic osteoblasts' proliferation and differentiation. Real-time acquisition and wireless transmission of self-powered cardiac monitoring data was demonstrated for the first time. It showed broad clinical applications of implantable self-powered medical systems for disease detection and health care. These works are concentrated on live-powered implantable medical devices. The NGs can convert the mechanical energy from human motion into electricity and drive the implanted long-term self-powered medical devices or biosensors. These are significant progress for fabricating implantable self-powered medical electronic devices using NGs as a power source and an active sensor.

Triboelectric Nanogenerator for Weak Mechanical Energy Source Yusufan Hu; Peking University, Beijing, China.

Energetic motions like wind and tide are already well handled with existing technologies on large industrial equipment for examples. Meanwhile, mechanical movements with small amplitudes and low frequencies are underexplored, which take place in a wider range of both time and space scales by random excitation in the environment. Fully utilizing such abundant weak energy sources ensures a more powerful and more sustainable self-powered system. However, higher requirements are put forward for weak energy harvesting technologies, especially in two terms of sensitivity and efficiency. Several recent progresses of weak mechanical energy harvesting based on triboelectric nanogenerators are summarized here, including designing the device with unstable mechanical structure, utilizing soft textile to capture subtle body movement, investigating mechanical motion in the system for efficiency optimization, realizing low-loss power management, etc.

9:30 AM ES21.08.05
Triboelectric Nanogenerators for Wearable Physical Monitoring Systems Wei Tang; Beijing Institute of Nanoenergy and Nanosystems, Beijing, China.

There have been profound research works aiming at monitoring humanity physiological signals for disease prophylaxis and treatment, health assessment, tactile (or touch) sensing,
and even security application by developing wearable/portable and sensitive nanogenerator-based sensors. More often, sensors focusing on diagnosis or precaution could meet practical demand by discovering bioelectric signals from special point, such as blood pressure from the radial artery revealing arterial sclerosis, movement of body and eyeballs telling sleep disorder, and motion of respiratory muscles for diagnosis of respiratory disease, respectively. Meanwhile, the foot pressure distribution not only can suggest footwear design and sport biomechanics information, but also indicate possible injury and even predict ulceration in the feet of patients with type 2 diabetes. Specifically, plantar pressure values from a lot of areas, including heel, lateral mid foot, metatarsal, and so on, can serve as a necessary medical indication. In this paper, we present two our recent works on utilizing nanogenerators as the sensing component and then constructing wearable physical monitoring systems for real-time foot pressure mapping and ankle rotation angle sensing. As for the foot pressure mapping, a flexible printed circuit board (FPC) with 32 pieces of PVDF as the PENG pressure sensors (PENG-PS) is employed, which can be large quantity manufactured at low cost. To convert the raw sensor signal to digital signal, the FPC with PENG-PS attached is connected to a designed data acquisition circuit (DAQ). These converted results can be transmitted to mobile terminal, such as laptop, pad, and smart phone through Bluetooth 4.2 protocol, then the real-time pressure distribution is reconstructed. More importantly, through driving by a hybridized triboelectric-electromagnetic nanogenerator, a self-powered and real-time pressure mapping system is demonstrated. As for the ankle rotation angle sensing, a free-standing rotary TENG is utilized. It achieved a rotation resolution less than 1 degree. Moreover, by employing two sets of TENGs, the rotation direction can be detected. We integrated the device with embedded circuits, which can convert the electric signal of TENG into digital data, and transmit to the laptop or smart phone through Bluetooth, forming the real-time monitoring. These works show the promising future of constructing wearable sport monitoring system by utilizing TENG.

Self-Powered Flexible Electronics Beyond Thermal Limits
Koon Jao Lee; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

This seminar introduces three recent progresses of self-powered flexible electronic systems beyond thermal limits. The first part will introduce self-powered systems for IoT sensors and flexible energy source. Flexible nanogenerator converts external bio-mechanical movement into electrical energy for self-powered IoT and biomedical devices such as pacemaker and transportation. In addition, flexible piezolectric materials detects the minute vibration of membrane or human skin that expands the application of self-powered acoustic sensor and healthcare monitor. The second part will introduce laser material interaction for flexible applications. Laser technology of ultra-short pulse duration becomes important for future flexible electronics since high temperature process can be adopted on plastic substrates, which is essential for high performance electronics. Exciting results of flexible laser material interaction will be explored from both material and device perspectives including nanomaterial synthesis, inorganic laser liftoff and plasmonic material realization. The third part will discuss flexible large scale integration (f-LSI) for flexible CPU and high density memory. Flexible LSI is an essential part of future electronics for data processing, storage, and radio frequency (RF) communication. To fabricate f-LSI, we integrated 0.18 CMOS process of single crystal silicon nano-transistors with flexible electronics. Simultaneous roll transfer and interconnection of flexible NAND Flash memory was achieved using anisotropic conductive film (ACF). Finally, we introduce the highly efficient and long-term stable flexible vertical micro LED (f-VLED) for full color displays, wearable and biomedical applications. Using optogenetic mouse models, f-VLED stimulated motor neurons deep below layer III from the brain surface and induced mouse behavior changes. These f-VLED can be also used as tools of skin research and phototherapy.

10:45 AM *ES21.09.02
A Quantum-Mechanical Treatment of Contact Electrification
Morten Willatzen1,2, and Zhong Lin Wang1,2,3; 1Chinese Academy of Sciences, Beijing Institute of Nanoenergy and Nanosystems, Beijing, China; 2University of the Chinese Academy of Sciences, School of Nanoscience and Technology, Beijing, China; 3School of Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

With the challenge of powering networks of trillions of sensors and devices for the Internet of Things the need for effective generators harvesting low-frequency vibrational energy from the ambient is expected to increase dramatically. This type of energy should be mobile and ubiquitously accessible entailing generators that are compact, effective over a large bandwidth, and of small physical dimensions. Triboelectric nanogenerators (TENGs) are ideal candidates [1] out-competing traditional electromagnetic generators as the latter is ineffective at the low frequencies characterizing ambient vibrational energy from wind, human activity etc. Further, TENGs may provide high power densities up to 500 W/m² or 15 MW/m³. The latter characteristics of TENGs have fuelled a huge interest in exploiting and designing effective generators experimentally. Despite triboelectric energy and charge transport in TENGs is an effect known since ancient times, a detailed microscopic understanding is still not available [2,3].

In this work, we present a quantum-mechanical model of contact electrification between atomic systems and then proceed to analyze the more complicated case involving crystalline solids [4]. The transfer mechanism in atomic systems, that we consider, is based on electron transfer from an atomic state with energy Eᵢ to a lower-energy (Eⱼ) state associated with material B and the emission of a photon with energy Eᵥ + Eᵥ. The spontaneous emission rate is determined using Fermi’s Golden Rule in the dipole approximation based on the one-electron Schroedinger equation. The process requires spatial overlap of the initial and final state wavefunctions, hence the electron transfer is a sensitive function of the distance between the two materials A and B as well as the symmetries of the atomic states. We start out by determining the spontaneous emission rate for a fixed distance between atoms and then analyze the temporal variation of level occupations, i.e., the time dependence of electron transfer, using the Einstein rate equations and assuming the higher-energy level is occupied initially. Next, we determine the transfer of electrons in a dynamic setup where the distance of the two materials changes in an oscillatory manner.

Inspired by this simple quantum-mechanical description of contact electrification between atomic systems we generalize the idea to crystalline solids. Using a one-band k.p envelope function approximation of electronic states [5], the dipole matrix elements between surface states in dielectric materials A and B are computed. Since solids are quasi-continuum systems the transfer rate depends intrinsically on the conduction and valence bands of the two interacting materials, Fermi levels of the two materials, temperature, the vacuum energy (since vacuum separates the two materials), effective masses, and the distance between materials A and B. We calculate the spontaneous emission rate as a function of distance by varying the Fermi levels, temperature, and the effective masses. The model can easily be generalized to describe contact electrification between conductors and/or dielectrics. Other transfer mechanisms such as phonon emission through, e.g., the Froehlich coupling can be described in a similar way.

Universal Approach of Enhancing Piezotronics by Creating Pores in Piezoelectric Semiconductors Chuan-Pu Liu1, Kapil Gupta1, Yu-Lun Su1 and Ruesy-Chi Wang2; 1National Cheng Kung University, Tainan, Taiwan; 2National University of Kaohsiung, Kaohsiung, Taiwan.

In the Internet of Things era, both self-powered nanodevices and nanogenerators (NGs) that harvest energy from mechanical vibrations are highly attractive, prompting a rapid surge in research on enhancing their performance. To this end, it becomes nature to search for new materials with higher piezoelectric coefficients. However, it is not always a simple task to fabricate large-scale and high-quality new materials as considering the limited synthesis techniques. Alternatively, to optimize the microstructure characteristics of a given material may be more beneficial and effective. To alter the properties of a given material, we have demonstrated several strategies including doping, oblique orientation and alloying and the output performances of various piezotronic devices as well as piezoelectric nanogenerators have been significantly improved. However, some of the strategies are specific to materials and those material-dependent characteristics may have limitations for universal utilization. We demonstrate a versatile approach for diverse materials, by altering microstructure with discontinuous nano-pores in one-dimensional nanostructures, which can be readily extended into higher-dimensional single crystal materials, such as epitaxial thin film. This novel approach is demonstrated for two applications, i.e., direct-current (DC) NGs and piezotronics by taking ZnO as a model, where remarkably enhanced performance is depicted in theoretical simulations and confirmed by experiments. Here, we report that porous ZnO nanowires-based DC-NGs demonstrate ~23 times enhancement in output performance, and strain-gated transistors exhibit ~6 times enhancement in force-sensitivity. This can potentially augment energy harvesting and pressure sensing for many applications, such as, self-powered nano-devices and touch-panels.

11:45 AM ES21.09.04 Porous Polymer Thin Films for Mechanical Energy Harvesting and Self-Powered Electronics Yanchao Mao; MOE Key Laboratory of Materials Physics, School of Physics and Engineering, Zhengzhou University, Zhengzhou, China.

Triboelectric nanogenerators (TENGs) are promising innovative energy conversion devices that convert mechanical energy to electricity based on triboelectric friction. We developed a series of TENGs based on sponge-like porous polymer thin films such as polydimethylsiloxane (PDMS) and polytetrafluoroethylene (PTFE). The porosity effect on the output performance of the porous TENG was investigated under mechanical impacts. The output voltage of the porous TENG is obvious higher than that of the solid polymer thin film based TENG under the same condition. The porous TENG can also generate considerable electricity by harvesting mechanical energy from human motions. The generated electric energy could instantaneously power some light emitting diodes (LEDs) and other small electronics without any energy storage process. The development of the porous TENG could open a new avenue toward developing self-powered personal electronics, owing to their flexibility, simple structure, and the ability to harvest mechanical energy from human motions.

1:30 PM *ES21.10.01 Optimized Interface Conditions for Piezoelectric and Energy Harvesting Potential in ZnO Juergen Roedel and Till Frömling; Earth and Materials Science, Technische Universität Darmstadt, Darmstadt, Germany.

The coupling between piezoelectric and semiconducting properties opens the pathway to the development of electronic devices with additional functionality. [1] In the past, the changes in potential barrier, which were achieved via application of mechanical stress, are only in the order of meV or a few percentage of the total height of the potential barrier. Similarly, charge screening is deemed critical and not necessarily the full piezoelectric potential of ZnO can be harvested.

The latter is addressed by conducting an experimental study using undoped intrinsically conductive ZnO single crystals with both Ohmic and Schottky contacts [2]. The effective piezoelectric response is then quantified at temperatures from -140°C and 20°C, and frequencies from 0.5 Hz to 160 Hz. The formation of an electrostatic potential barrier at the metal-semiconductor interface was found to increase electrical resistance and hence delivers full utility of unbiased piezoelectric coefficients of ZnO single crystals even at room temperature. This can also be seen as an illustration and quantification of the piezotronic effect on an ideal macroscopic single crystal. Due to the Schottky barrier the piezoelectric charge cannot be fully screened by electronic charge carriers.

An almost complete elimination of the potential barrier at the interface was achieved by utilizing a bicrystal ZnO / ZnO interface with well-defined polarization conditions. The methodology is based on bonding two well-aligned single crystals of ZnO with an intermediate thin polycrystalline sacrificial layer of doped ZnO. Subsequent high temperature growth treats the single crystals into the sacrificial layer and consumes the polycrystalline materials either partially or fully. The doping content is optimized so that a double Schottky barrier develops at the ZnO-ZnO interface. For full growth, a single interface evolves. Based on this structure, we will show how stress can tune the potential barrier in head-to-head and tail-to-tail orientation of the polarization vector to enhance/lower the conductivity across individual ZnO bicrystal interfaces. Surpassing the stress sensitivity of previous piezotronic systems. [3]

2:00 PM ES21.10.02 A Biomimetic Pressure Sensor Based on Ultrathin Supercapacitor and Flexible Triboelectric Nanogenerator Xia Cao1; Jingdian Zou1, Meng Zhang1, Ning Wang2 and Zhong Lin Wang1; 1Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, Beijing, China; 2University of Science and Technology Beijing, Beijing, China.

With the fast development of supercapacitor and triboelectric nanogenerator (TENG), it is now possible to fabricate biomimetic pressure sensors with high flexibility and sustainability. Herein, an ultrathin supercapacitor is fabricated with the paper sheet and the solid electrolyte for storing energy generated by TENG. With a sandwich design, the triboelectrets sandwiched within the two solid supercapacitors can not only store electrical energy by a wireless energy transfer mode but also help TENG imitate the receptor’s
unique characteristics by simultaneously measuring both static and dynamic pressures in a self-driven mode. The linear detection range of dynamic pressure is from 1 to 4 N cm⁻² with a sensitivity of 17.5 V cm⁻² N⁻¹ and a detection limit of 0.3 N cm⁻². The detection range of static pressure is from 0.5 to 4 N cm⁻² with a sensitivity of 12.1 mV cm⁻² N⁻¹ and a detection limit of 0.07 N cm⁻². In addition, the voltage of the supercapacitor increases linearly with the vibration times, which hints that this integrated device also endows functions such as vibration counting and frequency computing. This work contributes to new strategies for making multifunctional biomimetic electronics that promote the development of artificial intelligence.

2:15 PM *ES21.10.03 Design and Energy Application of Piezoelectric Biomaterials Rusen Yang; School of Advanced Materials and Nanotechnology, Xidian University, Xian, China.

Multifunctional materials have received increasing attention in recent years. Owing to their inherent biological nature as well as piezoelectric properties, piezoelectric biomaterials are considered as promising candidates for application in fields ranging from electrochemical energy storage to biological systems. The rational material design is important to enhance their piezoelectric and biological activity. Herein, recent advancements to piezoelectric biomaterials like peptide-based micro/nanostructures are provided. Synthetic methods, morphological features, and piezoelectric performance of piezoelectric biomaterials are presented. The effect of growth direction, phase and structure of piezoelectric biomaterials on their piezoelectric activity are discussed. The applications of piezoelectric biomaterials in the field of nanogenerators are provided at the end.

2:45 PM ES21.10.04 Structural Design of Triboelectric Nanogenerator for Harvesting Environmental Mechanical Energy and Self-Powered Motion Sensing Yannan Xie; Nanjing University of Posts and Telecommunications, Nanjing, China.

Aiming at environmental renewable and sustainable energy sources, energy harvesting technology has been developing rapidly in the recent years. Emerging as significant applications of Maxwell’s displacement current in the energy field, triboelectric nanogenerator (TENG) has received worldwide attention and undergone speedy progress. In the field of TENG, structural design is an important research topic due to the diverse application circumstances. In our works, several device structures have been carefully investigated, including angle-shaped wind-driven TENG with enhanced output performance and very low start-up wind speed, kinesio-tape based TENG with compact structure for self-powered human motion sensing, and so on. We will also discuss the applications of TENG as flexible electronics for wearable device. Our works may provide design strategies for TENG and put forward its practical applications as newly energy harvesters and self-powered sensors.

3:00 PM BREAK

SESSION ES21.11: Piezoelectric and Triboelectric Nanogenerators VI
Session Chairs: Jürgen Roedel and Yunlong Zi
Thursday Afternoon, April 25, 2019
PCC North, 100 Level, Room 132 C

3:30 PM *ES21.11.01 Boosting the Output of Energy Conversion from Evaporation Driven Water Flow in Porous Carbon Film Jun Zhou; Huazhong Univ of S&T, Wuhan, China.

Harvesting energy from the environment offers great promise for the application of distributed sensor networks. Ideally, highly effective energy conversion processes should be environmentally friendly, spontaneous and maintenance-free. Recently, we have reported that evaporation-driven water flow within a porous carbon film can reliably generate sustainable electricity with open-circuit voltage (Voc) up to 1 V and short-circuit current (Io) of 100 nA, respectively[1]. The output performance of the device can be easily scaled up by using all print method[2]. A device based on freestanding and flexible carbon-based hybrid film with size of 400*450*0.13 mm³ produces an Io ~ 28 μA [3]. The Voc of the device can be tuned from -3 V to 3 V by manipulating the surface functional groups on the carbon nanoparticles. In addition, a hybrid energy utilization technology was also developed by using solar energy for desalination (solar thermal efficiency of ~75%) and extracting electricity (power of ~ 1 W m⁻²) from the evaporation induced salinity gradient [4]. Because of the ubiquity of water evaporation in nature and the low cost of materials involved, our study presents a novel avenue to harvest ambient energy and has potential applications in low-cost, green, self-powered devices and systems[5-6].

4:00 PM *ES21.11.02 Piezoelectric Energy HARVESTER Having a Wireless Communication Capability Without a Battery Demonstrated by the Piezoelectric Single Crystal PMN-PT Dongseok Suh¹, Yourack Lee¹, Jeong-Ho Lee², Sang-Goo Lee³ and Yong Sin Kim³;¹Sungkyunkwan University, Suwon-Si, Korea (the Republic of);²iBule Photonics Co. Ltd, Incheon, Korea (the Republic of);³Korea University, Seoul, Korea (the Republic of).

We have examined the piezoelectric single crystal PMN-PT (Pb(Mg1/3Nb2/3)O3-PbTiO3) as a piezoelectric energy harvester to convert the mechanical energy to electrical energy in various forms. One of those applications is the push-button-type energy harvester, which can directly generate the electrical energy enough to send a wireless signal to the nearby receiver without battery. The quantitative analysis of the voltage and the power generation during the push-button operation had been done, and it could be doubled when we employed the idea of snap-through buckling. The other is the vibration energy harvester that is designed for the status-monitoring purpose of a pole-mounted electrical power transformer. From the basic vibration originating from the AC voltage, it could permanently generate the electricity required for operating an event logger of partial discharge and sending the wireless message containing that data. From those two works, we demonstrate that the piezoelectric single-crystal PMN-PT can be one of the most reliable and powerful materials for the piezoelectric power generation combined with wireless communication capability. (This project is supported by the Korea Electric Power Corporation (KEPCO).)

4:30 PM *ES21.11.03
Standardization of Triboelectric Nanogenerators—Progress and Perspectives

Yunlong Zi; Mechanical and Automation Engineering, The Chinese University of Hong Kong, Shatin, Hong Kong.

The rapid development of the Internet of Things (IoT) and the increasing energy crisis call for a new type of energy sources. Triboelectric nanogenerators (TENGs), which can convert mechanical energies to be electricity, develop quickly in recent years and catch more and more people’s eyes in the world. Meanwhile the importance of the standardization for TENG has been emphasized, and developing the standardized theoretical models and experimental methods to evaluate the performance quantitatively becomes more and more important for the commercialization and industrialization of the TENG technology. This presentation will systematically review the origin of the V-Q plot based standardized characterization methods and the figure-of-merits (FOM) based the standard for quantitatively characterizing the energy output. This presentation will also discuss several essential factors, including the input energy, environmental factors, and life-time assessment, to be potentially involved in standards for TENGs in future. The standardization of TENG will greatly helpful to understand and improve this emerging energy harvester towards further applications. We believe the standardization of TENG will greatly facilitate the commercialization and industrialization of TENGs in future.

SESSION ES21.12: Nanogenerators and Piezoelectricity

Session Chairs: Kourosh Kalantar-zadeh and Wenzhuo Wu

Friday Morning, April 26, 2019

PCC North, 100 Level, Room 132 C

8:30 AM ES21.12.01

Computation of Electronic Energy Band Diagrams Applied to Piezotronic Photoelectrochemical Electrodes

Lazarus N. German1, Yanhao Yu1,2, and Xudong Wang1, Materials Science and Engineering, University of Wisconsin-Madison, Madison, Wisconsin, United States; 2School of Engineering and Applied Physics, Harvard University, Cambridge, Massachusetts, United States.

Photoelectrochemical (PEC) reactions are a promising pathway for the direct transformation of solar energy to chemical fuels.1–3 The past decade has produced significant progress in PEC reactions for this type of conversion, especially PEC water splitting for H2 generation.4–6 Despite these advancements, the ultimate industry-level solar-to-hydrogen productions through PEC still remains unreachable due to challenges in the stability, light absorption and charge separation.7 In regards to charge separation, the piezotronic effect has arisen as a new paradigm to break the forgoing capstone. Applying ferro- and piezoelectric materials an their polarization trigger considerable free carrier redistribution in the adjacent semiconductor. As a result, the charge separation and overall PEC performance can be effectively tuned.

Electronic energy band diagrams provide useful and illustrative information on how materials stacking might affect electronic properties and charge transport throughout a multi-junction device. However, schematic diagrams, which are often used in many publications, lack quantified changes in potential across junction interfaces. This is especially true as the energetics become increasingly untuitive when incorporating the effects of dielectric layers and applying ferro- and piezoelectric dipoles, such as the case of piezotronics. By applying the Poisson-Boltzmann equation and idealizing interfaces, we can produce first approximation, quantitative electronic energy band diagrams for solid/solid and solid/electrolyte heterojunctions that incorporate ferro- and piezoelectric elements.8 Using a Mathematica code that we developed, we can show that band bending at semiconductor/electrolyte interface can vary over several meV by adjusting piezotronic polarization.

Aside from the semiconductor/electrolyte interface, piezoelectric have also shown great promises in promoting the efficiency of PEC devices by other means. Full-gear functionalities of these devices are constrained by the longstanding contradiction between the charge collection of semiconductors and the screening effect of polarization materials. We tackled this issue by decoupling the collecting and screening trajectories using graphene as the charge collector.9 The moderate charge density of graphene ensures minimal screening of the adjacent electrical polarizations and concurrently delivers photogenerated free carriers toward the counter electrode. Based on a PMN-PT/graphene/TiO2 piezotronic PEC system, substantial performance gains were received through tuning the interfacial electronic energy level via ferroelectronic polarizations, obtaining a favorably shifted onset potential. Both calculation and experimental results suggest that this outcome was beneficial from the low screening effect from graphene. In contrast, a gold electrode will fully screen the polarization from PMN-PT and yield similar PEC performance despite of the polar conditions. This work reveals graphene could be an ideal conductive electrode selection for free piezoelectric PEC devices from the performance capstone imposed by the trade-off between carrier collecting and charge screening.

Energy Harvesting by Triboelectric Nanogenerators for Self-Powered Sensing Systems

Guang Zhu1,2 and Zhong Lin Wang1,3; 1Beijing Institute of Nanoenergy and Nanosystems, CAS, Beijing, China; 2University of Nottingham Ningbo China, Ningbo, China; 3Georgia Institute of Technology, Atlanta, Georgia, United States.

Converting ambient mechanical energy into electricity provides a viable solution to a sustained power source for distributed small electronic devices. It is particularly significant for the development of wireless sensor networks. In the past five years, we innovatively utilized contract electrification on the surface of flexible thin-film materials, proposing a new mechanism to convert mechanical energy to electrical energy through triboelectric conversion. This so-called triboelectric nanogenerator (TENG) has been developed for the past decade and attracted more and more research interest. However, the high performance of TENG is largely constrained by the low energy density of the piezoelectric nanogenerators. This work introduces a new approach to converting mechanical energy into electrical energy, and we will discuss the origin of this phenomenon. The mechanical energy conversion efficiency of the proposed energy harvester can be evaluated by the power density, which is calculated by the output voltage and current. The experimental results suggest that the proposed TENG can harvest energy from various mechanical sources with high energy conversion efficiency. This technique opens the door to the development of new energy harvesting devices for self-powered sensing systems.

9:15 AM *ES21.12.03

Ferroelectric and Piezoelectric Control of the Optical Properties of Advanced Materials

Yang Zhang1, Weining Jie1, Ping Chen1, Weimei Liu1 and Jianhua Hao2; 1Nankai University, Tianjin, China; 2The Hong Kong Polytechnic University, Hong Kong, Hong Kong; 3Sichuan Normal University, Chengdu, China.

Piezoelectric and ferroelectric materials have shown great potential for control of the optical process in emerging materials. There are three ways for them to impact on the optical process in various materials. They can act as external perturbations, such as ferroelectric gating and piezoelectric strain, to tune the optical properties of the materials and devices. Second, ferroelectricity and piezoelectricity as innate attributes may exist in some optoelectronic materials, which can couple with other functional features (e.g., semiconductor transport, photocexcitation, photoactivities) in the materials giving rise to unprecedented device characteristics. The last way is artificially introducing optical functionalities into ferroelectric and piezoelectric materials and devices, which provides an opportunity for investigating the intriguing interplay between the parameters (e.g., electric field, temperature, strain) and the introduced optical properties. Herein, the tuning strategies, fundamental mechanisms, recent progress in ferroelectric and piezoelectric effects modulating the optical properties of a wide spectrum of materials, including lanthanide-doped phosphors, quantum dots, two-dimensional materials, and wurtzite-type semiconductors are presented. The future outlook and challenges of this exciting field are suggested.

9:45 AM BREAK
Chip-based 3D subdiffraction microscopy with easy-configuration, fast-speed is highly desired. We propose wide-field far-field super-resolution imaging chip based on frequency shift effect. Our previous work demonstrates wide-field label free super-resolution imaging can be achieved utilizing a combination of a spatial frequency shift and a Stokes frequency shift [1, 2]. Recently, combining the broad spectra of polymer fluorescent film and well-designed polygon shape, full-angle wide wave vector coverage illumination was achieved for complete imaging reconstruction to eliminate distortion. By frequency shift and iteratively stitching different spatial frequency range together in Fourier space, reconstruction of two dimensional (2D) samples without distortion was achieved in a wide FOV. Furthermore, frequency loss free 3D super-resolution circuits was designed. The spatial-frequency of surface wave illumination can be tuned flexibly through wave vector modulation and operation, to achieve complete spatial-frequency detection for deep subwavelength imaging. Piezophotonic effect can be used to precisely control the phase and frequency shift in the circuit.

Piezoelectricity and Ferroelectricity in Nylons for Energy Harvesting
Sailem Arwa1, and Kamal Asadi1; 1Max Planck Institute for Polymer Research, Mainz, Germany;
2School of Chemical & Materials Engineering, National University of Sciences & Technology, Islamabad, Pakistan.

Research on piezoelectric polymers is mostly concentrated on polyvinylidene difluoride, PVDF, and its random copolymers, poly(vinylidene difluoride-trifluoroethylene), P(VDF-TrFE). Among engineering polymers, odd-nylons are ferroelectric. Since the discovery of ferroelectricity in polymers, nearly half a century ago, a solution processed ferroelectric nylon thin-film has not been demonstrated due to the strong tendency of nylon chains to form hydrogen bonds. In this contribution, we show that solution quenching allows for the fabrication of ultrathin and optically transparent nylon-11 thin-films which are crystallized in the polar piezoelectric/ferroelectric phase. The ferroelectric properties are on-par with those of PVDF and P(VDF-TrFE). However, nylon ferroelectric capacitors show superior fatigue-free behavior upon cycling in sharp contrast to PVDF and P(VDF-TrFE) capacitors.

Nylons are among the basic materials for textile industry. Hence realization of piezo/ferroelectricity in nylon fibers can readily lead to textiles that are responsive to electrical or mechanical stimuli, thereby enabling e- or smart textiles. We discuss fabrication of piezoelectric nylon fibers and nanogenerators thereof for energy harvesting.

Electromechanical Response of Few-to-Monolayer SnS PVDF-Grown on Flexible Mica
Naoki Hiragashita, Hayami Kamamoto and Kosuke Nagashio; The University of Tokyo, Tokyo, Japan.

Two-dimensional orthorhombic SnS has been recently attracted interests in the application to nanogenerators for its remarkable piezoelectric coefficient, \( d_{145} \) nm/V, for monolayer, which is much larger than MoS\(_2\), and comparable to PZT [1]. However, there has not been demonstrated any observation of piezoelectric response for SnS, because strong interlayer bonding by lone pair electrons in Sn atoms prevents the mechanical isolation of monolayer [2]. We have successfully realized the growth of few-to-monolayer SnS on mica substrate via physical vapor deposition (PVD), where the growth temperature was precisely controlled to balance adsorption/desorption of SnS. Synthesis mica, KMg\(_3\)Al\(_2\)O\(_6\)F\(_2\), is an attractive platform with atomically flat surface, thermal tolerance up to 1100°C, and flexibility, which enable a straightforward process from crystal growth to fabrication of flexible devices. In this work, for the first time, electromechanical response of SnS is demonstrated with using ultra-thin SnS layers grown on mica. SnS is a semiconductor piezoelectric unlike the traditional piezoelectric ceramics; therefore, understanding of piezoelectric effect in SnS is essential as well as piezoelectric effect, toward the nanogenerators application. In order to observe the piezoelectric effect, electromechanical response was investigated for ~10 layers SnS, which is supposed to be non-piezoelectric. Flexible device was fabricated with PVD-grown SnS on mica substrate directly bonded to PC or PET film. \( L_0 \)-time measurements at constant \( V_0 \) were performed with applying in-plain tensile/compressive strain of \( \varepsilon \sim \pm 0.5 \% \) respectively. Electrostatic responses were observed reproducibly; the resistance \( R \) increased with tensile strain and decreased with compressive strain. These results are consistent with the theoretical study on bandgap \( E_g \) of SnS with different strain, \( E_g \) increases with tensile strain and vice versa [3]. Based on these piezoelectric responses, the typical gauge factor was estimated as \( \Delta R/R = 1.24 \), which is comparable to that of metals. The present SnS on flexible mica platform will be able to extract the piezoelectric effect for monolayer SnS with negligible noise level.

Intrinsic Energy Conversions for Photon-Generation in Piezo-Phototronic Materials—A Case Study on Alkaline Niobates
Balong Huang; The Hong Kong Polytechnic University, Hong Kong, Hong Kong.

The creations of photons in response to mechanical stimuli in a crystal that has noncental symmetry are the great fundamental physics responsible for numbers of important technologies. The underlying mechanism and complete theory for a precise explanation of the mechanical-photonic energy conversion phenomena is vital important. We take commercial piezoelectric LN\(_\text{iMnO}_3\) (LiMNO\(_3\)) crystals as the example to interpret the detailed mechanisms of energy conversions for the photon-generation through a native point defects study. It was found the Frenkel and Schottky type complex pairs as well as the antisite pair defects acting as energy harvesting and migration centers, which are very easy to form and active. It does to be the extra deep electron or hole traps levels near the valence or conduction band edge, respectively. That is the substantial energy reduction via a spontaneous exchange effect by them to continuously collect and transport host charges along the path via localized states to the deep recombination levels. The initiating energy barrier is small.

In Vivo Implanted Battery-Free Direct-Current Micro-Power Supply from In Vivo Breath Energy Harvesting
Jun Li, Lei Kang, Yin Long, Hao Wei, WeiBo Cai and Xudong Wang; University of Wisconsin–Madison, Madison, Wisconsin, United States.

Majority of current IMDs are powered by conventional surgical or technical batteries that contribute up to 90% weight and volume of the entire device. [1,2] While replacement of or recharging the batteries requires conventional surgical or technical efforts, introducing additional suffering and complexity to the patients, other battery potential issues such as overheated and leakage of toxic electrolyte further prohibit the advancement and miniaturization of IMDS. Therefore, increasing efforts are now being focused on the innovation of designated IMD power sources. Implantable nanogenerators (i-NGs) have been designed to convert biomechanical energy into electricity. [3,4] In spite of their numerous merits, the outputs of state-of-the-art i-NGs are always in a form of largely discrete pulses. Although their theoretical output power could be sufficient for IMDS, battery component is still needed in the i-NG design to produce a steady and usable direct current (DC) output. Moreover, most i-NGs are non-stretchable with incompatible mechanical properties compared to soft biological tissues, which further challenges their practical application.

In this work, we reported an ultra-soft stretchable i-NG system that could function as a battery-free DC micro-power supply. The i-NG consisted of ultrathin micro-scale interdigital electrodes (IDES) and multi tribo-active layers with a small working area (approximately 2 cm\(^2\)), packaged with biocompatible silicone elastomer. While the micro IDES support the output of high frequency electricity (1 \( \mu \)A at 70 Hz) driven by slow mechanical stimulation, the silicone elastomer and an embedded cavity design enable i-NGs with extremely low Young’s Modulus (46 kPa), exactly matching the mechanical property range of most soft biological tissues. By implanted inside the abdominal cavity of Sprague Dawley (SD) adult rats, the i-NG could convert slow diaphragm movement during normal breath into stable high-frequency electrical spikes, which were readily transmitted into a continuous –2.2 V DC output on a LED load after being integrated with a basic electrical circuit (rectifier and capacitor) for a relatively long period of time.
This electric output could continuously power the LED without any observable power decay, successfully demonstrating a constant operation of small electronics DC power free of the battery component. This solely biomechanical-energy driven DC micro power supply offers a very promising solution for the development of self-powered IMDs in the near future.

Triboelectric Nanogenerators as Soft Power Sources Xiong Pu; Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, Beijing, China.

Rapid advancements in stretchable/multifunctional electronics impose the challenge on corresponding power devices that they should possess comparable flexibility, stretchability and functionalities. In this talk, we briefly summarize our recent progresses on wearable energy harvesting devices, especially triboelectric nanogenerators aiming to power soft electronic skins or soft electronics/robotics. We report a soft skin-like triboelectric nanogenerator that enables both biomechanical energy harvesting and tactile sensing by hybridizing elastomer and ionic hydrogel as the electrification layer and electrode, respectively. Ultra-high stretchability and transparency are achieved simultaneously for an energy-harvesting device. Lastly, we report our updated progresses on and self-healable soft TENGs by utilizing self-healable elastomers. Bulk thin layers of conductive polymers are achieved by transfer the film onto pre-strained self-healable elastomers, which later ensure the realization of self-healing, stretchability, and transparency of the TENG simultaneously. Our work provides new opportunities for soft power sources and potential applications in soft/wearable electronics.

SESSION ES21.13: Nanogenerators and Piezotronics III
Session Chairs: Qing Yang and Guang Zhu
Friday Afternoon, April 26, 2019
PCC North, 100 Level, Room 132 C

1:30 PM ES21.13.01
Boosting the Energy Conversion Efficiency of a Combined Triboelectric Nanogenerator-Capacitor Jin Poo Lee¹, Jae Won Lee¹, Bo-Kyung Yoon¹, Hee Jae Hwang², Sungwoo Jung¹, Katherine A. Kim¹, Dukhyun Choi¹, Changduk Yang¹ and Jeong Min Baik¹; ¹Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of), ²Kyung Hee University, Yongin, Korea (the Republic of).

With the growing popularity of various internet of things sensors and portable devices, such as smartphones and smartwatches, the demand for power generation sources for driving such electronic devices is becoming increasingly important and challenging. If we rely on batteries to drive all of the sensors related to Internet of things, most of the IoT would be impossible. Here, we report the exciting possibilities for the use of triboelectric nanogenerators (TENGs) toward real-time self-powered electronics, such as a smartphone-to-smartwatch telecommunication over Bluetooth via the capacitors charged by the TENGs, a self-powered pulse sensor, and a real-time self-powered calculator. To achieve the high-output power of the TENGs, we focused on multiple strategic points such as device structures, contacted materials, and mechanical systems, as well as circuit design methods of enhancing the charging efficiency to the energy storage device. The novel integration scheme of TENGs made it generate areal output power of approximately 3 mW/cm² under a low frequency of 3 Hz through a gear-cam system. Based on these results, fast-chargeable portable power-supplying systems for the continuous self-powered electronic systems were successfully developed.

1:45 PM ES21.13.02
A Novel Triboelectric Nanogenerator Based on Electrospun Polyvinylidine Fluoride Nanofibers for Effective Acoustic Energy Harvesting and Self-Powered Multifunctional Sensing Haiwu Zheng¹ and Yunlong Zi²; ¹Henan University, Kaifeng, China, ²The Chinese University of Hong Kong, Hong Kong SAR, China.

Acoustic energy is mostly wasted with out a proper energy harvesting approach. In this work, an integrated triboelectric nanogenerator (TENG) with a polymer tube is constructed to harvest acoustic energy from the environment, which can work stably in the frequency ranging from 20 Hz to 1000 Hz. The TENG is based on electrospun polyvinylidene fluoride (PVDF) nanofibers and two conductive fabrics. The unique structure design facilitates acoustic energy capturing and the enhancement of sound pressure. The TENG can deliver an open-circuit voltage and short-circuit current of 400 V and 175 μA, respectively, with instantaneous maximum output power density of 7 W/m² under a sound frequency of 170 Hz and sound pressure of 115 dB. The TENG can be used for audio frequency analysis and noise detection. Furthermore, self-powered active sensors are demonstrated for detecting sound source direction and motion velocity of an object making sounds. This work not only provides a simple, cost-effective approach for fabricating high performance TENG to recycle ambient noise energy into available electricity, but also enables self-powered sensing applications, with potential applications in military surveillance, artificial intelligence, Internet of Things, and jet engine noise reduction.

2:00 PM ES21.13.03
Remarkable Output Power Enhancement of Sliding-Mode Triboelectric Nanogenerator Through Direct Metal-to-Metal Contact with the Ground U Jeong Yang and Jeong Min Baik; Material Science and Engineering, Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Triboelectric nanogenerator (TENG) is one of alternative energy harvesting technologies of ambient mechanical energy source in nature environments. Here, a new-type of sliding-mode TENG with the enhanced potential through the direct metal-to-metal contact with the ground connection is reported. When the positively charged Al layer is contacted with the grounded Al, the electrons flow is promoted to the ground by large potential difference between the two metals. This induces the charge transfer between bottom electrodes, enhancing the electric potential, confirmed by the COMSOL simulations. This new type of TENG generates a maximum power of 0.13 W under low frequency of 3 Hz on an external load of 1 MΩ, corresponding to energy conversion efficiency of approximately 42 %. Performance of the working-mode are also systematically investigated in free-rotating disk-type and patch-type TENGs, which offered a lot of convenience and feasibility for energy harvesting from the wearable energy sources.

2:15 PM ES21.13.04
Mechanically Induced Light Generator Based on Doped Piezophotonic Quaternary Oxysulfide Dengfeng Peng; Shenzhen University, Shenzhen, Alabama, United States.

Piezoelectric semiconductor with optical, electrical and mechanical multifunctions has great potential applications in future optoelectronic devices, the rich physics and applications origin from the intrinsic structures and inner coupling effects. Here, we report that lanthanide ions doped piezoelectric quaternary oxysulfide semiconductor CaZnOS show strong light emission induced by dynamic mechanical stress, the emission is bright enough to see by the naked eyes even under the day light. We design the mechanically induced light generator by embedding the doped CaZnOS powder into the flexibly transparent polymer with good mechanical repeatability. The flexible light generator has a broad range of applications, such as advanced display, stress sensor and information safety.

Reference:
Polymeric piezoelectric nanogenerators (PNGs) have emerged as a suitable candidates to harvest waste mechanical energy to power up portable electronic devices. Smart textiles, with piezoelectric functionalities integrated in the fabrics have been envisioned. In this regards, numerous piezoelectric (nano-)generators based on PVDF or PVDF-TrFE nanofibers have been reported.

However, the piezoelectric polymer (nano-)generators have typically shown low output energy densities; A the common issue hindering their application. Introduction of porosity into the piezoelectric polymer has been proposed to increase the voltage output of PNGs. However, designing a process that allows introduction of pores in polymer fibers with typical diameter of the order 100 nm, would be a breakthrough in the field of PNGs. In this contribution, we discuss an elegant approach to tailor porosity in electrospun P(VDF-TrFE) nanofibers. The approach is based on the thermodynamics of polymer solutions, and solvent/non-solvent interactions with the polymer. We calculated the ternary phase diagram of P(VDF-TrFE)/non-solvent (water)/solvent, and experimentally verified it. Based on the phase diagram, a conscious amount of water is intentionally added into the P(VDF-TrFE) solution to induce porosity in the fiber. PNGs based on the porous electrospun P(VDF-TrFE) nanofibers show systematic increases of the output voltage with porosity. The output power increased from 0.1 mW/cm$^2$ for PNGs with zero porosity to 7 mW/cm$^2$ for PNGs with 50% porosity. Dielectric spectroscopy of the nanofibers attributes the enhanced output to the reduced dielectric permittivity of the fibers and that the voltage generation in the porous fibers is of the same origin as in neat piezoelectric P(VDF-TrFE) films and is due to the relaxation of segments within the restricted amorphous phase.

The triboelectric nanogenerator (TENG) has been investigated intensively during the last decade in terms of power improvement and application as sensors. However, its voltage is usually too high and spike-like to be used directly as a power source for electronic devices. Although there was an effort to adjust the voltage through the circuit design, the circuit board has limitations in the complexity and the bulkiness. Here, we propose a simple approach to change the spike-like voltage profiles to the square-like profiles and adjust the output voltage to be in the suitable range for electronics. We used printed ion gel electrolyte patterns as capacitors and investigated the effects of the dimension of the capacitor, the connection types (serial, parallel) of multiple capacitors, and the electrochemical conditions. The voltage profile of the TENG-ion gel system was modulated by the contact frequency applied to the TENG, the contact area of the ion gel with the electrode, the type of ions in the electrolyte, reduction/oxidation reaction in the gel, and the connection type (parallel, series) between ion gel patterns. We successfully demonstrated the light emission of a large number of printed electrochemiluminescence patterns.

The development of wearable electronics, implantable devices and internet of things put forward an ever-growing demand on distributed power supply, providing an opportunity for technologies that can harvest energy locally from environment. As a promising energy harvesting technology, triboelectric nanogenerators (TENGs) show merits of easy fabrication, low cost, abundant choice of structures and materials compared with other energy harvesting technologies. The working principle of the TENG is based on the conjugation of triboelectrification and electrostatic induction and its theoretical fundamental can be derived from the Maxwell's displacement current.

The practical application of TENGs imposes a challenging requirement to improve the power density of the device, which is highly related to the charge density because it has a quadratic dependence on the charge density. The enhancement of the charge density is restricted mainly by two issues for normal TENG devices under certain intensity of contact or rubbing. The first one is the triboelectrification capability of tribomaterial pairs with certain surface topographies, and the other is the discharge caused by air breakdown. In previous studies, great efforts have been conducted to improve the charge density, based on material selection, structure optimization, surface modification or environment control. The corona charging is a relative facile method that is widely adopted, which can inject charges into dielectric films to enhance the charge density from under 100 μC m$^{-2}$ to about 240 μC m$^{-2}$. However, the injected charges are not stable and the dielectric materials are restricted to electrets. High vacuum environment can suppress air breakdown, which can greatly enhance the charge density to 660 μC m$^{-2}$ for Cu versus polytetrafluoroethylene (PTFE), and 1003 μC m$^{-2}$ with an extra ferroelectric barium titanate (BT) layer. Still, this method is restricted by high requirements of device packaging.

To develop a facile and universal method to enhance the charge density of TENG devices, an integrated self-charge-pumping TENG (SCP-TENG) device with features of floating layer structure and charge pumping is proposed in this work. Derived from normal TENGs, the proposed device adopts a floating layer to store and bind charges for electrostatic induction, while a TENG based charge pump is designed to continuously pump charges into the floating layer at the same time. The SCP-TENG can operate like normal TENGs, while accumulating bound charges with high efficiency to ultrahigh effective surface density of 1020 μC m$^{-2}$ in ambient conditions, which is about 4 times of that of the density corresponding to air breakdown and has potentials to be further elevated in the future. More importantly, this method is rather facile and robust compared to other charge density enhancing approaches, providing an important strategy to achieve ultrahigh-performance for TENG devices, which is crucial for various practical applications ranging from wearable electronics to blue energy.
Advances in next-generation soft electronic devices rely on the development of highly deformable, and healable energy generators to power these electronics. Triboelectric nanogenerators (TENG) have emerged as a promising power source for portable and stretchable electronic devices. However, the development of deformable energy generators that can attain extreme stretchability with superior healability, and transparency simultaneously is difficult to achieve due to the use of metallic electrodes. We address this issue by the use of an ionic conductor as the current collector in a triboelectric nanogenerator, resulting in a highly transparent, stretchable and self-healing device. The energy harvesting performance of ionic triboelectric nanogenerator is 12 times higher than that of the metallic based triboelectric nanogenerator due to the formation of an electrical double layer (EDL). The developed slime-based ionic conductor owing to the non-Newtonian behaviour of the current collector, an extreme stretchability as high as 700% was achieved without degrading the device performance, thus enables the triboelectric device to act as an a power source for highly deformable electronics. The device has a transparency of 92% transmittance, while transparency helps in the visual transmission of information, which can be potentially utilized in user-interactive displays, biomedical imaging, therapeutic optogenetics, and touch screens. Due to the weak hydrogen bonding interactions of the ionic conductor, the TENG can autonomously self-heal and can recover its performance even after 300 times of complete bifurcation. The resulting device demonstrates an extremely stretchable, highly transparent self-heal power source to be used as a power supplies for sensors, wearable electronics and soft robotics.

Triboelectric charging is an electrical charging phenomenon that occurs when different materials come into contact and separate spontaneously. Irrespective of the magnitude, all materials could be charged by contact. Some of the common materials consistently exhibit triboelectric charging patterns, and based on the charging characteristics, empirical “triboelectric series between materials” was constructed by arranging them according to the relative polarity of the contact charge acquired.

Recently, a triboelectric nanogenerator, which offers a unique solution to convert mechanical energy into electricity via combining the concept of triboelectric charging and electrostatic induction, was invented as a new technology of energy harvesting. Furthermore, using a similar principle, triboelectric sensors and tribotronics that utilize triboelectric output to drive and control electronic devices were also introduced. One of the important factors that determine the performance of the device is the material. However, materials known to exhibit triboelectric charging behavior are only limited to some polymers and a few metals already located in the triboelectric series. Further investigating the triboelectric charging behaviors of new materials and widening the material library of the triboelectric series are required.

Here, we investigated the triboelectric charging behaviors of various two-dimensional (2D) materials (MoS$_2$, MoSe$_2$, WS$_2$, WSe$_2$, graphene, and graphene oxide), which have received great attention for decades owing to their distinct electronic, optical, mechanical, and thermal properties. The triboelectric charging behaviors were investigated using the concept of the triboelectric nanogenerator. Consistent results of contact-charging polarities were observed, using which, a modified triboelectric series including 2D materials was developed. For further verification, the effective work functions of the 2D materials, which are one of the main factors deciding their triboelectric charging behaviors, were estimated via Kelvin-probe force microscopy and calculated via first principles simulations as well. The charging polarity indicated the similar behavior regardless of the synthetic method and film thickness ranging from a few hundred nanometers (for chemically exfoliated and restacked films) to a few nanometers (for chemical-vapor-deposited films).

Further, the triboelectric charging characteristics could be successfully modified via chemical doping. This study provides new insights to utilize 2D materials in triboelectric devices, allowing the thin and flexible device fabrication.
We have performed an extensive high-throughput screening of known inorganic materials, in order to identify those that could be exfoliated into novel two-dimensional monolayers and multilayers [1]. The screening protocol first identifies bulk materials that appear layered according to a simple and robust chemical definition of bonding, determining then for all of these the binding energies of the respective monolayers, and their electronic state (metallic vs insulating), magnetic configuration (ferro-, ferrimagnetic, antiferromagnetic), and phonon dispersions (to evaluate mechanically stability). Such protocol identifies a portfolio of close to 2,000 inorganic materials that appear either easily or potentially exfoliable, to be investigated further for promising properties. First focus has been on the determination of the effective masses and mobilities (from the full solution of the Boltzmann transport equation) for electronic applications; of topological invariants; of superconductivity and charge-density waves; and of photocatalytic parameters for water splitting. Thanks to the use of the AiiDA (http://aiida.net) materials’ informatics platform, all the high-throughput calculations can be performed and streamed in fully searchable and reproducible ways, they are stored in a database with their full provenance tree of all parent and children calculations, and can be shared with the community at will.

1:30 PM *QN01.03.01
A Guided Safari Through the Properties of Over 1000 2D Materials Revealed by Data Mining Techniques Evan Reed; Stanford University, Stanford, California, United States.

Two-dimensional materials and weakly bonded layered materials exhibit potentially advantageous properties as thin electronic materials, but research has been largely focused on only a couple of dozen types. We have utilized data mining approaches to elucidate over 1000 2D materials and several hundred 3D materials consisting of van der Waals bonded 1D subcomponents, or molecular wires. I will provide a guided tour of the spectrum of properties of these materials that are of interest for electronic applications. We find that hundreds of these 2D materials have the potential to exhibit observable piezoelectric effects, representing a new class of piezoelectrics. A further class of layered materials consists of naturally occurring vertical hetero structures, i.e., bulk crystals that consist of stacks of chemically dissimilar van der Waals bonded layers like a 2-D super lattice.

2:00 PM QN01.03.02
A Simulation-Driven Database of 2D Materials for Growth Chambers Design Kasra Momeni1, Yanzhou Ji1, Kehao Zhang2, Joshua Robinson2 and Long-Qing Chen1; 1Louisiana Tech University, Ruston, Louisiana, United States; 2The Pennsylvania State University, State College, Pennsylvania, United States.

Chemical vapor deposition (CVD) is a powerful technique for synthesizing monolayer materials such as transition metal dichalcogenides. It has advantages over exfoliation techniques, including higher purity and the ability to control the chemistry of the products. However, controllable and reproducible synthesis of 2D materials using CVD is a challenge because of the complex growth process and its sensitivity to subtle changes in growth conditions, making it difficult to extend conclusions obtained in one CVD chamber to another. Here, we developed a multiscale model linking CVD control parameters to the morphology, size, and distribution of synthesized 2D materials, which then used for creating a database of growth condition-morphology relation. Its capabilities are experimentally validated via the systematic growth of MoS2. In particular, we coupled the reactor-scale governing heat and mass transport equations with the mesoscale phase-field equations for the growth morphology considering the variation of edge energies with the precursor concentration within the growth chamber. The predicted spatial distributions of 2D materials are statistically analyzed, and experiments are then performed to validate the predicted island morphology and distributions. It is shown that the model can be employed to predict and control the morphology and characteristics of synthesized 2D materials.

2:15 PM QN01.03.03
Rational Prediction of Synthesis of MAX Phases and MXenes Using Positive and Unlabeled Machine Learning Nathan Frey1, Jin Wang1, Gabriel Bellido1,2, Yury Gogotsi1,3 and Vivek B. Shenoy1; 1University of Pennsylvania, Philadelphia, Pennsylvania, United States; 2Office of Naval Research, Washington, Washington, United States; 3Drexel University, Philadelphia, Pennsylvania, United States.

Growing interest in the potential applications of two-dimensional (2D) materials has fueled advancement in the identification of new 2D systems with exotic properties. Increasingly, the bottleneck in this field is the synthesis of the materials. Although theoretical calculations have been able to predict a myriad of promising 2D materials, only a few dozen have been experimentally realized since the initial discovery of graphene. Here, we adapt the state-of-the-art positive and unlabeled (PU) machine learning framework to predict which theoretically proposed 2D materials have the highest likelihood of being successfully synthesized. Using elemental information and data from high-throughput density functional theory calculations, we apply the PU learning method to the MXene family of 2D transition metal carbides, carbonitrides and nitrides, and their layered precursor MAX phases, and identify 18 new MXene compounds that are highly promising candidates for synthesis. By considering both the MXenes and their precursors, we further propose 20 new synthetizable MAX phases that can be chemically exfoliated to produce new MXenes.

Localization with a Twist—Duality Between Configuration Space and Momentum Space in Incommensurate Stacked Layers of 2D Materials Efthimios Kaxiras and Stephen Carr; Department of Physics, Harvard University, Cambridge, Massachusetts, United States.

The stacking of individual layers of two-dimensional materials can be experimentally controlled with remarkable precision on the order of a tenth of a degree. The relative orientation of successive layers introduces variations in the electronic properties that can be controlled by the twist angle. We use simple theoretical models and accurate electronic structure calculations to predict that the electronic density in stacked 2D layers can vary in real space in a manner similar to the band-structure in momentum-space, creating moire super-lattices. A direct consequence of the patterns is the localization of electronic states. We demonstrate this effect in graphene, a semi-metal, and MoS2, a representative material of the transition metal dichalcogenide family of semiconductors. This effect can be useful in the design of localized electronic modes with specific geometries for experimental or technological applications, including superconductivity, as has been recently reported for 2D twisted bilayer graphene.

3:30 PM *QN01.04.02
Topics of Two-Dimensional Materials and Their Heterostructures Mei-Yin Chou1,2; 1Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei, Taiwan; 2School of Physics, Georgia Institute of Technology, Atlanta, Georgia, United States.

It has become possible in recent years to fabricate and manipulate two-dimensional nanomaterials in the laboratory that are as thin as one to few atomic layers. The reduced dimensionality gives rise to unique physical and chemical properties that differ from those of traditional bulk materials, and intriguing physical properties have been found in these few-layer systems. Computational studies have played a central role in understanding and predicting these novel properties. In this talk, I will focus on a few representative systems, including graphene systems and monolayers of transition metal dichalcogenides that exhibit properties ranging from charge density waves [1] to the quantum spin-Hall effect [2]. The hybrid system of boron nitride and graphene (h-BNC) at low BN doping serves as an ideal platform for band-gap engineering and valleytronic applications. The calculations find a linear dependence of the band gap on the BN concentration at low doping, arising from an induced effective on-site energy difference at the two C sublattices as
they are substituted by B and N dopants alternately. In addition, our calculations show that the Moiré patterns in van der Waals heterostructures will modify the local band gap, interlayer interaction, and structural parameters [3-5]. I will also discuss one-dimensional topological insulators manifested in graphene nanoribbons, in which localized spin states may exist at the end or near the junctions. A symmetry protected topological classification is formulated for any type of termination with quantized Berry phase when summed over all occupied bands.

Plasmonic MXene Thin Films for Flexible Visible-Light Photodetectors

Dhinesh B. Velusamy, Jehad K. El-Demellawi and Husam N. Alshareef; King Abdullah University of Science and Technology, Jeddah, Saudi Arabia.

MXenes, two dimensional (2D) nanosheets of transition metal carbides, have garnered significant interest due to their intriguing physicochemical properties associated with the unique 2 dimensionally confined chemical structures. These new classes of 2D materials have already shown promising electrochemical energy storage characteristics in both supercapacitor and Li-ion battery anode applications and endowed fascinating prospects for a variety of emerging applications in electronics, optics, energy conversion and storage. Recently, MXenes exhibited impressive optical properties e.g., tunable broadband absorption and intense surface plasmon excitations, underlining their potential for photonic and plasmonic devices. However, theoretical and experimental investigations in this context remain sparse and mainly limited to the most studied Ti3C2Tx MXene. Herein, we demonstrate molybdenum carbide MXene (Mo2Ct3) photodetectors for broadband visible light photodetection. The Mo2Ct3 MXene thin films deposited on paper substrates exhibit broad photosresponse in the range of 400-800 nm with high responsivity (9 A W⁻¹), detectivity (~5x10¹⁸ Jones) and reliable photo switching characteristics at a wavelength of 660 nm. Photodetectors made of four other MXenes have been also fabricated. We found that the photocurrent generation in Mo2Ct3 is principally controlled by surface plasmon-induced hot electrons. The existence and the distribution of a variety of surface plasmon modes over individual Mo2Ct3 nanosheets are visualized by the combination of scanning transmission electron microscopy (STEM) and ultra-high resolution electron energy loss spectroscopy (EELS). In addition, Mo2Ct3 thin film devices are shown to be resistant to environmental factors, illustrating their stable and durable photodetection operation. Moreover, the arrays of Mo2Ct3 thin film photodetectors are shown to be readily bendable under multiple and repeated deformations. The explicit ability to detect and excite individual surface plasmons, provide a viable platform for various MXene-based optoelectronic applications.

2D Rules—Band Gap Engineering in Weakly Interacting van der Waals Heterostructures

Francis H. Davies, Ned T. Taylor, Shane G. Davies, Conor J. Price and Steven P. Hepplestone; Department of Physics and Astronomy, University of Exeter, Exeter, United Kingdom.

The band gap is of paramount importance to almost all of the electronic and optical properties of semiconducting materials. By controlling the size of the band gap and their electronic structure, we can control both the transport properties and the optical interactions of such materials. The ability to energetically control electrons in solid-state devices is pivotal in the fields of sensing, renewable energy [1], information processing and communications technology [2]. Here we present the rules of 2D band gap engineering in 2D heterostructures. Our insights offer the potential of engineering not just the band gap, but the electronic dispersion itself; making it far more versatile than strain engineering of band gaps.

The field of 2D semiconductors has been of growing research interest in recent years, but 2D heterostructures have only recently become experimentally viable [3]. We have performed a large scale first principles study of many transition metal dichalcogenides and other 2D semiconductors using density functional theory. These 2D layered heterostructures demonstrate weak inter-layer interactions. Due to this, the band structures of individual layers of a heterostructure have a high fidelity to their isolated counterparts. We show that a layered heterostructure will, therefore, have a dispersion which consists of an overlay of its components’ band structures. We determine that the electronic dispersions of 2D layered heterostructures can be tailored by layer composition, and demonstrate a wide range of potentially attainable tunable band structures.

Optical Properties of Two-Dimensional InSe, GaSe and Their Heterostructures, from Visible to the THz Range

Vladimir Falko; National Graphene Institute, University of Manchester, Manchester, United Kingdom.

We present the analysis of electronic band structure of InSe and GaSe films, from the stoichiometric mono- to N-layer films which determines optical properties of these 2D materials [1,2]. This study is based on the ab initio DFT and related multi-orbital tight-binding model analysis of the electronic band structure and wave functions in N-layer InSe and GaSe films, and it is compared to the results of ARPES and luminescence spectroscopy of this material [3]. We show [1,2] that the band gap in InSe (and GaSe) strongly depend on the number of layers, with a strong (more than two) reduction from the monolayer to crystals with N>6. We find that the conduction-band-edge electron mass in few-layer InSe is quite light (comparable to Si), which suggests opportunities for high-mobility devices and the development of nanocircuits. In contrast, the valence band in mono-, bi- and trilayer InSe is flat, opening possibilities for strongly correlated hole gases in p-doped films. Using the band structure and wave functions, we analyse optical transitions in thin films of InSe and GaSe, identify their polarisation and compare the results of modelling to the measurements performed on hBN-encapsulated atomically thin InSe and GaSe crystals.

Then, we show that the same materials have potential for optical functionality in the far-infrared range, for which one can exploit the intersubband transitions in InSe and GaSe few-layer films [4].

Manipulating Light Flow with 2D Materials

The deliberate tailoring of semiconducting 2D transition metal chalcogenides for optoelectronic applications – via an understanding of their emergent electronic structure and photophysics in their chemical composition and atomic arrangement – presents significant opportunities, due to their strong light-matter interactions, reduced dimensionality, and chemical diversity and heterogeneity. Here, I will describe the use first-principles computational methods – including density functional theory, ab initio many-body perturbation theory, and materials databases – to predict and understand the electronic structure, chemical bonding, and excited state phenomena in these systems, leading to new intuitive and not important about class of materials. I will review our recent calculations of point defects, and in their impact on electronic structure and valley polarization, in 2D transition metal dichalcogenides; I will also discuss ongoing work in which we interface these systems with magnetic substrates to break valley degeneracy. Additionally, time permitting, I will discuss the opportunity for large nonlinear optical responses in monolayer transition metal monochalcogenides; and for photocatalytic reduction of CO₂. In each case, I will emphasize implications for experiments and new principles for the design of functional layer materials. Bright and Dark Exciton Landscape in Two-Dimensional Molybdenum Disulfide
Hongyu Yu¹; Magdalena Lauren¹ and Oleq Rubel²;¹ Materials Science and Engineering, McMaster University, Hamilton, Ontario, Canada; ²School of Physics, Nankai University, Tianjin, China.

Excitonic effects dominate the optical properties of materials, especially of low-dimensional materials such as transition metal dichalcogenides, e.g. monolayer molybdenum disulfide [1]. When considering the excitonic effect, the band structure changes remarkably which can even result in a change of the material’s bandgap type (e.g. from indirect to direct) [1]. However, while primary bright excitonic transitions are well studied, a systematic approach to dark transitions is still lacking. In this research, we study the excitonic effect in transition metal dichalcogenide monolayers starting with MoS₂ using density functional theory, quasiparticle methods (GW0) and the Bethe-Salpeter equation for calculating electronic excitations. In order to show the bandgap and exciton landscape, we include bright and momentum-resolved dark excitons in a novel approach of plotting the excitonic band structure. This way of visualizing the band structure allows us to easily tell if the material has a direct band gap after considering excitonic effects or not. Further, it enables the classification of dark excitons into spin-forbidden and/or momentum-forbidden transitions while clearly displaying the respective exciton binding energies. We believe that our approach will allow for exciting results, especially for the application to materials like ReSe₂ for which the nature of the band gap is still debated.

Tuning the Fröhlich Exciton-Phonon Scattering in Monolayer MoS₂
Bastian Müller¹, Jessica Lindlau¹, Andre Neumann¹, A.W. Holleitner¹, Alexander Högel¹ and Ursula Wurstbauer¹,²; Technical University of Munich, Garching, Germany; ²WWU Münster, Münster, Germany; ³LMU Munich, Munich, Germany.

A direct band gap [1], remarkable light-matter coupling [2] as well as strong spin-orbit and Coulomb interaction establish two-dimensional (2D) crystals of transition metal dichalcogenides (TMDs) as an emerging material class for fundamental studies as well as novel technological concepts. Valley selective optical excitation allows for optoelectronic applications based on the momentum of excitons [3]. In addition to lattice imperfections and disorder, scattering by phonons is a significant mechanism for valley depolarization and decoherence in TMDs at elevated temperatures preventing high-temperature valley polarization required for realistic applications [4]. Thus, a detailed knowledge about strength and nature of the interaction of excitons with phonons is vital. We directly access exciton-phonon coupling in charge tunable single layer MoS₂ devices by polarization resolved Raman spectroscopy. We observe a strong defect mediated coupling between the long-range oscillating electric field induced by the longitudinal optical (LO) phonon in the dipolar medium and the exciton. We find that this so-called Fröhlich exciton LO-phonon interaction [5] is suppressed by doping. This suppression correlates with a distinct increase of the degree of valley polarization of up to 60% even at elevated temperatures of 220 K [6]. Our result demonstrates a promising strategy to increase the degree of valley polarization towards room temperature valleytronic applications.

9:30 AM QN01.05.04
Manipulating Light Flow with 2D Materials Plasmons
Tony Low; Department of Electrical & Computer Engineering, University of Minnesota, Minneapolis, Minnesota, United States.

Recent years have observed a plethora of strong dipole type polaritonic excitations in 2D materials owing to the reduced screening. These polaritons can be sustained as electromagnetic modes at the interface between a positive and negative permittivity material. In the case of the plasmon-polaritons (e.g. in semi-metallic graphene), the negative permittivity is provided by the coherent oscillations of the free carriers. For exciton-polaritons (e.g. in semiconducting transition metal dichalcogenides, TMD) and phonon-polaritons (e.g. in diatomic hexagonal boron nitride, hBN), it is associated with their resonant optical absorption, resulting from a highly dispersive permittivity. These optical resonances can also result in a negative permittivity, albeit over a narrow spectral window.

In this talk, I will discuss our recent efforts in understanding plasmons behavior in 2D materials, such as graphene and its bilayer, black phosphorus, and transition metal dichalcogenides, and using them to control the flow of light both in the far- and near-field. The general constitutive materials response of 2D materials, in conjunction with metasurface approaches, can potentially enable arbitrary control of phase, amplitude, polarization and directionality of light.

Photonic Response of 2D Nanostructures by Theoretical Analysis
Jie Jiang and Ruth Pechter; Materials & Manufacturing Directorate, Air Force Research Laboratory, Wright-Patterson AFB, Ohio, United States.

Development of 2D transition metal dichalcogenides (TMDs) for photonic applications advanced greatly in recent years, for example, in providing improvements in optical nonlinearities, such as two-photon absorption (TPA) cross-sections. Interestingly, recently, even larger TPA cross-sections were measured for 2D organic-inorganic perovskites (OIPs). The 2D OIP structure emerges when Goldschmidt’s tolerance factor, which depends primarily on the ionic radius of the organic cation in this case, is larger than 1. 2D OIPs exhibit a large increase in the exciton binding energy due to quantum and dielectric confinement, and provide spectral tunability. Here we report on 2D OIPs with organic chromophore incorporation, in comparison to previously investigated cations, aiming to design materials for intensity enhancements. Density functional theory calculations of 2D OIP structures will be described, and quantification of the geometrical distortion by the bond length quadratic elongation, bond angle variance, and perovskite layer distortion. Electronic structure calculations, including spin-orbit coupling, demonstrate variations in the band alignments of the organic and inorganic parts, leading to varying confinement of the electrons and holes. The interplay between hybridization and band alignment type, as well as the calculated absorption spectra, as dependent on the chromophore type, will be discussed. Finally, in the context of tunability in the optical properties of 2D photonic nanostructures, the optical response of a defective monolayer TMD (WSe₂) will be reported.
Upon introduction of single or double Se vacancies, or a single V vacancy within monolayer WSe$_2$, the computational results demonstrate emergence of deeper defect excitons in comparison to shallower values observed for edges. Defect excitons are shown to red-shift significantly for large rotational defects that pattern the monolayer.

11:00 AM *QN01.05.06
Doped Graphene—Advantages for Sensing Individual Molecules 
**Mauricio Terrones**
The Pennsylvania State University, University Park, Pennsylvania, United States.

This talk will discuss the synthesis of large-area, high-quality monolayers of nitrogen-, silicon- and boron-doped graphene graphene sheets on Cu foils using ambient-pressure chemical vapor deposition (AP-CVD) [1-3]. Scanning tunneling microscopy (STM) and spectroscopy (STS) reveal that the defects in the doped graphene samples arrange in different geometrical configurations exhibiting different electronic and magnetic properties. Different substitutional nitrogen sites could be controlled by controlling the CVD temperature, flowrate and the duration of the doping precursor inside the reactor. Interestingly, these doped layers could be used as efficient molecular sensors. We will show that B-doped graphene (BG) exhibits unique sensing when detecting toxic gases such as NO$_2$ and NH$_3$. [2]. The detection limit for BG can reach as low as 95 ppt for NO$_2$ gas and 60 ppb for NH$_3$. BG has enhanced sensitivity values of 27 and 105 times better than graphene for NO$_2$ and NH$_3$ detection [3]. This is attributed to the presence of B atoms within the graphene lattice that results in a high affinity to both donor and acceptor molecules, leading to stronger interactions between the molecules and graphene. Finally we will discuss the use of graphene for enhancing Raman signals for specific molecules, also known as graphene enhanced Raman scattering (GERS). NG and Si-doped graphene (SiG) could significantly enhance the Raman signal of fluorescent molecules: Rhodamine B (RhB), crystal violet (CRV) and methylamine blue (MB) [1]. SiG exhibits an enhancement factor 10-40 times higher than that of PG (see Fig. 1) [1]. We will also show that by using NG as a substrate, Raman signals of dye molecules can be detected at a record low concentration of 10$^{-11}$ M [4]. This is very close to single molecular detection. However, this enhanced Raman sensing requires the Fermi energy of the substrate to match the LUMO level of the probe molecule, which allows an effective charge-transfer excitation [4].

References
Deep-level defects in wide-bandgap semiconductors exhibit localized electronic energy levels with paramagnetic spin states, and hence they constitute promising platforms for quantum bits (qubits). Defect-based solid-state spin qubits have been widely studied, including the nitrogen-vacancy (NV) center in diamond, vacancies in SiC, donor spins in silicon, and rare-earth ions, targeting quantum computing and sensing applications. The spin coherence time $T_2$, usually measured by Hahn-echo experiments, is a critical property for qubit applications. In quantum computers, in order to achieve quantum error correction, at least $10^9$ quantum gate operations need to be performed within $T_2$, yielding a desired coherence time larger than 100 $\mu$s. The sensitivity of quantum sensors, which is inversely proportional to $T_2$, benefits as well from qubits with long coherence times.

The decoherence of spin qubits can arise from different sources, including the magnetic noise from high-density paramagnetic defects and dangling bonds on the material surface. In highly purified bulk solids, the phase decoherence is mainly caused by the entanglement between the electron spin qubit and the nuclear spin bath of the host material. Thus, reducing the concentration of nuclear spins, e.g. through isotopic purification, is an effective technique to enhance $T_2$. For example, the ensemble $T_2$ of the NV center in diamond has been extended from 0.63 ms to 1.8 ms by reducing the concentration of $^{14}$C nuclear spins from 1.1% to 0.3%.

The nuclear spin density can also be reduced by decreasing the dimensionality of the nuclear spin bath from three dimension to two dimension or even lower dimensions. In addition, two-dimensional (2D) layered materials exhibit a variety of promising properties for the realization of hosts of defect-based spin qubits. 2D layered materials can be easily transferred and integrated into hybrid quantum systems. In 2D systems, point defects can be created and precisely located using a scanning transmission electron microscope or an annular dark field microscopy. Furthermore, compared with thin films of three-dimensional (3D) solids, 2D layers are free from unsaturated dangling bonds at the surface that are detrimental to spin coherence. However, the nuclear spin environments in many 2D materials are much more complex than, e.g. in diamond. Currently, h-BN and MoS$_2$ are among the most studied 2D material host candidates, and in h-BN all nuclei have large nuclear-spin moments.

In this talk, we investigate the coherence of spin qubits in 2D materials. We first explore the effect of dimensionality on spin decoherence and discuss the interplay of dimensionality, crystal geometry and nuclear spin concentration in determining $T_2$. We then predict the coherence time of spin qubits in 2D materials such as MoS$_2$ and h-BN, and show that isotopic purification can be much more effective in 2D than in 3D, leading to a spin coherence time of more than 30 ms in isotopically pure monolayer MoS$_2$. However achieving low nuclear spin concentration is not the only design rule to obtain optimal spin qubit hosts: the important roles of gyromagnetic ratios, homo-nuclear distance and nuclear magnetic moments are also discussed. Overall we predict that single-layer MoS$_2$ layers and delta-doped diamond slabs can be promising hosts for spin qubits, while the $T_2$ of h-BN appears to be much more challenging to engineer, due to the large gyromagnetic ratio of the boron nuclei.

3:30 PM *QN01.07.04
Origin of Antiferromagnetism and Magnetoelastic Effect in CrI$_3$ Bilayers Di Xiao; Department of Physics, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

Since the demonstration of intrinsic ferromagnetism in atomically thin crystals, there has been a lot of interest in two-dimensional (2D) magnets. Among them, CrI$_3$ presents an intriguing case. While bulk CrI$_3$ is a ferromagnet, it becomes a layered antiferromagnet when thinned down to a few atomic layers. A number of interesting phenomena associated with this layered antiferromagnetism have been observed, including giant tunneling magnetoresistance and electrostatic doping control of magnetism. In this talk, I will present our study of the stacking dependent magnetism of bilayer CrI$_3$, using first-principles calculations. We show that the stacking order defines the magnetic ground state. By changing the interlayer stacking order one can tune the interlayer exchange interaction between antiferromagnetic and ferromagnetic. We propose that the predicted stacking-dependent magnetism can be probed via linear magnetoelastic effect. Our results not only gives a possible explanation for the observed antiferromagnetism in bilayer CrI$_3$, but also have direct implications in heterostructures made of two-dimensional magnets.

4:00 PM *QN01.07.05
Calculating Critical Temperatures for Ferromagnetic Order in 2D Materials—The Critical Role of Magnetic Anisotropy Daniele Torelli and Thomas Olesen; Technical University of Denmark, Roskilde, Denmark.

Magnetic order in two-dimensional (2D) materials is intimately coupled to magnetic anisotropy (MA) since the Mermin-Wagner theorem implies that rotational symmetry cannot be spontaneously broken at finite temperatures in 2D. Large MA thus comprises a key ingredient in the search for magnetic 2D materials that retain the magnetic order above room temperature. Magnetic interactions are typically modeled in terms of Heisenberg models and the temperature dependence on magnetic properties can be obtained with the Random Phase Approximation (RPA), which treats magnon interactions at the mean-field level. In the present work we show that large MA gives rise to strong magnon-magnon interactions that leads to a drastic failure of the RPA. We then demonstrate that classical Monte Carlo (MC) simulations correctly describe the critical temperatures in the large MA limit and agree with RPA when the MA becomes small. A fit of the MC results leads to a simple expression for the critical temperatures as a function of MA and exchange coupling constants, which significantly simplifies the theoretical search for new 2D magnetic materials with high critical temperatures. The expression is tested on a monolayer of CrI$_3$, which were recently observed to exhibit ferromagnetic order below 45 K and we find excellent agreement with the experimental value.

We apply the developed methodology to perform a computational screening for magnetic 2D materials with large critical temperatures based on the computational 2D database C2DB. We identify several stable materials, which are predicted to exhibit magnetic order above room temperature.

Defects and Substrate Screening on the Electronic, Optical and Plasmonic Properties of 2D Materials Steven Louie1,2; University of California, Berkeley, Berkeley, California, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Symmetry, interaction and topological effects greatly influence the quantum properties of atomically thin two-dimensional (2D) materials. Defects and environmental screening can play equally important roles in determining their behaviors. In this talk I present several interesting phenomena related to point defects and substrate screening on the properties of 2D materials. 1) We study, using ab initio GW-BSE theory, the effect of point-defect chalcogen vacancies on the optical properties of monolayer transition metal dichalcogenides (TMDs). The chalcogen vacancies introduce unoccupied in-gap states and occupied resonant quasiparticle defect states. These defect states give rise to strongly bound defect excitons and hybridize with excitons of the pristine system, reducing the valley-selective circular dichroism. The results suggest a pathway to tune spin-valley polarization and other optical properties through defect engineering. 2) A fascinating property of monolayer semiconductors is that the electronic bandgap ceases to be an intrinsic physical parameter and can be engineered through the surrounding dielectric environment. We have exploited such a dielectric-dependent electronic bandgap and demonstrated the formation of a lateral heterojunction within a homogeneous MoS$_2$ monolayer through substrate engineering. The capability to tailor the local band structure and electrical transport in 2D semiconductors through dielectric engineering can open exciting new ways to design 2D nanoelectronic and optoelectronic devices. 3) Plasmons in atomically thin 2D materials are distinct from those of the bulk and traditional 2D electron gas systems. We have discovered that the plasmon dispersion in real quasi-2D metals is qualitatively different, being virtually dispersionless for wavevectors of typical experimental interest. This stems from a lack of continuous translational symmetry, making dispersionless plasmons a universal phenomenon in quasi-2D metals. Moreover, our ab initio calculations show that plasmons on monolayer metallic TMDs are long lived and localizable in wave packets (within ~15 nm) which does not significantly disperse over practical measurement time. Their slow propagation opens the possibilities of tracking plasmon wave packets in real...
time and of localizing long-lived, boson-like excitations in extended, atomically thin materials.

Two-Dimensional Cross-Linked Polythiophene Network 
Kongyang Yi and Dacheng Wei; State Key Laboratory of Molecular Engineering of Polymers, Department of Macromolecular Science, Fudan University, Shanghai, China.

Solution-processed polythiophene thin films suffer from low efficient inter-molecular carrier hopping and undermined conjugation arising from chain twist and random entanglement. To form a graphene like two-dimensional (2D) cross-linked conjugated polymer network is one of promising strategies to solve this problem. Here, we synthesize decimeter-sized 2D cross-linked polythiophene network (2DPT) by surface-confined Ullmann coupling, with 1.6 nm thickness and transmittance of ~97% at 550 nm. The 2D cross-linked network improves charge carrier transport, resulting in carrier mobility up to 4.6 cm² V⁻¹ s⁻¹ and conductance of 206 S cm⁻¹, much higher than that of normal solution-processed conjugated polymer films. Owing to efficient carrier transport, atomic thickness and large conjugated surface, this new conjugated polymer exhibits fast response to stimuli as the channel in a liquid-gated H₂SO₃ sensor, and low contact resistance as bottom-contact electrodes in organic field effect transistors with high carrier mobility.

QN01.09.02
A Nonthermal Plasma Synthesis Route to Two-Dimensional MoS₂
Chad Beaudette, Jacob Held, Andre Mkhiyan and Uwe Kortshagen; University of Minnesota, Minneapolis, Minnesota, United States.

In this work we investigate the production of two-dimensional molybdenum disulfide, MoS₂, through two nonthermal based routes of synthesis: plasma enhanced atomic layer deposition (PEALD) and plasma enhanced chemical vapor deposition (PECVD). MoS₂ is a class of van der Waals two-dimensional materials whose applications include transistors, memristors, hydrogen evolution reactions, photodetectors, lithium ion batteries, water purification, and dye sensitized solar cells. However, many production methods for two-dimensional molybdenum disulfide suffer from either high temperatures, long time scales, dangerous chemicals (hydrogen sulfide) or low yield. Here, we describe two processes capable of producing large area films of MoS₂ utilizing molybdenum pentachloride and elemental sulfur as precursors. Both PECVD and PEALD can produce polycrystalline material at low temperatures (275-315 °C). In the case of PECD grown films, time scales for nucleation and large area growth occurs on the order of one to two minutes to produce few layer molybdenum disulfide. For PEALD, due to the steric factor of the molybdenum pentachloride precursor, only 2 cycles are required for a complete polycrystalline two-layer MoS₂ film with Angstrom level surface roughness. Film quality and structure are confirmed by Raman spectroscopy, transmission electron microscopy, and atomic force microscopy. This work was supported primarily by the U.S. National Science Foundation through the University of Minnesota MRSEC under Award Number DMR-1420013. Parts of this work were carried out in the Characterization Facility, University of Minnesota, which receives partial support from NSF through the MRSEC program.

QN01.09.03
Etching Anions from Layered Materials for MXene-Like Synthesis of 2D Materials 
Daniel Druffel, Katie Scott, Jacob Pawlik and Scott Warren; Chemistry, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

MXenes have attracted significant attention since their discovery because their elegant synthesis yields nearly 100% monolayer samples. MXenes are prepared from a layered MAX (metal aluminum carbide) phase by selectively etching layers of aluminum (or Si, Ga) atoms using HF, leaving the 2D metal carbide lattice intact. Building on the synthetic concepts of MXenes, here we report the first synthesis of 2D materials made by selectively etching halides from layered phases. First, we synthesized layered metal carbide iodides by high temperature reactions of the metal, carbon, and the metal iodide. By tuning the temperature, pressure, and stoichiometry, we produced powders consisting of thin platy crystals about 1 μm thick and 10-100 μm. Then we explored routes to etch the iodide layers selectively, including solution-based methods using lithium naphthalide as the etchant and a gas-phase method using potassium vapor at 200 °C. Like the oxidative etchings used to produce MXenes, we find that these reductive etchings produce materials with hollow, accordion-like behaviors, which can be delaminated further by sonication to few-layer 2D materials. We performed X-ray diffraction to reveal that the reaction of layered metal carbide iodides with potassium vapor extracts iodide and forms potassium iodide, which can be dissolved and removed. Interestingly, unlike traditional MXenes, the surface of the reductively etched metal carbides do not have hydroxyl or fluoride ions bound to the surface. In fact, our XAFS calculations show that the reductively etched 2D materials, under appropriate conditions, can remain functionalized at the surface, offering unique properties that could be useful in a number of applications in energy storage, catalysis, and electronics. Motivated by our initial promising findings, further experimental characterization of the 2D materials and their surfaces are underway.

QN01.09.04
Highly Crystalline Synthesis of vdW Tellurene Sheets on Two-Dimensional Surfaces 
Sijie Yang, Bin Chen, Ying Qin, Yi Zhou, Lei Liu, Michael Darso, Houlong Zhuang, Yuxia Shen and Sefaattin Tongay; Arizona State University, Tempe, Arizona, United States.

Recent results have identified two-dimensional (2D) tellurene as a potential van der Waals (vdW) material for thermoelectric and optoelectronics applications owing to their pseudo-one-dimensional (anisotropic) behavior and structure. While hydrothermal synthesis is suitable for yielding potentially crystalline materials, it is well known for its incompatibility with manufacturing and scaling. This talk will introduce novel synthesis of tellurene sheets onto a variety of surfaces of vdW-bonded 2D layered crystals. Our systematic tellurene growth studies on six different vdW surfaces show that GaSe and GaS surfaces enable highly crystalline and self-oriented tellurene sheets. Detailed cross-sectional transmission electron microscopy (TEM), angle-resolved Raman spectroscopy, scanning electron microscopy, and energy-dispersive spectroscopy measurements provide fundamental insights into the growth dynamics and characteristics of tellurene. First-principles calculations and cross-sectional TEM measurements suggest that tellurene chains are well-oriented along the GaSe armchair lattice direction owing to the much-reduced total energy of the system and a stronger degree of coupling across adjacent layers. Synthesized tellurene sheets exhibit remarkable structural anisotropy, as evidenced by angle-resolved Raman measurements, and the overall results open a clear pathway for layer-by-layer growth of tellurene sheets with controlled crystalline anisotropy through conventional synthesis techniques.

QN01.09.05
High-Throughput Prediction and Charge-Transfer Stabilization of Multidimensional Electrides 
Jack D. Sundberg, Daniel Druffel, Jacob Pawlik, Adam Woonger and Scott Warren; University of North Carolina, Chapel Hill, North Carolina, United States.

Electrides have gained considerable attention in recent literature thanks to demonstrated applications as superconductors, catalysts, and solid-state dopants. However, current electrode materials are largely limited by the tradeoff between desired electronic properties and the preventive reactivity of these materials. This is caused by the distinctive feature of electrodes: bare-electrons that exist at isolated lattice sites. Further, reactivity increases when bare electrons form interconnected pathways, but these ‘multidimensional’ electrides also provide desirable properties like heightened electrical conductivity. Thus, this tradeoff must be addressed by discovery of electrides specialized for given applications (i.e. where stability is vital) and/or stabilization of highly desired multidimensional electrides. Both strategies are employed here. High-throughput screening is used to address the scarcity of stable multidimensional electrides and propose a new series of robust, low-work function compounds. This screening is driven by derivatives of known halide materials, where electrochemical dehalogenation can produce electrode forms, and the synthetic approach is experimentally demonstrated with previously reported two-dimensional (layered) electrides. By avoiding high-temperature synthesis, kinetically stable and oxidation-resistant electrodes can be realized. Secondly, stabilization of known and
newly reported electrodes are computationally examined and experimentally applied via novel charge-transfer stabilization at the electrode-substrate interface. By reducing the reactivity of electrodes, previously metastable forms can be synthesized as electrode thin-films, where their increased surface area is idealistic for the aforementioned applications and further enables new uses. Together, the discovery of multidimensional electrodes and charge-transfer stabilization expands on reported multidimensional electrodes and their corresponding applications as low work-function materials.

QN01.09.06
Large-Area Ultra-Clean Dry Transfer of 2D Materials by Spin-Coated Pressure Sensitive Adhesive Polymers Yoon Seok Choi, Dong Heon Shin and Byung Hee Hong; Seoul National University, Seoul, Korea (the Republic of).

In recent years, researchers have tried to develop various methods to synthesize high-quality large-scale graphene using chemical vapor deposition (CVD) processes. However, the performance of CVD graphene is often degraded by defects, cracks and polymer residues that occur during transfer processes, which causes the similar problems in the transfer of other 2D materials. The PMMA coating is still a very effective method for the transfer of 2D materials, but the wet process to remove PMMA using acetone is problematic for device integration with soluble layers. Here we report a novel transfer method based on the use of pressure sensitive adhesive (PSA) that can be simply spin-coated on the sample, and completely removed by peeling-off after transfer, which is expected to allow the use of soluble layers for various 2D device fabrication processes. We confirmed that the sheet resistance of graphene has not been altered after transfer thanks to the good adhesion between graphene and PSA layers. In addition, the transparent graphene FETs transferred by PSA shows high charge carrier mobility compared to the FETs transferred by PMMA or thermal release tapes (TRT), implying that the graphene surface is ultra-clean without residues after the removal of PSA. We believe that the current method is applicable to various flexible and wearable applications that have been limited by wet transfer conditions for more practical and larger scale device fabrications of 2D materials.

QN01.09.07

Two-dimensional (2D) materials can be single layer because the bonds between each layer are made up of Van der Waals bonds while interlayer atoms bind together as covalent bonds. They can be separated into atomic-level single layers, which are very flexible and transparent, and are suitable for future electronics because of their various electrical and physical properties. Among 2D materials, MoS2 has drawn much attraction and chemical vapor deposition (CVD) is most popular method for synthesizing large size 2D materials. However, this process is difficult to control the temperature accurately and causes problems of the non-uniformity depending on the distance (sulfur position), and the internal contamination of furnace. In this study, a novel chemical vapor deposition (CVD)-free and solution-processed synthetic method were developed and successfully synthesized large size and uniform MoS2 thin films. The MoS2 precursor solution was formulated by sulfur-dissolving method to obtain uniform coating property. MoS2 thin films were prepared by simple spin-coating and one-step annealing method without any CVD process (CVD-free). The solution-synthesized MoS2 thin films were characterized to confirm 2H-MoS2 structure. The various atomic layers of synthesized MoS2 could be controlled with the precursor concentrations, such as two-layer for 0.0070 M, three-layer for 0.0125 M, and five-layer for 0.025 M of MoS2 precursor solution, which were confirmed by STEM.

QN01.09.08
Size and Strain Effects on Mechanical and Electronic Properties of 2D Green Phosphorene Monolayer and Nanoribbons Guang Yang1, 2; Evan Garrison1; Tianxing Ma3 and Xihong Peng1; 1Arizona State University, Mesa, Arizona, United States; 2Beijing Normal University, Beijing, China.

A phosphorus isomer named green phosphorus was recently predicted by theory with a similar interlayer interaction compared to that of black phosphorus, which indicates that individual layers can be mechanically exfoliated to form two-dimensional (2D) layers called green phosphorene. This 2D monolayer showed high stability and was predicted to have a direct band gap up to 2.4 eV. First-principles density functional theory calculations were used to investigate the mechanical properties and strain effect on electronic band structure of the 2D green phosphorene along two perpendicular in-plane directions, namely armchair and zigzag. It was found that the 2D green phosphorene ribbon with width up to 57 Å. Effects of ribbon width (size) and strain on the mechanical and electronic properties of the ribbons were studied. The Young’s modulus, effect of quantum confinement on the band gap, and effect of strain on the electronic band structures of the ribbons were investigated. The green phosphorene ribbons were found to exhibit prominent anisotropic properties, with the Young’s modulus in the range of 10-35 GPa for the armchair green phosphorene nanoribbons (AGPNR) and 160-170 GPa for the zigzag green phosphorene nanoribbons (ZGPNR), which are the same order of magnitude as those of its 2D sheet. The work function was found to be between 5 eV – 5.7 eV for the range of ribbon widths studied. Both size and strain trigger direct-indirect bandgap transition in the ribbons and their transition mechanisms were discussed.

QN01.09.09
Investigating the Exfoliation of Ni-B 2D Sheets from Ni2ZnB MAB Phase Amir Rezaei and Boniface Fokwa; University of California, Riverside, Riverside, California, United States.

MXene materials, 2D transitional metal carbides, have shown some promising properties in battery, supercapacitor and energy applications. These 2D layers have been exfoliated from ternary carbides named MAX phases. However, recently, a new group of 2D materials called MBene have been in interest since they have a similar structure and exfoliation mechanism to MXene. In this study, we discuss the possibility of forming 2D Nickel boride layers via selectively etching Ni2ZnB MAB phase. Single phase Ni2ZnB MAB phase has been synthesized for the first time. The zinc interlayer was then etched out, via immersing the MAB phase in diluted HCl. The selectively etched particles were investigated via scanning electron microscopy and powder X-ray diffraction. It was observed for the first time that ternary Ni2ZnB phase can be exfoliated via selectively etching the zinc interlayer. Demonstrating the zinc interlayer etching opens a door to the synthesis of a large number of new 2D borides from ternary MAB phases, especially those containing Zn.

QN01.09.10
Intercalation-Tuned Chemochromism in 2D Layered MoO3 Bryan P. Moser and Kristie Koski; University of California, Davis, Davis, California, United States.

We demonstrate that intercalation of zero-valent atoms can be used to chemically change the color of molybdenum trioxide (MoO3) from transparent white to dark blue. Chemochromism is achieved through dilute creation of a zero-valent atomic species in solution (such as V, Mo, Sn, and Co) which is then intercalated into the van der Waals gap. Chemochromism of MoO3 is shown to be reversible, robust, and has remarkably high absorptivity. We show that this 2D layered oxide shows promise in color-changing smart devices.

QN01.09.11
Linking DFT Calculations on Hydroxyl Group Concentration with Experimental ALD Growth Mechanics Matthew Lawson; Materials Science and Engineering, Boise State University, Boise, Idaho, United States.

Transition metal dichalcogenides (TMDs) are rapidly becoming of interest when transitioning from bulk phase to two dimensional structures. Not only do they boast high carrier mobilities, but first-principles calculations and experimental results have demonstrated that methods like doping and alloying can tailor critical properties such as the band gap. Now, the focus on first-principles calculations on TMDs has shifted from predicting performance and properties, to understanding and controlling TMD growth and processing. Our experimental collaborators have successfully growth MoS2 via atomic layer deposition (ALD) but have little insight into how the hydroxyl concentration on the substrate affects growth kinetics. We use density functional theory (DFT) to model the initial growth mechanisms between the gas precursors and substrate and predict the optical hydroxyl surface concentration for ALD growth. By thermally controlling hydroxyl groups on our alumina surface we characterize our substrates with x-ray photoelectron spectroscopy (XPS) to determine experimental hydroxyl concentration. We propose a novel approach of combining DFT calculations and ALD growth measurements for finding optimal
CO\textsubscript{2} Capture and Conversion Chemistry with 2D Layered Materials

Calley N. Eads, Samuel A. Tenney, Ashley R. Head and Dario Stacchiola; Brookhaven National Laboratory, Upton, New York, United States.

CO\textsubscript{2} emissions have increased substantially in recent years, to a point that is detrimental to the environment and needs to be addressed. Methods to capture CO\textsubscript{2} and convert the greenhouse gas into its fundamental components are underway but are currently energy-intensive. We aim to approach this existing problem with novel materials, such as doped-2D layered materials and metal-organic frameworks on metal supports, and understand the interfacial interactions using microscopy, infrared and photoemission spectroscopy at near-ambient pressures.

Mechanical and Thermal Properties of Grain Boundary in a Planar Heterostructure of Graphene and Hexagonal Boron Nitride

Anran Wei and Yinfeng Li; Department of Engineering Mechanics, Shanghai Jiao Tong University, Shanghai, China.

In this study, the mechanical properties of grain boundaries (GBs) in planar heterostructures of graphene and hexagonal boron nitride (h-BN) were studied using the molecular dynamics method in combination with the density functional theory and classical disclination theory. The hybrid interface between graphene and h-BN grains was optimally matched by a non-bisector GB composed of pentagon-heptagon defects arranged in a periodic manner. GB was found to be a vulnerable spot to initiate failure under uniaxial tension; moreover, the tensile strength was found to anomalously increase with an increase in the mismatch angle between graphene and h-BN grains, i.e., the density of pentagon-heptagon defects along the GBs. The disclination theory was successfully adopted to predict the stress field caused by lattice mismatch at the GB. Comparison between stress contours of GBs with different mismatch angles demonstrates that the arrangement of 5\textendash{}7 disclinations along the GB is crucial to the strength, and the stress concentration at the GB decreases with an increase in disclination density; this results in an anomalous increase of strength with an increase in the mismatch angle of grains. Moreover, the thermal transfer efficiency of the hybrid GB was revealed to be dependent not only on the mismatch angle of grains but also on the direction of the thermal flux. Thermal transfer efficiency from graphene to h-BN is higher than that from h-BN to graphene. Detailed analyses for the phonon density of states (PDOS) of GB atoms were carried out for the mismatch angle-dependence of interfacial conductance. Our results provide useful insights for the application of two-dimensional polyhexystalline heterostructures in next-generation electronic nanodevices.

Growth of MoS\textsubscript{2} Nanotubes by Chemical Vapor Deposition Using FeO Nanoparticles as Catalysts

Takashi Yanase, Mengting Weng, Fumiya Uehara, Taro Nagahama and Toshihiro Shimada; Engineering, Hokkaido University, Sapporo, Japan.

Introduction: MoS\textsubscript{2} nanotube (MoS\textsubscript{2}NT) that composed of semiconducting layered material has potential applications to the sensors, transistors, catalysts, etc. due to the unique 1D geometry and the edge state. Several methods have been used to synthesize MoS\textsubscript{2}NT such as physical vapor transport, thermal decomposition of the precursor and hydrothermal synthesis. However, there were some disadvantages in these methods, for example, long time reaction and necessity of toxic gas (H\textsubscript{2}S). Therefore, it is important to establish the economical and environmentally friendly way for the synthesis. We found that MoS\textsubscript{2}NT can be synthesized by chemical vapor deposition (CVD) using SiO\textsubscript{2}/Si substrate dispersed with FeO nanoparticles\textsuperscript{(1\textendash{}3)}. It can be considered that FeO nanoparticles work as catalysts as seen in the growth of carbon NT. The characterization and the growth mechanism of the MoS\textsubscript{2}NT are focused in this study.

Method: MoS\textsubscript{2}NTs were synthesized using a home-built CVD apparatus\textsuperscript{(3)} with two-flow system. Several kinds of metal or metal oxide nanoparticles (Fe, FeO, Fe\textsubscript{2}O\textsubscript{3}, CuO, Cu\textsubscript{2}O, NiO) were used to investigate their catalytic activity. SiO\textsubscript{2}/Si wafers dispersed with the nanoparticles were used as substrates. The temperatures and flow rates of the source materials (MoO\textsubscript{3} and sulfur) were separately optimized for the growth of the MoS\textsubscript{2}NTs. The MoS\textsubscript{2}NTs were characterized by transmission electron microscopy, energy dispersive spectrometry and Raman spectroscopy.

Results and Discussion: Among the prepared nanoparticles, only FeO is active for the synthesis of MoS\textsubscript{2}NT. Nothing or leaf-shape MoS\textsubscript{2} formed when the other nanoparticles were used. This is probably because FeO nanoparticles are reactive due to the O vacancy (non-stoichiometry) and Fe-Mo-S system forms layered material. We also found that the shape of the FeO nanoparticles affect the yield of the MoS\textsubscript{2}NTs. The spherical and truncated octahedral FeO nanoparticles can be synthesized by optimizing the synthetic conditions\textsuperscript{(4)}. It was found that the truncated octahedral FeO nanoparticles have greater catalytic activity than the spherical one. This is probably because the MoO\textsubscript{3} and sulfur vapor easily deposit on the sharp edges. Furthermore, the size of MoS\textsubscript{2}NTs also affects the growth of MoS\textsubscript{2}NT. SEM images clearly revealed that the 30-nm truncated octahedral FeO nanoparticles show the highest catalytic activity among the prepared FeO. The NTs on the SiO\textsubscript{2}/Si substrate were identified as MoS\textsubscript{2} by Raman spectroscopy because the two distinctive peaks, A\textsubscript{1g} and E\textsubscript{2g}, were detected. EDS spectra that showed the existence of Mo and S is another evidence for the formation of MoS\textsubscript{2}. The growth mechanism was concluded as VS mechanism by TEM observation because there was no FeO nanoparticles on the tip of the MoS\textsubscript{2}NT. The TEM observation also clarified that the MoS\textsubscript{2}NT has multilayer structure. The chirality of MoS\textsubscript{2}NT was armchair that was determined by electron diffraction pattern.

Hydrophilic Tannic Acid-Modified WS\textsubscript{2} Nanosheets for Enhanced Polysulfide Conversion in Aqueous Media

Yuheng Tian; University of New South Wales, Kensington, New South Wales, Australia.

Polysulfide-based organic battery systems have demonstrated great potential for large scale energy storage, but are restricted by the cost and the flammability of the organic solvents. It would be ideal to establish the aqueous-based polysulfide electrochemistry to enable cost-effective stationary energy storage. However, the sluggish reaction kinetics of polysulfide placed serious fundamental barrier to implementation. Here we developed hydrophilic tannic acid-modified WS\textsubscript{2} nanosheets as polysulfide conversion electrocatalysts in alkaline aqueous solutions. The tannic acid not only acted as a negatively charged surfactant to effectively delaminate the bulk WS\textsubscript{2} sheets, but also functionalized the delaminated WS\textsubscript{2} nanosheets through the coordination of tannic acid functional groups with tungsten atoms resulting in greatly improved hydrophilicity. Using graphene as the conductive support, the tannic acid-modified hydrophilic WS\textsubscript{2} nanosheets demonstrated a promoting electrocatalytic activity for polysulfide oxidation and reduction in aqueous solution. The incorporation of tannic acid imposed the collective interactions between polysulfide and the hydrophilic WS\textsubscript{2} nanosheets via the negatively charged molecules and the polar surfaces. With a 0.5 M Li\textsubscript{2}S\textsubscript{2} electrolyte, the graphene and modified WS\textsubscript{2} mixture gave an areal specific capacity of 0.37 mA h/cm\textsuperscript{2}, compared to 0.27 mA h/cm\textsuperscript{2} for the pure graphene.

2D Titanium Carbide (MXene)/Silver Nanoparticle Hybrid Material for Highly Sensitive and Selective Surface-Enhanced Raman Scattering

Abubakar Mohammed, Tej Limbu, Martha Garcia, Fei Yan, Bassant Chitara, Jacob Boggs, Lauren Odom and Yongan Tang; North Carolina Central University, Durham, North Carolina, United States.

Transition metal carbides (MXenes) have emerged as a promising family of 2D layered materials, and are considered as potential candidates for a myriad of applications including plasmonic sensing due to their outstanding electronic, optical, mechanical, and thermal properties. Herein, we report a flexible and reusable substrate made from a hybrid material consisting of 2D titanium carbide MXene (Ti2C) and silver nanoparticles, fabricated by spray coating for highly sensitive surface-enhanced Raman scattering (SERS). The 2D Ti2C layers were delaminated from their bulk Ti2C\textsubscript{10} MAX phase by using a mixture of hydrochloric acid and potassium fluoride as the etchant solution and silver nanoparticles were synthesized by thermal reduction of silver trifluoroacetate in soxymethyl ether in the presence of oleic acid. The as-prepared hybrid materials were characterized by UV-visible spectroscopy, Raman spectroscopy, X-ray photoelectron spectroscopy, atomic force microscopy, scanning electron microscopy, and X-ray diffractometry. The plasmonic properties of 2D Ti2C/silver nanoparticles hybrid material was evaluated with several organic dyes, which showed significantly different enhancement factors for different dyes.
In this talk, I present recent theoretical discoveries of several fascinating manifestations of topological effects in the electronic and optical properties of atomically thin one-dimensional (1D) and two-dimensional (2D) materials. First, we find that symmetry-protected topological phases exist in graphene nanoribbons (GNRs) [1]. Semiconducting GNRs of different width, edge shape, and terminating unit cells can belong to different electronic topological classes, characterized by a $Z_2$ invariant. Junctions between segments of topologically distinct GNRs are predicted to support robust in-gap topological junction states which can be used for band engineering. Experimental realizations of these predictions have been achieved [2]. Second, we show that the conventional optical selection rules for excitons must be replaced in 2D by a novel simpler formula, owing to a topological characteristic inherent to the photocexcitation of excitons in 2D [3]. The new selection rule is dictated by a winding number of the interband optical transition matrix elements (a heretofore unrecognized topological invariant). This appealingly simple and general new rule is applied to elucidate the optical spectra of gapped graphene systems [4]. Finally, if time permits, I will discuss some very recent work on the effects of electron-hole interactions on shift currents in non-centrosymmetric 2D crystals (the so-called bulk photovoltaic effect), in which we show excitonic effects lead to an enormous enhancement and, more interestingly, gives rise to DC conduction with sub-bandgap-frequency excitations [5].

This work was supported by the U. S. Department of Energy, National Science Foundation, and Office of Naval Research. I would like to acknowledge collaborations with members of the Louie group.

9:00 AM QN01.10.02 Application of High-Throughput DFT Methods to Low-Dimensional, Topological and Energy-Related Materials Kamal Choudhary and Francesca Tavazza; MML, National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

JARVIS (Joint Automated Repository for Various Integrated Simulations) is a NIST-developed, unique integrated framework to accelerate material design using classical force-fields (FF), density functional theory (DFT) and machine learning (ML). The JARVIS-DFT hosts data for more than 30000 bulk and 800 monolayer materials. We identified more than 1500 2D materials using lattice parameter criteria and carried out exfoliation energy calculations. We charted improved lattice parameters and formation energies using van der Waals functional for all the 30000 materials in the database and also calculated elastic tensors for more than 12000 bulk and 250 monolayer materials. Using the above data, we established relations between exfoliation energies and elastic constants. To alleviate bandgap underestimation in conventional DFT and to improve frequency dependent dielectric function predictions, we re-evaluated band gaps and dielectric functions using meta-GGA based approaches for more than 10000 materials. We used a spectroscopic limited maximum efficiency approach to identify potential photovoltaic materials. Using spin-orbit spillage criteria, we identified more than 1500 potential topological materials including topological insulators, Weyl and Dirac semimetals, and topological crystalline insulators. The database is publicly available at https://jars.nist.gov/.

9:15 AM QN01.10.03 Quantum Nonlinear Ferroic Optical Hall Effect Hua Wang and Xiaofeng Qian; Department of Materials Science and Engineering, Texas A&M University, College Station, Texas, United States.

Nonlinear optical responses provide basis for ultrafast probing of material's intrinsic symmetry. Here we present first-principles theory of quantum nonlinear ferroic optical Hall effect (QNFHE), a Hall like photocurrent originated from the second order current response in (multi-)ferroics. The interplay of crystalline, permutation, gauge, time reversal symmetries and inherent causality governs the symmetry of QNFHE. We elucidate QNFHE in a class of 2D multiferroics using first-principles calculations and group theoretical analysis. Our results suggest QNFHE-based optical technique as a route for ultrafast characterization of multiferroic order and domain evolution in multiferroic materials. These microscopic understandings of QNFHE from first-principles theory, together with very recent discoveries of 2D ferroics/multiferroics, will open up a variety of new avenues for nonlinear optoelectronics. This research was supported by the National Science Foundation under award number NSF DMR-1753054. References: [1] H Wang and X Qian, Nano Letters 17, 5027-5034 (2017). 9:30 AM QN01.10.04 Optoelectronic Properties of Topological Transition Metal Chalcogenides Ji Feng; Peking University, Beijing, China.

Transition metal chalcogenides have traditionally attracted broad research attention owing to their unique layered structure and the coexistent charge-density wave, superconductivity and correlation effects, among other things. The reason for the recent surge of interest in this family of materials is two-fold: they are precursors to fascinating 2-dimensional materials, and some members are topological. In this talk, we will report our computational and theoretical progresses in the studies of topological insulating and metallic transition metal chalcogenides. In particular, we will discuss the interaction-induced quantum spin Hall gap in 17 $\text{WTe}_2$, where it is found that a positive band gap is present in the hybrid density functional approach. The nonlinear optical properties in type II Weyl semimetal TaI$_2$Te, will also be reported, where usually large photocurrents owing to the presence of Weyl nodes are detected by our collaborators. I will discuss how symmetry determines the nonlinear optical response in this material, in conjunction analysis with quantitative computation of effective third-order response functions.

10:00 AM BREAK

10:30 AM QN01.10.05 Topological Magneto-Optical Effect and Its Quantization in Noncoplanar Antiferromagnets Yugui Yao; School of Physics, Beijing Institute of Technology, Beijing, China.

Magneto-optical (MO) effects, referring to changes in the polarization state of light upon interacting with magnetic matter, are one of the most basic phenomena in solid-state physics. MO effects have been known for more than a century, whose origin is usually ascribed to the simultaneous presence of band exchange splitting and spin-orbit coupling. However, using a tight-binding model and first-principles calculations, we show that topological MO effects, in analogy to the topological Hall effect, can arise in noncoplanar antiferromagnets entirely due to the scalar spin chirality instead of spin-orbit coupling. Here, the band exchange splitting and spin-orbit coupling are not required for topological MO effects. Moreover, we discover that the Kerr and Faraday rotation angles in two-dimensional insulating noncoplanar antiferromagnets can be quantized in the low-frequency limit, implying the appearance of quantum topological MO effects, accessible by time-domain THz spectroscopy [1]. Also, I will show our group’s recent research results on MO effects in novel two-dimensional materials if time permits [2-5].

Prediction of 2D Topological Insulators from First-Principles Calculation Honming Weng; Institute of Physics, Chinese Academy of Sciences, Beijing, China.

Two-dimensional (2D) topological insulators (TIs) have been recognized as a new class of quantum state of matter. They are distinguished from normal 2D insulators with their nontrivial band-structure topology identified by the Z2 number as protected by time-reversal symmetry (TRS). 2D TIs have intriguing spin-velocity locked conducting edge states and insulating properties in the bulk. In the edge states, the electrons with opposite spins propagate in opposite directions and the backscattering is fully prohibited when the TRS is conserved. This leads to a quantized dissipationless “two-lane highway” for charge and spin transportation and promises potential applications. Up to now, only very few 2D systems have been discovered to possess this property. The lack of suitable material obstructs further study and application. In this talk, I will introduce by using first-principles calculations we have proposed that the layer compounds ZrTe5 and HfTe5, the transition metal dichalcogenide (TMD) haekelites with square-octagonal lattice, the functionalized MXenes with oxygen M2CO2 (M=W, Mo, and Cr), are 2D TIs with quite large band gap. Importantly, ZrTe5 and HfTe5 are very easily to be synthesized by exfoliating. This will pave the way to tremendous applications of 2D TIs, such as “ideal” conducting wire and the realization of topological superconductivity and Majorana modes for quantum computing.

First-Principles Prediction of Stable Transition Metal Dichalcogenide Alloys

John Cavin 1, Sung B. Cho 2 and Rohan Mishra 2; 1Department of Physics, Washington University in St. Louis, St. Louis, Missouri, United States; 2Virtual Engineering Center, Korea Institute of Ceramic Engineering and Technology (KICET), Ichon, Korea (the Republic of); 1Department of Mechanical Engineering and Material Science, Washington University in St. Louis, St. Louis, Washington, United States.

Quasibinary alloying among pairs of 2-dimensional (2D) transition metal dichalcogenides (TMDs) is an attractive method for tuning properties for applications such as optoelectronics and catalysis. Of the many possible combinations of TMDs, the small subset of semiconductor alloys has garnered widespread attention. Outside this limited subset, the synthesizability of alloys remains largely unknown. In order to guide the synthesis of such alloys, we present ab initio calculations of equilibrium phase diagrams with regions of stability for 27 TMD alloys: M(1-x)M'X2 and MX(2-2x)X'(2x) (M,M'= V, Nb, Ta, Mo, or W; X,X'= S or Se) and two heterostructural alloys, Mo(1-x)WTe2 and WS2(2-2x)Te(2x). We predict four new alloys that are miscible at all temperatures: Nb(1-x)TaS2, Nb(1-x)TaSe2, VS2(2-2x)Se2x, and TaS2(1-x)Se2x. For the rest of the alloys, we present a qualitative analysis of synthesizability based on miscibility temperatures. We relate TMD size mismatch with a mixing asymmetry that indicates the synthesizability of low concentration alloys. Our results open new compositional spaces that can be used to design and synthesize TMD alloys for various applications. Acknowledgments: This work was funded by NSF DMREF-1729787.

Intrinsic Magnetic Topological Insulators in van der Waals Layer MnBi2T34-Family Materials

Yong Xu 1, 2; 1Department of Physics, Tsinghua University, Beijing, China; 2RIKEN Center for Emergent Matter Science (CEMS), Saitama, Japan.

The interplay of magnetism and topology is a key research subject in condensed matter physics and material science, which offers great opportunities to explore emerging new physics, like the quantum anomalous Hall (QAH) effect, axion electrodynamics and Majorana fermions. However, these exotic physical effects have rarely been realized in experiment, due to the lacking of suitable working materials. In this talk, we will review recent research progresses of magnetic and topological materials. In particular, we will present our recent works of finding intrinsic magnetic topological insulators in van der Waals layered MnBi2Te4-family materials [1,2]. The materials intrinsically show two-dimensional (2D) ferromagnetism in the single layer and three-dimensional (3D) A-type antiferromagnetism in the bulk, which could serve as a next-generation magnetization platform for the state-of-art research. Remarkably, we predict extremely rich topological quantum effects with outstanding features in an experimentally available material MnBi2Te4, including a 3D antiferromagnetic topological insulator with the long-sought axion states, the type-II magnetic Weyl semimetal (WSM) with simply one pair of Weyl points, and the high-temperature intrinsic QAH effect. These striking predictions, if proved experimentally, could profoundly transform future research and technology of topological quantum physics.

Defects and Phase Transformations in 2D Materials

In Li; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

2D materials have unique structural mechanics [Nano Letters 15 (2015) 1302] that makes their defects and phase transformations dramatically different from those of 3D materials. I will focus on light-structure and electron-structure interactions in this talk, with a range of behaviors such as ferroelasticity [Nature Comm 7 (2016) 10843], ferroelectricity and electronic topology change [Science 346 (2014) 1344] in one to few-layer transition metal dichalcogenides. Design of ultrafast responsive 2D materials is emphasized.

Phase Polymorphism and Electronic Structures of TeSe2 and Its Ferroelectricity

Takuhisa Terfs Debe 1 and Hong Seok Kang 2; 1Institute for Application of Advanced Materials, Jeonju University, Jeonju, Korea (the Republic of); 2Department of Nano and Advanced Materials, College of Engineering, Jeonju, Korea (the Republic of).

Structure prediction complemented by density functional theory (DFT) calculation indicates that TeSe2 is the most stable among the various Te2-xSe x compounds. Different from the case of bulk Te, the material can equally adopt three different crystal structures: H2, M6, and M8 phases, which are similar to 1T-TiSe2, trigonal Te, and orthorhombic Te, respectively. These phases can be transformed from one to another by uniaxial tensile and shear stresses; they can be even transformed to their chiral mirror images. Band structure calculations including spin-orbit coupling (SOC) show that all three phases are semiconductors. The band gap (= 0.43 eV) increases with density, being the largest (= 1.86 eV) in the M8 phase with the highest density. The H2 phase exhibits hidden spin texture because of centrosymmetry. The other two phases display chiral spin texture due to the lack of the symmetry, in that two spin components of frontier bands can split by more than 100 meV in opposite directions. In addition, the layered TeSe2 possess ferroelectricity. It can be used for optoelectronic applications.

Supported Two-Dimensional Materials Under Ion Irradiation—The Substrate Governs Defect Production

Silvan Kretscmer 1, Michael Maslov 1, Sadegh Ghaderzadeh 1, Mahdi Ghorbani-Asl 1, Gregor Hlawacek 1 and Arkady Krasheninnikov 1, 2; 1Helmholtz-Zentrum Dresden, Dresden, Germany; 2Department of Applied Physics, Aalto University, Helsinki, Finland.

Ionen and electron irradiation suits particularly well for engineering the properties of nanostructures, see Refs. [1-2] for an overview. In particular, focused ion beams can be used for patterning two-dimensional (2D) materials, but the optimization of irradiation parameters requires full microscopic understanding of defect production mechanisms. In contrast to freestanding 2D systems, the details of damage creation in supported 2D materials are not fully understood, whereas the majority of experiments have been carried out for 2D targets deposited on substrates. Here, we suggest a universal and computationally efficient scheme to model the irradiation of supported 2D materials, which combines analytical potential molecular dynamics with Monte Carlo simulations and makes it possible to independently assess the contributions to the damage from backscattered ions and atoms sputtered from the substrate. Using the scheme, we study [3] the defect production in graphene and MoS2 sheets, which are two of the most important and widespread 2D materials, deposited on a SiO2 substrate. For helium and neon ions with a wide range of initial ion energies including those used in a commercial helium ion microscope (HIM), we demonstrate that depending on the ion energy and mass, the defect production in 2D systems can be dominated by backscattered ions and sputtered substrate atoms rather than the direct ion impacts and that the amount of damage in 2D materials heavily depends on whether a substrate is present or not. We also study the factors which limit the spatial resolution of the patterning process. Our results agree well with the available experimental data, provide not only insights into defect production but also quantitative information, which can be used for the minimization of damage during imaging in HIM or optimization of the patterning process.

Hexagonal boron nitride (h-BN) also known as “white graphene” is a prominent member of the 2D materials family, which has gained a significant attention for its remarkable properties in the last decade. Its superior thermal conductivity (1700-2000 W mK⁻¹), high mechanical strength (15.7 Nm⁻¹), large band gap energy (6 eV), atomically smooth surface, ultra-high flexibility, and transparency make h-BN a suitable candidate for numerous applications such as flexible and transparent electronics.

Characterization of h-BN samples has been done by XPS, UV-Vis spectroscopy, Optical microscopy RAMAN, ToF-SIMS, and SEM. XPS data confirms that the binding energy of boron and nitrogen is around 190 eV and 398 eV, respectively, which are very close to the values reported in the literature. As grown h-BN on the top surface of the foil (directly exposed to precursor flow) and on the bottom surface (confined with the quartz support) shows variable nitrogen to boron ratio. We calculated N:B ratio ranging from 0.7 to 1.11 in our samples, which clearly signifies nitrogen-rich or boron-rich h-BN regions. UV-Vis spectroscopy confirms a very sharp absorption peak near 202 nm corresponding to a bandgap of 6.13 eV.

The evolution of these morphologies is attributed to the alteration of N:B ratio evolved by the mass of the AB, which has a significant impact on the decomposition process. N:B ratio can be tuned by the decomposition monitoring of ammonia borane in order to get better control over the shape of synthesized h-BN domains. Furthermore, optimal AB decomposition conditions will be investigated by the AB mass, AB heating profile, background pressure and concentration of carrier gases to get direct access to N:B ratio.

In summary, the shape of the h-BN domains can be used as a direct indicator of nitrogen-rich or boron-rich growth. Certainly, variation in the shape of domains will influence the intrinsic and functional properties of grown h-BN layers. These results envisage that depending on the shape of individual h-BN domains, CVD synthesis will lead to either nitrogen-rich or boron-rich in-plane regions of the 2D h-BN.

that induces a strong electrical polarization perpendicular to the atomic planes. As a result of the polarization, electrons and holes are spatially separated and their energies strongly reduced by the polarization field. Thus, electrical polarization plays an essential role in controlling the exciton binding energy and radiative lifetime, and can be exploited in multilayered structures to tune the luminescence to the visible from the deep to UV. Binary Compound Bilayer with Vertical Polarizations—Two-Dimensional Ferroelectrics, Multiferroics and Nanogenerators  Menhao Wu; Huazhong University of Science and Technology, Wuhan, China.

Vertical ferroelectricity in two-dimensional (2D) materials is desirable for high-density data storage. Herein we report the first-principles evidence of 2D vertical ferroelectricity induced by interlayer translation, which exists extensively in graphitic bilayer of BN, AIN, ZnO, MoSe2, GaSe, etc.; the bilayer of some 2D ferromagnets like MXene, VS1 and MoN2 can be even multiferroics with switchable magnetizations upon ferroelectric switching, rendering efficient reading and writing for high-density data storage. Especially, the electromechanical coupling between interlayer translation and potential can be used to drive the flow of electrons as nanogenerators for harvesting energy from human activities, ocean waves, mechanical vibration, etc.. Ferroelectric superlattice with spatial varying potential can be formed in bilayer Moire pattern upon a small twist or strain, making it possible to generate periodic n/p doped domains and shape the periodicity of the potential energy landscape. Finally, some of their multilayer counterparts with wurtzite structures like ZnO multilayer are revealed to exhibit another type of vertical ferroelectricity with greatly enhanced polarizations.

Giant Spin Hall Effect in Two-Dimensional Monochalcogenides Jagoda Sławinska1; Franklin T. Cerasoli1; Haihang Wang2; Sara Postorino2; Andrew Supka2; Stefano Curtarolo3; Marco Fornari4; and Marco Buongiorno Nardelli4; 1Department of Physics, University of North Texas, Denton, Texas, United States; 2Department of Physics, Science of Advanced Materials Program, Central Michigan University, Mount Pleasant, Michigan, United States; 3Center for Materials Genomics, Duke University, Durham, North Carolina, United States.

One of the most exciting properties of two dimensional materials is their sensitivity to external tuning of the electronic properties, for example via electric field or strain. Recently discovered analogues of phosphorene, group-IV monochalcogenides (MX with M = Ge, Sn and X = S, Se, Te), display several interesting phenomena related to the in-plane strain, such as giant piezoelectricity and multiferroicity, which combines ferroelastic and ferroelectric properties. Here, using calculations from first principles, we predict for the first time giant spin Hall effect (SHE) in these materials which suggests their high potential for 2D spintronics. We reveal that the spin Hall conductivity is tunable via combinations of external strain and doping. In some configurations, the strain-induced semiconductor to metal transition enables the logic functionality of switching on/off spin currents which indicates a new route for the design of multi-tunable spintronics devices.

Theoretical Investigations on Structural Stability of Two-Dimensional Ultrathin Films in Group III-V Materials Toru Akiyama, Yuya Hasegawa, Kiyoshi Koyama, Kohji Nakamura and Tomonori Ito; Department of Physics, Engineering, Mie University, Tsu-shi, Japan.

There has been increasing research interest in two-dimensional (2D) materials with honeycomb structure due to their potential applications in electronic devices. Among various 2D materials, group III-V materials such as BN with hexagonal (Hex) structure have been paid much attention. However, this is available mainly in the form of small flakes, and successful fabrication of BN thin films with large area is limited. Recently, Tsipas et al. have successfully fabricated graphene-like ADN by molecular beam epitaxy (MBE) on Ag(111) substrate. [1] They have also reported that ultrathin (sub-monolayer to 12 monolayers) AIN adopts Hex structure with larger lattice constant compared to bulk AIN with three-dimensional wurtzite (WZ) structure. Two-dimensional GaN can also be formed by migration-enhanced encapsulated growth technique using epitaxial graphene. [2] In spite of the experimental findings, there is a still open question how many layers the Hex structure is stabilized for group III-V materials. From theoretical viewpoints, we have previously investigated the stability of group-III nitrides with Hex structure by mean of density functional theory (DFT) calculations, and revealed that five-fold coordinated Hex structure is more stable than WZ structure for the films up to 15 bilayers due to interlayer electrostatic interactions. [3] In this study, we extend our approach to various group III-V materials including binary and ternary alloys. Our DFT calculations for various III-V materials (BP, AlP, GaP, InP, GaAs, AlAs, and etc.) demonstrate that they forms five-fold coordinated Hex structure and its stability depends on their ionicity: The number of layers up to which Hex structure has a lower cohesive energy than WZ structure, Lb, becomes large for III-V materials with larger ionicity. [4] Furthermore, the calculations using empirical bond-order potentials with the aid of DFT calculations [5] for B,Al,N and B, Ga, N alloys reveal that the Hex structure can be stabilized depending on the number of film thickness. The calculated Lb is also found to be dependent on boron composition of x, and the miscibility of these alloys with Hex structure is lower than those with WZ structure due to the contribution of relaxation of atoms depending on the crystal structure. These calculated results thus suggest that various 2D ultrathin films can be formed in group III-V materials. Effects of substrates such as Ag(111) and graphene on the stability of 2D ultrathin films are also examined.

Understanding Axis-Dependent Conduction Polarity in Goniopolar Layered Metals from Ab Initio Informed Tight Binding Theory Yaxian Wang, Joseph P. Heremans, Joshua Goldberger and Wolfgang Windl; The Ohio State University, Ohio, United States.

We have recently shown that NaSn2As2 exhibits opposite conduction polarities along in-plane and cross-plane directions, defined as “goniopolarity”. On the lowest level of theory, we can show that this novel phenomenon originates from a special topology of the Fermi surface, which is essentially determined by the nature of the bonding states in this layered crystal. In this paper, we present an improved fundamental understanding of goniopolarity based on a novel formulation of goniopolarity within the tight-binding model. The tight-binding matrix elements are calculated from GW calculations based on Density Functional Theory (DFT) by maximally localized Wannier functions. Considering a minimum-basis set with sp2 orbitals for both Sn and As, the 64 hopping integrals are evaluated. Within our model, we provide a new tight-binding based formulation for both Seebeck and Hall coefficients for NaSn2As2 and can show that critical ratios of hopping and on-site matrix elements exist that pose limits for goniopolarity to appear in materials. Based on that, additional candidate materials for goniopolarity can be proposed, and the design space for goniopolar materials in general will be defined.

10:00 AM BREAK
exhibit unusual polarization properties. Their in-plane piezoelectric coefficients are about two orders of magnitude larger than those of monolayer transition metal dichalcogenides and conventional bulk piezoelectric materials. Moreover, these monolayer group IV monochalcogenides are essentially spontaneously polarized and exhibit a robust in-plane ferroelectric effect above room temperature. Many of these predictions have been confirmed by recent experiments, and they also provide guidance for future applications.

11:00 AM QN01.14.07
Understanding Electrons in Flat Land for Electronic and Energy Applications
Yuanyue Liu; The University of Texas at Austin, Austin, Texas, United States.

Two-dimensional (2D) materials have great potential for many applications such as electrocatalysis and electronics. However, their developments are impeded by a number of significant challenges, many of which root in the ‘problems of electrons’. On the physics side, the electrons/holes in current 2D semiconductors do not move fast enough under electric field (i.e. low mobility), impeding their use in high-performance electronics and optoelectronics. On the chemistry side, the current 2D electrocatalysts still suffer from relatively low activity/selectivity, hindering their use in efficient energy conversion. These challenges urge for an improved understanding of the electrons in 2D materials, and using these insights to design/discover 2D host materials with better performance.

Here I will discuss our recent progress in understanding the chemistry and physics of electrons in 2D materials for electronic and energy applications. Specifically, I will show (1) what limits the intrinsic carrier mobility of two dimensional metal dichalcogenides, and how to find high-mobility 2D semiconductors [1]; (2) the significant impact of charge on electrochemical reactions of 2D materials, which is often neglected in modeling their electrochemistry, and the implications for energy applications [2].

Exceptional Points in Energy Spectrum of Magnetic Materials
Alexey Gaidal’, 1 and Valerii Vinokur’; 1 James Franck Institute, University of Chicago, Chicago, Illinois, United States; 2 Materials Science Division, Argonne National Laboratory, Lemont, Illinois, United States.

We investigate topological structure of complex energy surfaces of non-equilibrium magnetic systems. We consider one- and two-dimensional spin-transfer torque-driven models described by non-Hermitian Hamiltonians. The spectrum of the Hamiltonian admits branch point singularities that appear as chiral exceptional points where both eigenvalues and eigenstates coalesce. Encircling individual exceptional points in parameter space has non-trivial physical consequences resulting in non-reciprocal spin wave transfer through the system. This effect can be used in a spintronic spin filter device.

MXene-Based Electrode with Tunable Catalytic Activity for Oxygen Reduction/Evolution Reaction in Lithium-Air Batteries
Ali Reza Ostadhosseini, Jack Guo, Filip Simeski and Matthias Ille; Stanford University, Stanford, California, United States.

Ubiquitous applications of rechargeable batteries, particularly in portable electronics and electric vehicles, have stimulated a vigorous search for high-capacity electrode materials. In particular, Lithium-Oxygen batteries have attracted substantial attention due to their superior energy-density; yet several technical challenges must be overcome in order to enable their successful commercialization. It is well-known that the precipitation of the reaction products from the oxygen reduction reactions (ORR) during the discharge process increases the overpotential and in turn leads to reduced cyclability. MXenes are a new class of two-dimensional inorganic compounds. The versatile chemistry and the high electrical conductivity of these materials make them a prevalent candidate for catalysis. In this study, free-standing 2D titanium nitride MXene is proposed as an efficient cathode-catalyst for non-aqueous Li-O2 batteries. By performing comprehensive first-principles simulations employing density-functional theory and reactive molecular dynamics, we discovered the enhanced catalytic activity for ORR and oxygen evolution reactions (OER) through surface functionalization of MXene monolayers. Atomic-scale analysis was performed to identify the role of surface functionalization for controlling nucleation of Li2O2 and electrochemical reaction steps of ORR/OER on MXene surfaces. The free-energy pathways for adsorption of the intermediate and final products of ORR are determined, demonstrating that synergistic effects of vacancies and functionalized groups accelerate ORR by up to a two orders of magnitude compared to commonly used graphene-based cathode electrodes. These results contribute towards the design of functionalized MXene for modulating catalytic properties of ORR/OER in cathodes of Li-air batteries.

11:45 AM QN01.14.10
Bond Saturation Significantly Enhances Thermal Energy Transport in Two-Dimensional Pentagonal Materials
Zeyu Liu, Xufei Wu and Tengfei Luo; University of Notre Dame, Notre Dame, Indiana, United States.

Thermal transport in nanoscale two-dimensional (2D) materials is of great scientific interest and has practical implications for energy related applications like thermal management of energy devices, composite battery materials and on-board thermoelectric power generation for sensors. The abilities to manipulate thermal transport in 2D materials is thus highly desirable for future nano energy technologies. In this work, we identify a general rule for controlling the thermal transport in 2D pentagonal materials through bond saturation. We use first-principles calculations to investigate the phonon properties of a series of pentagonal materials, including penta-graphene (PG), hydrogenated PG (h-PG) and fluorinated PG (FPG), and find that the bond saturation of the carbon atom can modulate the bond anharmonicity and thus increase the phonon lifetime. We can follow this rule to predict very high thermal conductivity of other pentagonal structures with saturated bonds, including penta-CN2 (1027 W/mK) and two three-dimensional counterparts of PG called Tl2-carbon (819 W/mK) and AA Tl2-carbon (1049 W/mK). Moreover, similar trend of bond saturation-induced thermal conductivity enhancement can be found in other 2D pentagonal materials, such as penta-SiC2 and penta-SiN2. The results from this work unveil a general bonding-thermal transport relation for 2D materials, which can provide important guidance for designing novel materials with desirable thermal transport properties for energy applications.
Physical behaviors of 2D materials are ultimately governed by complex interactions of electrons and ions, ranging from ultrafast process at atomic scale to slow dynamics at mesoscale. Here we present our recent development of first-principles theory based on simple linear chain (LCM) and interlayer bond polarizability models. Here, we show unusual effects of strong interlayer coupling on low-frequency Raman scattering in PdSe$_2$ crystals with different number of layers. We found that the measured frequencies of the breathing modes cannot be described by a conventional LCM that treats each layer as a single rigid object. We show that strong deviations from layer rigidity can occur for the LF breathing vibrations of PdSe$_2$, which accounts for the observed disagreement with the conventional LCM. The layer non-rigidity and strong interlayer coupling could also explain the unusual strong intensities of the LF breathing modes that are comparable with those of the high-frequency Raman modes. These strong intensities allowed us to use a set of the measured LF Raman lines as unique fingerprints for a precise assignment of the layer numbers from 2 to 19. The assignment of the layer numbers was further confirmed using second harmonic generation that appeared only in the non-centrosymmetric even-layer PdSe$_2$ crystals. This work demonstrates a simple and fast approach for the determination of the number of layers in 2D materials with strong interlayer coupling and non-rigid interlayer vibrations.

2:30 PM BREAK
Molybdenum disulfide (MoS$_2$) is a promising two-dimensional (2D) semiconductor. Similar to graphite, MoS$_2$ has a layered structure comprising weak van der Waals bonding between layers, and strong covalent bonding within layers. The weak secondary bonding allows for isolation of these 2D materials to a single layer, like graphene. While bulk MoS$_2$ is an indirect band gap semiconductor with a band gap of ~1.3 eV, monolayer MoS$_2$ exhibits a direct band gap of ~1.8 eV, making it an attractive candidate for replacing Si in electronic devices. Atomic layer deposition (ALD) has been used previously to grow MoS$_2$ films using molybdenum chloride and carboxyl precursors. However, these precursors are solids at room temperature and require high temperature vapor transport. Recently, MoS$_2$ ALD using molybdenum hexafluoroide (MoF$_6$), a high vapor pressure liquid at room temperature, and hydrogen sulfide (H$_2$S) has been demonstrated. While the nucleation of MoS$_2$ during chemical vapor deposition (CVD) is understood, the nucleation of MoS$_2$ ALD using MoF$_6$ and H$_2$S on dielectric surfaces has yet to be explored. Unlike films grown by high temperature CVD, ALD MoS$_2$ is amorphous as deposited and must be annealed to crystallize the film. In this study, we utilized in situ quartz crystal microbalance and Fourier transform infrared spectroscopy measurements to investigate the first few cycles of MoS$_2$ ALD on Al$_2$O$_3$, HfO$_2$, and MgO surfaces prepared in situ by ALD. The MoS$_2$ nucleation, and in particular the effect of the first MoF$_6$ exposure, was found to depend strongly on the underlying metal oxide, the OH surface concentration, and the growth temperature. Following these in situ studies, we prepared ultrathin ALD MoS$_2$ films and subsequently annealed them in H$_2$ to crystallize the films for device measurements. Our work will provide a solid understanding of the interactions of MoF$_6$ and H$_2$S with dielectric surfaces, which is critical for the implementation of ALD MoS$_2$ in microelectronics.

Transition metal dichalcogenide (TMD) thin films are promising candidate materials in the continuing development of nanoscale devices. These materials exhibit a direct band-gap when thinned down to a single layer and also provide properties that include an improved on-off ratio and photonic application which set them apart from bulk silicon. Methods to produce wafer-scale TMD films include powder chemical vapor deposition (CVD), liquid-phase and mechanical exfoliation, metal-organic CVD, and atomic layer deposition (ALD). These methods suffer from issues with particulate contamination, pyrophoric precursors, and costly precursors along with the lack of reproducibility and layer thickness controllability. Here we demonstrate the growth of homogeneous wafer-scale mono-, bi-, and tri-layer molybdenum disulfide (MoS$_2$) using solid inorganic and liquid organic precursors in a high-vacuum environment. These samples are grown on amorphous 30-300 nm SiO$_2$ substrates and fused silica windows and without any powder or metal-organic precursors. Growth proceeds by the decomposition of carbon disulfide at a heated molybdenum filament, which yields volatile MoS$_2$ precursors that aggregate on a heated wafer. We have developed a procedure to control our thin film growth using a standard video camera from the top of the chamber to monitor the hue (0-255) of the film from the reflection of the film onto the top of the SiO$_2$. This allows controlled integer number layer thickness of our films. The continuous and homogeneous single-layer film of MoS$_2$ is deposited at wafer-scale with a total growth time of approximately an hour. Optical and electrical characterization indicates performance comparable to or better than MoS$_2$ film grown by other wafer-scale growth techniques. Our method provides a scalable process to deposit thin TMD films in a high-vacuum environment using a colorimetric hue control.

X-ray Studies of Tungsten-Based Transition Metal Dichalcogenides Narayavachari V. Kondapalli, Anusheela Das and Michael J. Bedzyk; Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States.

The demand to exploit the unique properties of 2D materials requires the synthesis of large-scale high-quality 2D materials. While epitaxial growth of 2D materials on single-crystal substrates can generate large-scale production of 2D materials without compromising the quality, it is unclear whether the 2D materials can exist as structurally and electronically distinct layers anchored by van der Waals (vdW) forces, as opposed to more strongly bound adlayers. The strength of these interactions, from weak van der Waals to strong covalent bonds, is linked to the local atomic structure of the interface. The resulting 2D materials exhibit different properties depending on the strength of the interactions with the underlying substrate.

We used x-ray standing waves (XSW) generated by Bragg diffraction from a sapphire single crystal substrate to excite X-ray fluorescence (XRF) from a 2D epitaxial layer of WSe$_2$. These measurements, performed at rotating anode and synchrotron x-ray sources, were used to find the positions of Se and W atoms relative to the substrate lattice with subangstrom resolution.

These results combined with DFT calculations could give distinct insights into WSe$_2$ and other transition metal dichalcogenides integrated epitaxially on oxide substrates. Overall, the work herein reveals how distinct X-ray surface science techniques can be used to understand questions about 2D material structure and interfaces.

Metallo-Hydrogel-Assisted Synthesis and Direct Writing of Transition Metal Dichalcogenides Xining Zang1, J. Nathan Hohman2 and Liwei Lin3; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3University of California, Berkeley, Berkeley, California, United States.

Two-dimensional transition metal dichalcogenides (TMDs) have attracted interest for their compelling nanoscale new properties and numerous potential applications including fast optoelectronic devices, ultrathin photovoltaics, and high-performance catalysts. Large-scale growth of uniform TMD materials is essential for investigating their physics and for their integration into device. However, the wafer scale deposition of TMDs on arbitrary non-selective substrates is still beyond the current state-of-the-art. In this article, we report a method to synthesize layered TMDs (MoS$_2$ and WSe$_2$) at the wafer-scale by sulfurization of transition metal ions (Mo$^{6+}$ and W$^{6+}$) in a gelatin template (metallo-hydrogel). This process is adaptable to versatile substrates, including amorphous silicon oxide, high-temperature quartz, and silicon. Although the products are nominally few layer materials, we observe direct band photoluminescence (~1.8 eV), consistent with single- or decoupled multilayer MoS$_2$. This is attributed to the presence of surfactants included in the template.
that serve to isolate the TMDC layers electronically. Finally, the solution-based deposition enables contact printing of TMDC channels useable for device applications including thin film transistors with printed silver contacts using the same process.

**Epitaxial Growth of Antimonene-Graphene van der Waals Heterostructures**  
Matthieu Fortin-Deschenes and Oussama Moutanabbir; Polytechnique Montreal, Montreal, Quebec, Canada.

van der Waals (vdW) heterostructures display a tremendous potential as building blocks for novel nanoscale and quantum technologies. These stacks of various two-dimensional (2D) materials can exhibit a wide variety of tunable physical properties. Nonetheless, their integration in mainstream technologies is hindered by the lack of large-scale synthesis methods. In fact, most vdW heterostructures are produced by chemical transfer and yield micrometer scale heterostructures. Developing large-scale epitaxial growth processes for vdW heterostructures is therefore critical. Even though some vdW heterostructures have been produced by epitaxy, the control over their growth is remains limited and no global understanding of the vdW epitaxy mechanisms currently exist. In fact, their growth has never been observed in real-time. To address this problem, we present here an in situ low-energy electron microscopy (LEEM) study of the vdW epitaxy of antimonene-graphene vdW heterostructures on germanium substrates. Graphene was grown by Chemical Vapor Deposition (CVD) on Ge(100), Ge(110) and Ge(111). Then antimonene, a newly discovered two-dimensional material with several intriguing thickness dependent electronic and topological properties, is grown by solid-source molecular beam epitaxy (MBE) under direct LEEM observation. Nucleation of antimonene mainly occurs on small 3D nuclei which form on defects on the graphene surface. The antimonene then grows laterally to form few micrometers large flakes. The antimonene islands rarely coalesce due to competition for the precursor Sb$_4$ species. The growth morphology is strongly influenced by the Sb$_4$ deposition rate. In fact, high deposition rates (>10 nm/minute) lead to the growth of large flat islands with 3 branches, whereas lower deposition rates lead to triangular atoll-like islands with thick bands along the edges. The transition from 2D to atoll-like growth is explained based on the interplay between the growth rate, surface diffusion and edges orientation. The understanding of the vdW growth developed in this study will allow for a better control of the large-scale growth of vdW heterostructures with highly tunable physical properties.

### TUTORIAL: Defects and Magnetic Properties of Two Dimensional Materials

April 22 - April 22, 2019

Defects in crystalline solids are ubiquitous. It is the second law of thermodynamics that gives rise to the appearance of a certain amount of disorder in crystalline materials at finite temperatures. Moreover, defects can be present in synthetic materials well above the equilibrium concentration due to the imperfections in material production processes or due to the exposure of the system to irradiation with energetic particles. Such lattice imperfections have a strong influence on the electronic, magnetic, optical, thermal, and mechanical properties of the solids, normally deteriorating their characteristics. However, defects not always have detrimental effects on material properties, with the most prominent example being the doping of semiconductors by controllable introduction of impurities using ion implantation.

All of the above is relevant to two-dimensional (2D) materials, such as graphene and hexagonal boron nitride, or transition metal dichalcogenides (TMDs). It is intuitively clear that due to the reduced dimensionality the defects should have a much stronger influence on the properties of 2D materials, as compared to their bulk counterparts. Moreover, due to the morphology of 2D systems, it is much easier to introduce defects into them in a controllable manner and add new functionalities. Furthermore, the experimental realization of ferromagnetism at the monolayer level in 2D van der Waals materials beyond graphene has drawn a great deal of research interest in the recent past. In addition, these materials have exciting prospects for next generation low-power ultra-compact spintronic applications. This tutorial will review the recent developments in the rapidly growing field of defects and magnetic properties of a broad spectrum of 2D materials through a combination of theoretical and sensitive experimental approaches, and will immensely benefit scientists at all the levels.

### 1:30 PM

**Defects in 2D Materials – Theory**  
Arkady V. Krasheninnikov; Helmholtz-Zentrum Dresden-Rossendorf

In this tutorial, Krasheninnikov will present the "state of the art" in the physics of defects in two-dimensional (2D) inorganic materials with the main focus on the theoretical developments. The computational and analytical methods used in theoretical physics to get insights into defect behavior will be briefly summarized, and then the effects of impurities and point/line defects on various properties of 2D inorganic materials will be addressed. He will further discuss defect- and impurity-mediated engineering of the electronic structure of inorganic 2D materials. He will also present the results of the theoretical studies of electron-beam induced phase transformations in 2D transition metal dichalcogenides (TMDs) when electric charge, mechanical strain and vacancies are present.

### 2:30 PM BREAK

### 3:00 PM

**Defects in 2D Materials – Electron Paramagnetic Resonance Spectroscopy**  
Andre Stesmans; KU Leuven

In this tutorial, Stesmans will deal with some basic principles and methodology of the electron paramagnetic resonance (EPR) spectroscopy, outlining it as a reliable 'magnetic' technique based on non-destructively sensing of unpaired electrons, which is successfully applied in a broad range of scientific fields. Next, the attention will be directed to its application in tracing the nature of point defects, both intrinsic as well as of impurity related nature, in 2D semiconducting materials. In an exploring attitude, the latter include bulk TMD's, both of geological origin as well synthetically composed, where the research is focused on robust p-type doping by covalently bonded impurities. It will be outlined how EPR can arrive at in-depth reliable characterization of these dopants, including solid atomic identification, accurate quantification, spatial distribution, and inference of electrically key properties such as their thermal activation energy, and a fortiori, defect level(s) in the semiconductor bandgap. In combination with its outstanding selectivity, EPR takes a unique position when it comes to selectively dopant characterization on true atomic level. A separate part will deal with intrinsic defects in synthetic large-area 2D TMD layers.
in 2D magnets with dilute magnetic doping. With the goal of getting participants up to speed on this fast moving topic, the tutorial will blend a number of experimental and theoretical concepts in the topics of sample fabrication and characterization, exchange coupling in intrinsic and extrinsic magnetic systems, considerations for stability of magnetic order in 2D systems, electric field control of magnetism, spin transport in magneto-tunnel junctions, and prospects for future science and applications.

SESSION QN02.01: Magnetism in 2D Materials
Session Chairs: Je-Geun Park and Srinivasa Rao Singamaneni
Tuesday Morning, April 23, 2019
PCC North, 100 Level, Room 128 B

10:30 AM QN02.01.01
2D Magnets—Discovery, Challenges and Opportunities Xiang Zhang; Nano-Scale Science and Engineering Center (NSEC), University of California, Berkeley, Berkeley, California, United States.

In this talk, I will present our work on 2D ferromagnet, antiferromagnet, and multi-phase interconversion. Specifically, it includes the discovery of the intrinsic ferromagnetism in 2D van der Waals materials, the new design of spin field effect transistor based on 2D antiferromagnets, and the interconversion between multiple magnetic phases in 2D magnets. These advances not only deepen the fundamental understanding of the 2D magnets physics, but also suggest possible outlets for the existing challenges in this emerging field such as high-temperature 2D magnets and low-power spintronics.

11:00 AM QN02.01.02
What Magnetic Can Teach Us About 2D Magnets Kenneth Burch; Boston College, Chestnut Hill, Massachusetts, United States.

In this talk, I will discuss the exciting theoretical possibilities for new phases that can emerge and the van der Waals materials within which they may be realized. I will focus on the utility of Raman spectroscopy for characterizing and identifying the novel aspects of the magnetic excitations in these materials.

11:15 AM QN02.01.03
Magnetic and Electrocatalytic Properties of Transition Metal Doped MoS2 Nanocrystals Jose Delgado1, Luis M. Martinez1, Christian Saiz1, Adrian Cosio1, Yanyu Wu2, Dino Villagran3, Kinjal Gandha4, Chinnathambi Karrhik4, Ilena Nebedim2 and Srinivasa Rao Singamaneni5; 1Physics, The University of Texas at El Paso, El Paso, Texas, United States; 2Chemistry, The University of Texas at El Paso, El Paso, Texas, United States; 3Arnes Laboratory, Critical Materials Institute, Ames, Iowa, United States; 4Micron School of Materials Science and Engineering, Boise State University, Boise, Idaho, United States.

In this paper, the magnetic and electrocatalytic properties of hydrothermally grown transition metal doped (10% of Co, Ni, Fe, and Mn) 2H-MoS2 nanocrystals (NCs) with a particle size 25–30 nm are reported. The pristine 2H-MoS2 NCs showed a mixture of canted anti-ferromagnetic and ferromagnetic behavior. While Co, Ni, and Fe doped MoS2 NCs revealed room temperature ferromagnetism, Mn doped MoS2 NCs showed room temperature paramagnetism, predominantly. The ground state of all the materials is found to be canted-antiferromagnetic phase. To study electrocatalytic performance for hydrogen evolution reaction, polarization curves were measured for undoped and the doped MoS2 NCs. At the overpotential of η ~ 300 mV, the current densities, listed from greatest to least, are FeMoS2, CoMoS2, MoS2, NiMoS2, and MnMoS2, and the order of catalytic activity found from Tafel slopes is CoMoS2 > MoS2 > NiMoS2 > FeMoS2 > MnMoS2. The increasing number of catalytically active sites in Co doped MoS2 NCs might be responsible for their superior electrocatalytic activity. The present results show that the magnetic order-disorder behavior and catalytic activity can be modulated by choosing the suitable dopants in NCs of 2D materials.
monolayers and multilayers [1]. The screening protocol first identifies bulk materials that appear layered according to a simple and robust chemical definition of bonding, determining then for all of these the binding energies of the respective monolayers, and their electronic state (metallic vs insulating), magnetic configuration (ferro-, ferri- or antiferro-magnetic), and phonon dispersions (to evaluate mechanically stability). Such protocol identifies a portfolio of close to 2,000 inorganic materials that appear either easily or potentially exfoliable, to be investigated further for promising properties. First focus has been on the determination of the effective masses and mobilities (from the full solution of the Boltzmann transport equation) for electronic applications; of topological invariants; of superconductivity and charge-density washes; and of photocatalytic parameters for water splitting. Thanks to the use of the AiDA (http://aiida.net) materials' informatics platform, all the high-throughput calculations can be performed and streamlined in fully searchable and reproducible ways, they are stored in a database with their full provenance tree of all parent and children calculations, and can be shared with the community at large in the form of raw or curated data via the Materials Cloud (http://www.materialscloud.org) dissemination portal.

SESSION QN02.03: Defects in 2D Materials
Session Chairs: Jian-Hao Chen, Harikrishnan Nair and Oleg Yazyev
Tuesday Afternoon, April 23, 2019
PCC North, 100 Level, Room 128 B

1:30 PM *QN02.03.01

The research on two dimensional (2D) materials keeps attracting much interest as being propelled by compelling features like the emergence of new physical properties in the transition from bulk to the 2D aspect and the promising potential to create a multitude of innovative device structures, with the projected horizon to push beyond the boundaries of current semiconductor device technology. Among the 2D materials, layered transition metal dichalcogenides (TMDs) experience an ever-growing research interest as these could potentially replace traditional semiconductors in next generation nanoelectronic devices. Among this group of TMDs, molybdenite (MoS₂) has surfaced as a particularly interesting TMD. However, different from other semiconductors, the presence of structural defects in the 2D crystal lattice considerably affects the performance of TMD-based devices. Hence, defect identification, characterization and quantification, more specifically the evaluation of the impact of processing, is considered indispensable in the progress of device technology research. In this respect, electron spin resonance (ESR) arises as an exclusive technique for atomic assessment and quantification of point defects.

In this regard, we will present on overview of the results obtained from multifrequency ESR study of TMDs, mainly focused on MoS₂, as encountered in various forms according to origin, including p-type geological 2H MoS₂ bulk crystals, synthetic bulk 2H MoS₂ grown by chemical vapour deposition, and large-area few-layer 2H MoS₂ films grown on SiO₂ by Mo sulfurization, and metal-organic chemical vapour deposition (MOCVD) grown on c-plane sapphire template wafers after a wet transfer procedure to another substrate. The results will deal with point defects, either of intrinsic or extrinsic origin. With respect to the bulk MoS₂ crystals, a main focus has been on impurities operating as dopants. Accordingly, data will be presented on As and N impurities substituting for S sites, operating as stable, covalently bonded substitutional acceptors. Added to this are the results of one more newly-observed ESR signal, tentatively assigned to Pb impurities substituting for Mo sites, also operating as acceptors.

Besides identification of the impurity-associated defects, largely based on the uniquely revealed hyperfine structure in the ESR spectra, ESR is demonstrated as an exclusive technique for indisputable and due impurity-specific inference of the thermal activation energy (level in the bandgap) of dopants, where the As and N acceptors are found to be characterised by an activation energy of \(E_a = 0.7 \pm 0.2 \text{ meV}\) and \(45 \pm 7 \text{ meV}\), respectively.

In a final part, the work will deal with synthetic large-area polycrystalline few-layer 2D MoS₂ crystals grown on SiO₂ by Mo sulfurization or MOCVD, where the latter films are studied after layer transfer to a target thermal SiO₂/(100)Si substrate – this with the intent to probe the impact of the act of layer transfer. The large area synthetic films were found to suffer from substantial amounts of intrinsic defects: in the latter MOCVD grown films, a previously unreported signal has been observed, which based on a comparison with previous ESR data, first principles simulations, and Rutherford backscattering spectrometry data, is assigned to an intrinsic defect, most likely a Mo or MoS₂ vacancy at grain boundaries.

As to the films synthesized by sulfurization of Mo films, the presence of a previously unreported anisotropic defect of axial symmetry about the c-axis, characterized by \(g_{\perp} = 2.00145\) and \(g_{\parallel} = 2.0027\), is revealed. Based on the analysis of the ESR signal features in combination with computational results on defect g factors, the signal has been tentatively assigned to a (di)sulfur antisite defect (S or S₂ substituting for a Mo atom) with energy levels in the MoS₂ bad gap, associated with grain boundaries, the latter thus emerging as intolerably impairing the carrier mobility and layer functionality.

2:00 PM QN02.03.02
Line Defects in Two-Dimensional Transition Metal Dichalcogenides—Insights from First-Principles Calculations Arkady Krasheninnikov, \(^1,2\) Helmholtz-Zentrum Dresden, Dresden, Germany; \(^3\)Department of Applied Physics, Aalto University, Helsinki, Finland.

Line defects, such as vacancy agglomerations and grain boundaries, strongly affect the properties of 2D, see Ref. [1] for an overview. The effects can be not only detrimental, but also beneficial in transition metal dichalcogenides (TMDs), so that controlling the density and type of the boundaries in these systems should be important for engineering their properties. In my presentation, I will touch upon the energetics and formation mechanisms of mirror twin boundaries in various TMDs during their growth [2] or under electron irradiation [3,4] and post-synthesis deposition of Mo atoms [5] with the main focus on the theoretical results obtained using DFT calculations in collaboration with several experimental groups. I will then discuss how controllable introduction of mirror twin boundaries and inversion domains can be used to add new functionalities to 2D TMDs.

2:15 PM QN02.03.03
Defect-Induced Phase Transformation in Low-Symmetry 2D Materials for High Performance Electronics Kai Xiao, \(^1\) Akinola D. Oyedele, \(^2\) Shizé Yang, \(^3\) Tianli Feng, \(^4\) Yiyi Gú, \(^5\) Chenze Liu, \(^6\) Amanda Haglund, \(^7\) Alexander Puretzky, \(^8\) Gerd Duscher, \(^9\) Matthew Chisholm, \(^10\) Sokrates Pantelides, \(^11\) Christopher M. Rouleau, \(^12\) David Mandrus, \(^13\) David B. Geohegan, \(^14\) Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; \(^5\) The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; \(^3\) The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; \(^14\) Vanderbilt University, Nashville, Tennessee, United States.

Two-dimensional (2D) materials especially transition metal dichalcogenides usually have diverse structural and electronic phases, which offer tremendous opportunity to explore and ultimately tailor many optoelectronic properties and quantum phenomena, including charge density waves, magnetic, topological insulators, and Weyl semimetals. However, understanding and control the phase transition process in 2D materials is still a great challenge. Our recent work shows that the defects in low symmetry 2D PdSe₂ crystals break the lattice symmetry and induce large structural distortion and ultimately form a new phase, however high symmetry 2D materials such as MoSe₂ still retain their crystalline lattice even under the defect density up to 20%. Various methods triggered the phase transformation in 2D PdSe₂ crystals will be discussed. The defect-mediated transformation process in this material was studied by using in-situ scanning transmission electron microscopy (STEM) combined with theoretical calculation. Through selective phase engineering, single material devices based on few-layer PdSe₂ crystal with the new metallic phase as the contact display the significantly enhanced electrical performance due to the reduced contact
resistance and Schottky barrier height. Our results suggest that phase engineering provides a promising way in tuning the properties in 2D materials for applications in electronics, catalysis, or magnet.

**Acknowledgment:** Synthesis science was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences (BES), Materials Sciences and Engineering Division and characterizations were performed at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.

2:30 PM BREAK

3:00 PM QN02.03.04 Interfacial and Defect Engineering of 2D Materials for Optoelectronics Ashwin Ranasubramaniam; Mechanical & Industrial Engineering, University of Massachusetts Amherst, Amherst, Massachusetts, United States.

A persistent challenge in realizing the potential of 2D materials for optoelectronics is the lack of precise control over carrier doping levels and work functions. Here, I focus on results from first-principles calculations, accompanied by complementary experiments, that seek to address these fundamental questions through various interfacial- and defect-engineering strategies. On the one hand, we explore strategies based on noncovalent functionalization of 2D materials with functional polymers that allow for spatially-targeted tuning of electronic properties of the active channel material. On the other hand, we explore strategies for small-molecule, covalent functionalization of 2D materials that result in unexpected magnetic properties with potential for spintronic applications. A common feature of the approaches proposed here is their amenability to conventional solution-processing and/or lithography that are inherently scalable for technological applications.

3:30 PM QN02.03.05 In Situ Study of Defects Produced in Free-Standing MoS\textsubscript{2} During Irradiation KoreyBurns and Assel Aiikalyeva; University of Florida, Gainesville, Florida, United States.

A number of bi-elemental two-dimensional (2D) nanomaterials (2DNMs) have been experimentally realized in recent years, including stable families of 2DNMs such as transition metal dichalcogenides (TMDs) and MX\textsubscript{2}. Unlike mono-elemental graphene, MoS\textsubscript{2} (a prototype for TMDs) consists of two atomic layers of close-packed sulfide atoms separated by one close-packed molybdenum atomic layer. TMDs exhibit a number of attractive physical properties, including electronic, optical, and mechanical. However, throughout their lifetime 2DNMs can be exposed to high temperatures and particle irradiation environments, which can dramatically alter the structure-property relationships and degrade their physical properties. This contribution seeks to understand the physical processes occurring at multiple length scales in MoS\textsubscript{2} and determine the structural stability and property evolution in MoS\textsubscript{2} in conditions far away from equilibrium. Irradiation and high temperatures push materials out of equilibrium, thus producing dynamic systems, which can result in unexpected behaviors. Defect formation and interaction mechanisms in free-standing MoS\textsubscript{2} under irradiation (and various temperatures) were observed in-situ using various experimental techniques, including high resolution transmission electron microscopy (TEM) and X-ray photoelectron spectroscopy (XPS). The phenomena of interest included energy dissipation, defect formation and interaction mechanisms, and the role of defect sinks in the material’s radiation response. The irradiation response of monolayer MoS\textsubscript{2} will be compared to that of a bilayer and a material to discern the differences in their radiation response. This work was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award # DE-SC0019014.

3:45 PM QN02.03.06 Interlayer Couplings in Tuning Magnetic Properties of Two-Dimensional Materials Wei Ji; Department of Physics, Renmin University of China, Beijing, China.

Van der Waals interactions were believed dominant for interlayer interactions in layered two-dimensional (2D) materials. We recently found wavefunction overlaps do occur at vdW gaps, namely covalent-like quasi-bonding (CLQB)[1-5]. Here, we show that such overlaps strongly affect interlayer magnetism using density functional theory calculations. In particular, the interlayer magnetic couplings (IMCs) of CrS\textsubscript{2} [6] and CrI\textsubscript{3} [7] bilayers were discussed since they are at two extremes for the strength of IMC. The interlayer FM coupling in CrS\textsubscript{2} is very robust and is nearly unable to be tuned under usual external fields, but the intra-layer magnetism does vary under layer stacking. An opposite case was found in CrI\textsubscript{3} bilayers where the intra-layer FM coupling is, however, very strong but the interlayer magnetism was found governed by a subtle change of interlayer stacking; this shows a decoupled magnetic interaction between intra- and inter-layer directions.

References

4:00 PM QN02.03.07 Contact-Free Electrical-Acoustic Characterization of Transition Metal Dichalcogenide Films Grown by Chemical Vapor Deposition Miguel Isarraraz, Ludwig Bartels and Jacob Rodriguez; Materials Science and Engineering, University of California, Riverside, Riverside, California, United States.

Surface Acoustic Waves (SAWs) and Transition Metal Dichalcogenides (TMDs), separately, are topics of current research due to their present and future use in telecommunications and beyond-CMOS technology. The interaction between a SAW and a 2D electron gas has been previously studied by measuring the absorption of the SAW by GaAs and, more recently, graphene.

Here, the interaction between a SAW and a TMD is studied using MoS\textsubscript{2} directly grown by chemical vapor deposition on 128°YX-cut LiNbO\textsubscript{3}. By focusing a 532 nm laser on the sample, the generation of electron-hole pairs is found to enhance the attenuation of the SAW as expected. We present a hybrid FET-SAW (field effect transistor-surface acoustic wave) device. Our experiments reveal close agreement between the SAW spectroscopy and the FET transport measurements. SAW spectroscopy can be used to spatially resolve variations inside triangular MoS\textsubscript{2} islands. Furthermore, the time dependence of the SAW attenuation with laser exposure is used to distinguish between semiconductor film and the substrate. This technique provides a means of electrically characterizing atomically thin semiconducting film that avoids the limitations of metallic contacts.

4:15 PM QN02.03.08 Adhesion of Pd Metal Clusters to WTe\textsubscript{2}—Binding at the Ideal and Defective Lattice Sites Yang Wang, Zdenek Dohnalek and Peter V. Sushko; Pacific Northwest National Laboratory, Richland, Washington, United States.

Robust operation of quantum devices relies on the chemical and structural stability of their parts, including electrical contacts. Given that temperatures and environmental conditions at which quantum devices are synthesized can differ dramatically from their operating conditions, it is imperative to understand how temperature variations, material imperfections, exposure to contaminants, and behavior of metal contacts are inter-related.

Here we focus on metal adhesion to a prototype 2-dimensional metal dichalcogenide WTe\textsubscript{2}, which exhibits topological behavior in a monolayer limit. We have developed a
reliable procedure to mechanically exfoliate single crystal WTe$_2$ in ultra-high vacuum in our scanning tunneling microscopy (STM) system. This approach allows for the STM images with atomic resolution to be readily acquired without further treatment. Few defects, attributed to Te vacancies, were observed. Our experiments on Pd deposition on WTe$_2$ surface show that structurally ideal sites and defects, provide stable adsorption sites for small Pd clusters (~2 nm in diameter) even after annealing to 523 K. Tip manipulation experiments demonstrate that Pd particles anchored on defects are more stable than those on non-defective surface sites: we can remove and split Pd nanoparticles above the non-defect sites using STM. The nanoparticle anchored to defects can only be altered but cannot be completely removed demonstrating a strong binding. The atomic-level insight into Pd cluster bonding to the ideal and defective sites was obtained using \textit{ab initio} (density functional theory) simulations. We discuss how the local atomic structure and charge redistribution in the vicinity of the binding site affects the stability and electronic properties of this system.

**4:30 PM QN02.03.09**

Tuning the Interlayer Properties of van der Waals Heterostructures with Substrate Surface Defects—van der Waals to Covalent Bonding Transformation Se-Yang Kim$^1$, Jung Hwa Kim$^1$, Sangwoo Lee$^2$, Jinmu Kwak$^1$, Yongse Jo$^1$, Euijoon Yoon$^2$, Gun-Do Lee$^2$, Zongheon Lee$^2$ and Soon-Yong Kwon$^1$; 1UNIST, Ulsan, Korea (the Republic of), 2Seoul National University, Seoul, Korea (the Republic of).

The physical properties of vdW heterostructures are significantly affected by their stacking geometries and interlayer coupling (including interlayer charge transfer and energy transfer). In a previous study, we showed that monolayer WS$_2$ flakes grown onto a graphene substrate exhibit outstanding air stability compared to the flakes grown on a SiO$_2$/Si substrate.$^{11}$ Using various characterization tools and based on previous reports, we demonstrated that the surface charge transfer significantly affects the prevention of air degradation for the first time. This result suggested that understanding the effect of interlayer coupling in the stacking geometry of vdW heterostructures is highly important for obtaining materials with desirable properties.

Chemical vapor deposition (CVD) has received attention for the scalable synthesis of layered 2D materials and their heterostructures. However, typically synthesized large-scale 2D films by the CVD process are polycrystalline in nature and include a high density of atomic and structural defects, which are associated with a broken lattice symmetry, a modified energy landscape, and quantum confinement. These localized heterogeneities strongly affect the electronic properties of 2D materials. Since dangling bonds at vacancy defects, curved wrinkles, and grain boundaries (GBs) are more reactive and have interaction strengths different from that of a pristine region, defects in the template layer can have a profound effect on the nucleation and growth of heterostructures. However, the effects of atomic and structural defects on the interlayer properties or configuration have not yet been considered; instead, previous theoretical and experimental studies have considered only defect-free templates.

In this study, we demonstrate that the intrinsic properties of subsequent layers of a vdW heterostructure are based on the structural features of the template layer (e.g., the basal plane of graphene), using two types of WS$_2$ flakes grown directly on graphene defects (D-WS$_2$) and a pristine basal plane (B-WS$_2$). Both types of WS$_2$ flakes have the same crystal structure despite the atomic displacement and lattice distortion beneath the D-WS$_2$ flakes; however, they strongly influence the interlayer interactions between the stacked layers, thus affecting the layer deformability, thermal stability, and physical and electrical properties. Combined experimental and computational studies showed that the difference in the behavior of D-WS$_2$ flakes could be attributed to the formation of covalent bonds via W atomic bridges (i.e., formation of larger overlapping hybrid orbitals) at defect sites. Our results reveal the importance of understanding the interlayer coupling in stacking geometries and its correlation effect for designing desirable properties in 2D vdW heterostructures.

**4:45 PM QN02.03.10**

Atomic Structure, Stacking Order and Electronic Structure of Two-Dimensional III-VI Alloys Amin Azizi$^{1,2}$, Gabriel Antonius$^1$, Emma Regan$^{1,2,3}$, Rahmatollah Eskandari$^1$, Salman Kahn$^{1,3}$, Feng Wang$^{2,5}$, Steven Louie$^{1,3}$ and Alex Zettl$^{1,2,3}$; 1Department of Physics, University of California at Berkeley, Berkeley, California, United States; 2Kavli Energy Nanoscience Institute, University of California at Berkeley, Berkeley, California, United States; 3Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Alloying two-dimensional (2D) semiconductors provides a powerful method to tune their physical properties, especially those relevant to optoelectronic applications. Visualizing the atomic-scale crystal structure of multielemental materials is crucial in order to correlate their structures-property relationship and engineer their functionality. However, constructing the atomic structure of alloys becomes more difficult as the number of atomic planes and atomic species in an alloy increases. Here, we reveal structural information about the atomic lattice of monolayer and few-layer III-VI alloys using annular dark-field scanning transmission electron microscopy (ADF-STEM) imaging combined with image simulation, second harmonic generation (SHG), and first principles calculations. In addition, we correlate the atomic and electronic structure of the alloys and probe change in their electronic structure as a function of layer number using low-loss electron energy loss spectroscopy (EELS) and density functional theory (DFT) calculations.

8:00 AM *QN02.04.01*

Understanding Properties of Advanced Two-Dimensional Materials Based on Low-Voltage Atomic Scale TEM Experiments Ulre Kaiser; Central Facility of Materials Science Electron Microscopy, University of Ulm, Ulm, Germany.

To obtain structural and electronic properties of advanced two-dimensional material at the atomic scale is a growing demand in materials science. A new type of transmission electron microscope operating at electron energies between 80keV and 20keV has been developed. It allows to undercut most of the materials knock-on damage thresholds and enables sub-Angstrom resolution in an 4000x4000 pixels, single-shoot image down to 40keV by correcting not only the geometrical aberrations of the objective lens but also its chromatic aberration [1,2]. During the imaging process, the interaction of the beam electrons with the low-dimensional material can, nevertheless, result in changes of the atomic structure due to ionization and radiolysis [3], and sophisticated sample preparation methods are employed to reduce these effects [4,5]. We briefly outline key instrumental and methodological developments.

To modify properties of two-dimensional materials, we use the electron beam not only for imaging its original structure but also for engineering new properties. Thus we report on the structure as well as on electron-beam-induced transformations from point to extended defects in 2H-MoTe$_2$ and their changes to the distorted 1T-MoTe$_2$ phase. In the case of TaSe$_2$, we demonstrate the creation of commensurate charge density wave (CDW) in a monolayer 1T-TaSe$_2$, and show in addition that the CDW’s order varies due to an increase in the S/Se vacancies. For the two-dimensional material MnPS$_2$, we show that EELS experiments provide a means to identify single-layer MnPS$_2$ from bulk structures and give the signature of the low dimensionality in their electronic excitations [7]. Finally we intercalate bilayer graphene by lithium and study the lithiation and delithiation between bilayer graphene, as well as the structure of the new high density crystalline Li-Phase [8].

Most of our studies are accompanied by first principle calculations to understand the structural and electronic properties. [9].

Critical Behavior and Magnetocaloric Effect in CrI

Properties of Monolayer Vanadium Dichalcogenides Grown by Molecular Beam Epitaxy

Matthias Batzill
University of South Florida, Tampa, Florida, United States.

Ferromagnetic ordering in monolayer vanadium dichalcogenides was predicted by DFT, despite the lack of ferromagnetic ordering in its bulk form. Ferromagnetic 2D materials with high Curie temperatures are highly sought to enable spintronic devices based on van der Waals heterostructures. In this talk we present a discussion of VSe$_2$ and VTe$_2$ monolayers grown by molecular beam epitaxy and study the difference of their monolayer properties compared to the bulk. In addition, to charge order states and structural variations of the monolayer and the bulk, we critically assess the origin of the measured ferromagnetic properties [1] in (sub)monolayer VSe$_2$.

Magnetic Characterizations of Proton Irradiated van der Waals Magnets CrSiTe$_3$

Luis M. Martinez$^{1}$, Yu Liu$^{2}$, Cedomir Petrovic$^{2}$, Lin Shao$^{2}$ and Srinivasa Rao Singamaneni$^{1}$
$^{1}$Physics, The University of Texas at El Paso, El Paso, Texas, United States; $^{2}$Condensed Matter Physics and Materials Science, Brookhaven National Laboratory, Upton, New York, United States; $^{3}$Nuclear Engineering, Texas A&M University, College Station, Texas, United States.

Magnetic van der Waals (vdWs) crystals have gained a great deal of attention in the recent past owing to their attractive layer-dependent anisotropic magnetic properties, and for next generation low power spintronic applications. Irradiation with high energetic particles such as protons is an effective route to manipulate the magnetic properties of these materials. In this work, we present the magnetic properties of proton irradiated (10$^{15}$/cm$^2$) vdWs crystal, namely, CrSiTe$_3$ (CST). Pristine CST is a ferromagnetic (Curie temperature, T$_C$ = 32 K) semiconductor (band gap = 0.7 eV). The magnetic measurements were performed both in-plane (IP) and out-of-plane (OOP) geometry as a function of temperature and magnetic field. Most significantly, at 2 K, the IP saturation magnetization increased from 3.85 to 4.77 $\mu_B$ upon proton irradiation. Furthermore, proton irradiation causes an increase in the coercive field (H$_C$) from 465 to 542 Oe and remnant magnetization (M_r) from 0.783 to 1.375 $\mu_B$. In OOP geometry, due to proton irradiation, both H$_C$ (from 138 to 223 Oe) and M_r (0.0493 to 0.247 $\mu_B$) have increased, and noticeable (168 Oe, 1 K) an exchange bias is observed. No significant change in T$_C$ is noted upon proton irradiation. The temperature dependent (10-50 K) X-band (~9.43 GHz) electron paramagnetic resonance (EPR) measurements performed on both pristine and proton irradiated CST crystals show a strong modification in the EPR signal shape from Dysonian to Lorentzian—inferring that the magnetic (super) exchange interactions and electronic behavior are altered. We will present and discuss our comprehensive experimental findings and offer plausible explanation for the observed behavior.

The olivine A2BX4 are potential candidates for thermoelectric and magnetic applications. An orthorhombic Pnma symmetry is adopted by A2BX4 where the A site forms a triangle-based low dimensional saw-tooth chain. In the present work, we have studied Mn$_2$SiS$_4$-xSex (0 < x < 4) using magnetization, specific heat, thermal conductivity and density functional theory. In general, the compounds undergo antiferromagnetic transitions and display spin-flip transition upon application of magnetic field. The TN shows a linear decrease from 86 K for Mn$_2$SiS$_4$ towards 66 K for Mn$_2$SiSe$_4$ as x varied, whereas the critical field for spin-flip varied non-linearly. The specific heat of Mn$_2$SiS$_4$-xSex revealed very low magnetic entropy at the TN thereby bringing out the underlying frustrated nature of the Mn$^2+$ ions in the saw-tooth lattice. The density functional theory calculations show an energy gap of 0.5 eV between the valence and conduction bands and accordingly, a semiconducting-like thermal conductivity is revealed by the olivines. Our results are explained based on the emergence of frustration in the triangular units of the saw-tooth Mn lattice.

9:30 AM QN02.04.05
Magnetism and Chemical Disorder in van der Waals Bonded Crystals

Michael McGuire; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

I will discuss examples of chemically disordered materials recently studied in our laboratory, with a focus on crystallographic and magnetic behaviors in bulk crystals of cleavable, layered halides and chalcogenides. In several cases, both x-ray diffraction and atomic resolution electron microscopy were key in understanding the average structure, local disorder, and defect ordering. Much of the work is motivated by efforts to move toward higher magnetic ordering temperatures, and to achieve stronger magnetic anisotropy by incorporating more spin orbit coupling. With these aims in mind, the target materials include metallic systems with strong magnetic interactions and insulating compounds with 4d and 5d transition metals.

Gate-Tunable Room-Temperature Ferromagnetism in Two-Dimensional FeGeTe$_2$

Yuanbo Zhang and Yujun Deng; Fudan University, Shanghai, China.

The advent of two-dimensional van der Waals crystals creates new possibilities in developing novel spintronic devices. Recent experiments have demonstrated that it is possible to obtain two-dimensional ferromagnetic order in insulating Cr$_2$Ge$_2$Te$_5$ and CrI$_3$ at low temperatures. Here, we developed a new device fabrication technique, and successfully isolated monolayers from layered metallic magnet Fe$_3$GeTe$_5$. We found that the itinerant ferromagnetism persists in Fe$_3$GeTe$_5$ down to monolayer. The ferromagnetic transition temperature, T$_C$, is suppressed in pristine Fe$_3$GeTe$_5$ thin flakes. An ionic gate, however, dramatically raises the T$_C$ up to room temperature. The gate-tunable room-temperature ferromagnetism in two-dimensional Fe$_3$GeTe$_5$ opens up opportunities for potential voltage-controlled magnetoelectronics.

Critical Behavior and Magnetocaloric Effect in CrI$_3$ and Cr$_2$Ge$_2$Te$_5$

Yu Liu and Cedomir Petrovic; Condensed Matter Physics and Materials Science Department, Brookhaven National Laboratory, Upton, New York, United States.

Layered intrinsically ferromagnetic (FM) semiconductors hold great promise for both fundamental physics and future applications in nanospintronics [1-5]. CrI$_3$ and Cr$_2$Ge$_2$Te$_5$ have recently attracted wide attention since long-range ferromagnetism persists in atomically thin devices due to large magnetocrystatalline anisotropy [5-7]. In this talk we will discuss the nature of the FM transition in bulk crystals based on a detailed study of the critical properties and scaling analysis of magnetic entropy change. The obtained critical exponents suggest three-dimensional (3D) long-range magnetic coupling in CrI$_3$ and two-dimensional (2D) Ising-like type coupled with a long-range interaction in Cr$_2$Ge$_2$Te$_5$ [8,9]. The rescaled magnetic entropy changes collapse onto a universal curve independent of temperature and field for both materials, confirming a second-order type of the magnetic transition [10,11]. Considering its ferromagnetism can be maintained upon exfoliating bulk crystals down to a single layer, further investigation on the size dependence of critical properties and magnetocaloric effect is of high interest.

This work has been supported by the Research supported by the U.S. Department of Energy, Office of Basic Energy Sciences as part of the Computation Material Science Program (Y.L. and C. P.) and by the U.S. DOE under Contract No. DE-SC0012704 (C.P.).
The recent discovery of 2D magnets provides new ways to study 2D magnetism by harnessing the unique features of atomically-thin materials, such as electrical control for magnetoelectronics and van der Waals (vdW) engineering for novel interface phenomena. In this talk, I will describe our recent magneto-optical spectroscopy experiments on vdW magnets. I will discuss the layered antiferromagnetic properties of CrI3 with electrical control, giant tunneling magnetoresistance through spin filtering effect in vdW magnetic tunnel junctions, magnetic dynamics in zigzag antiferromagnets, and progress on exfoliable 2D magnets with stable magnetic order near room temperature.

SESSION QN02.05/QN01.06/QN03.08: Keynote: Joint Session: 2D Magnets and Heterostructures
Session Chair: Srinivasa Rao Singamaneni

The Origin of Single Photon Emission in 2D WSe$_2$
Yu Jie Zheng$^1$, Lan Wang$^2$, Cheng Tang$^3$, Changgu Lee$^4$, Gian Nguyen$^5$ and An-Ping Li$^6$; $^1$Sungkyunkwan University, Suwon Gyonggi, Korea (the Republic of); $^2$RMIT University, Melbourne, Victoria, Australia; $^3$Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Several experimental groups have shown that defect structures in 2D WSe$_2$ result in single photon emission (SPE). However, the origin of SPE is still unknown. We present a first principles study of the nature and optical properties of point defects in 2D WSe$_2$, together with scanning tunneling microscopy (STM) and scanning transmission electron microscopy images. We predict that O$_{ins}$ can dissociate easily at Se vacancies, resulting in O-passivated Se vacancies (O$_{pass}$) and O interstitials (O$_{int}$), which give STM images in good agreement with experiment. Our GW-Bethe-Salpeter-equation calculations show that O$_{pass}$ defects give exciton peaks $\sim 50$–100 meV below the free exciton peak, in good agreement with the localized excitons observed in independent SPE experiments. No other point defect (O$_{ins}$, Se vacancies, W vacancies, and Se$_x$ antisite defects) gives excitons in the same energy range. We conclude that the O$_{pass}$ defect is a likely source for the SPE previously observed in 2D WSe$_2$.

SESSION QN02.06: Theory and Other Physical Properties of 2D
Session Chairs: Matthias Batzill, Srinivasa Rao Singamaneni and Oleg Yazyev
Wednesday Afternoon, April 24, 2019
PCC North, 100 Level, Room 128 B
Three-dimensional (3D) topological insulators (TIs) have emerged as an important class of materials for realizing novel quantum phenomena. Doping 3D TIs with various elements, both magnetic and non-magnetic, has played a vital role in improving the quality of 3D TIs and/or manipulating their surface states for novel quantum phenomena. The success of this strategy has been manifested in seminal observations of the quantum anomalous Hall effect and the quantum Hall effect in doped TIs. In this talk, however, we would like to demonstrate that complications could arise from the doping with two TI systems. One is the (Bi,Sn)Te$_3$, in which strong electrostatic fluctuations lead to formation of electron-hole puddles and a sublinear power law temperature dependence of the electron dephasing rate [1]. The other is Mn-doped Bi$_2$Se$_3$, in which the spin structure of its ground states has been controversial and new insights could be gained from our recent observation of a two-component anomalous Hall effect [2].

Electronic Structure of Single and Double Transition Metal MAX Phases and MXenes Weiwei Sun$^{1,2}$, David Mullins$^3$, Michael Naguib$^1$ and Paul Kent$^{1,4}$; $^1$Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; $^2$Chemical Science Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; $^3$Department of Physics and Engineering Physics, Tulane University, New Orleans, Louisiana, United States; $^4$Computational Sciences and Engineering Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

MXenes are a large family of conducting two-dimensional (2D) materials, synthesized by the chemical etching method using acids such as HF or HCl from their parental ternary carbides MAX phases, where M stands for transitional metal elements, A stands for the A group elements, and the X is either C or N. [1-3] MXenes show great promise for the usage of supercapacitors, in part due to pseudocapacitance induced by the reversible surface binding processes. [4-5] However, a comprehensive investigation of the valence and oxidation state changes is still lacking.

In this work, by means of X-ray absorption spectra (XAS) and density functional theory (DFT), we have systematically investigated the valence states of a series of Ti, Mo containing Ti$_3$AlC$_2$ (Ti$_3$C$_2$T$_x$), Ti$_3$MoAlC$_2$ (Ti$_3$MoC$_2$T$_x$) as well as Ti$_3$Mo$_2$AlC$_3$ (Ti$_3$Mo$_2$C$_3$T$_x$), where T stands for terminations, e.g. O. F. Experimentally, the low-dimensional MXenes exhibit greater valence states for metal atoms compared with those in their parent bulk MAX phases. The increasing thickness of the M-X blocks suppresses the valence states of Ti atoms. Our DFT calculations employed special quasi-random structures (SQS) for bcc (Mo) and central metal (Ti) layers. We also tested a variety of density functionals to locate the most suitable one to describe the structure and the chemical bonding, including the Perdew-Burke-Ernzerhof (PBE) generalized gradient approximation, [7] Van der Waals corrections, [8] and the Hubbard U correction for the localized d electrons in Ti/Mo. [9] We determine that the intermixing as well as the Van der Waals corrections play significant roles on the structural and electronic properties, which effectively tunes the oxidation state. Including all of these effects leads to the agreement with our experimental observations and suggests that the synthesized MXenes also has significant intermixing. The unveiled tendencies of alloying, varying the thickness, dimensionality and surface terminations give insight to the measured capacitive properties of these materials.

References
type. Finally, relaxation of the localized GHz modes to the excitation of low-frequency (MHz) whole-flake oscillations emerges as cantilever-type dynamics in the microsecond UEM image sequence. Altogether, these results produce a comprehensive picture of the effects of local structure and morphology on the excitation and decay of coherently phonon modes in multilayer MoS₂.

Symmetry, interaction and topological effects greatly influence the quantum properties of atomically thin two-dimensional (2D) materials. Defects and environmental screening can play equally important roles in determining their behaviors. In this talk I present several interesting phenomena related to point defects and substrate screening on the properties of 2D materials. 1) We study, using ab initio GW-BSE theory, the effect of point-defect chalcogen vacancies on the optical properties of monolayer transition metal dichalcogenides (TMDs). The chalcogen vacancies introduce unoccupied in-gap states and occupied resonant quasiparticle defect states. These defect states give rise to strongly bound defect excitons and hybridize with excitons of the pristine system, reducing the valley-selective circular dichroism. The results suggest a pathway to tune spin-valley polarization and other optical properties through defect engineering. 2) A fascinating property of monolayer semiconductors is that the electronic bandgap ceases to be an intrinsic physical parameter and can be engineered through the surrounding dielectric environment. We have exploited such a dielectric-dependent electronic bandgap and demonstrated the formation of a lateral heterojunction within a homogeneous MoS₂ monolayer through substrate engineering. The capability to tailor the local band structure and electrical transport in 2D semiconductors through dielectric engineering can open exciting new ways to design 2D nanoelectronic and optoelectronic devices. 3) Plasmons in atomically thin 2D materials are distinct from those of the bulk and traditional 2D electron gas systems. We discover that the plasmon dispersion in real quasi-2D metals is qualitatively different, being virtually dispersionless for wavevectors of typical experimental interest. This stems from a lack of continuous translational symmetry, making dispersionless plasmons a universal phenomenon in quasi-2D metals. Moreover, our ab initio calculations show that plasmons on monolayer metallic TMDs are long lived and localizable in wave packets (within ~15 nm) which does not significantly disperse over practical measurement time. Their slow propagation opens the possibilities of tracking plasmon wave packets in real time and of localizing long-lived, boson-like excitations in extended, atomically thin materials.

This work was supported by the U. S. Department of Energy, National Science Foundation, and Office of Naval Research. I would like to acknowledge collaborations with members of the Louie group.

Electron Spin Resonance Properties of CrI₃ and CrCl₃ Single Crystals Christian Saiz₂, Michael McGuire¹, Johan van Tol¹ and Srinivasa Rao Singamaneni³; ¹University of Texas at El Paso, El Paso, Texas, United States; ²Florida State University, Tallahassee, Florida, United States; ³Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

The discovery and subsequent research excitement of new van der Waals magnetic semiconductors such as CrI₃ and CrCl₃, in the post silicon era, offers novel applications in computing and data storage due to the unexpected magnetic properties associated with the reduced dimension and layered structure. Electron spin resonance (ESR) spectroscopy is an ideal local experiment that can pinpoint the atomic origin and underlying mechanisms of magnetic interactions in these materials. This work presents our recent experimental findings on ESR investigations in these compounds as a function of temperature (5-500 K) and microwave frequency (9.43 and 120 GHz). The temperature dependences of the ESR line width and g-value show clear magnetic phase transitions at 61 K and 17 K, in the case of CrI₃ and CrCl₃, respectively. These results are consistent with magnetization and heat capacity data. For CrI₃ at room temperature, the estimated g-value from the single Lorentzian signal is 1.986 and peak-to-peak line width (ΔHpp) is 336 Gauss (G). In the case of CrCl₃, the estimated g-value is 1.986 and ΔHpp is 82 G. These are the benchmark signatures of Cr⁺⁺(S = 3/2) ions in the octahedral site where all the three spins are in the t2g state, which are responsible for the magnetic behavior of this compound. Interestingly, the ESR signal appearing from CrCl₃ is narrower by a factor of four, which is a direct consequence of different magnetic exchange interaction strengths between CrCl₃ and CrI₃ single crystals. This is due to the more coherent nature of the interactions of Cr⁺⁺ with iodine than with chlorine. This observation not only confirms the presence of Cr⁺⁺ ion, but also shows the effect of halide ion on the magnetic interaction of these layered compounds. In addition, we will also present light-induced ESR properties of these materials.

Magnetic Properties of Proton Irradiated van der Waals Fe₂₋₃GeTe₂ Adrian Cosio¹, Ruhvyan Olmos¹, Luis M. Martinez¹, Yu Liu², Cedomir Petrovic², Lin Shao¹ and Srinivasa Rao Singamaneni³; ¹Physics, The University of Texas at El Paso, El Paso, Texas, United States; ²Condensed Matter Physics and Materials Science, Brookhaven National Lab, Upton, New York, United States; ³Nuclear Engineering, Texas A&M University, College Station, Texas, United States.

There has been an intense research interest in exploring the magnetic properties of van der Waals (vdWs) crystals owing to their interesting layer-dependent anisotropic magnetic properties. These materials are expected to show great potential for next generation low power spintronic applications. Proton irradiation is an effective route to manipulate the magnetic properties of these materials. In this work, we present the magnetic properties of proton irradiated (10⁶ cm⁻²) Fe₂₋₃GeTe₂ (FGT) single crystal. FGT is a strongly correlated ferromagnetic metal with a Curie temperature (Tc) of 151 K, which is confirmed through magnetization vs. temperature (M(T)) and heat capacity measurements. The effective moment for pristine FGT was found to be μeff = 5.84 μB for H//ab and 5.81μB for H//c. After proton irradiation, FGT displays the same behavior as the pristine M(T) measurement and exhibits a slight increase in the effective moment to 5.99 μB (H//ab) and 5.95 μB (H//c). The isothermal magnetization for pristine FGT shows the c-axis as the easy axis for both pristine and irradiated FGT. A slight increase is observed in the magnetization saturation after proton irradiation from Ms = 1.044 μB/Fe (H//c) and 0.9535 μB/Fe (H//ab) to Ms = 1.0867 μB/Fe (H//c) and 0.9796 μB/Fe (H//ab). Heat capacity (HC) measurements were also performed on pristine and irradiated samples. Both samples exhibit a
clear peak at 151 K, which is consistent with the PM-FM transition. The magnetic heat capacity, which was obtained by subtracting the phonon contribution using the Einstein model, was used to derive the magnetic entropies. The obtained entropies were ~0.153 J mol\(^{-1}\) K\(^{-1}\) for pristine and ~0.198 J mol\(^{-1}\) K\(^{-1}\) for irradiate samples. Electron Paramagnetic Resonance studies have also been performed on both the crystals to better understand the effects of proton irradiation on an atomic level. We will present and discuss our comprehensive experimental findings.

Solution-Processable Method for Producing High-Quality Reduced Graphene Oxide Displaying ‘Self-Catalytic Healing’  
Geonhee Lee,1,4, Du Won Jung,1, Wonki Lee2, Sanghee Nah1, Seulgi Ji2, Jun Yeon Hwang2, Sun Sook Lee1, Sungsu Park1, Soo Sang Che1 and Jeong-O Lee1; 1Advanced Materials Division, Korea Research Institute of Chemical Technology, Daejeon, Korea (the Republic of); 2Institute of Advanced Composite Materials, Korea Institute of Science and Technology (KIST), Jeonbuk, Korea (the Republic of); 3Korea Basic Science Institute (KBSI), Seoul, Korea (the Republic of); 4School of Mechanical Engineering, Sungkyunkwan University, Suwon, Korea (the Republic of); 5Leibniz Institute of Polymer Research Dresden, Dresden, Germany; 6Department of Physics, Sungkyunkwan University, Suwon, Korea (the Republic of).

Reduced graphene oxide (rGO) has potential as a mass-productive and cost-effective substitute for graphene, but displays poor crystal quality due to various types of structural defects. Though many attempts have been reported to improve the quality of rGO, most of them require sophisticated equipment or severe conditions such as toxic chemicals, high temperature, and electron beam or plasma treatment in ultra-high vacuum (UHV) conditions. Here, we report a mild and simple solution-based healing method for obtaining high-quality rGO using this method involving the use of a simple camera flash light treatment and the nonreactive chemicals such as acetic acid and ethanol. Exposing a GO solution containing L-ascorbic acid and ethanol to the flash light irradiation for a short amount of time (<10 min) resulted in the formation of rGO displaying high quality both with respect to its chemical composition and morphology.

To elucidate the mechanism of the flash-light-induced healing of rGO, we acquired and analyzed the transient absorption spectrum for the healing reaction by using femtosecond pump-probe spectroscopy; this analysis revealed the photo-catalytic activity of GO by itself to repair chemical and topological defects, and we hence named this process ‘self-catalytic healing’.

QN02.08.04

Synthesis of Amorphous 2D Metal Oxides and Hybrid Organic-Inorganic Films  
Sean Martens, Jessica Coleman and Scott Warren; University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

2D materials are frequently derived from layered crystalline materials, however bottom-up syntheses present the opportunity to explore amorphous 2D materials with high defect densities. The high concentration of defects along the surface of amorphous 2D materials suggests unique transport properties like faster ion diffusion kinetics than crystalline 2D materials. We report the synthesis of amorphous thin films via Atomic Layer Deposition (ALD) and substrate dissolution. Here, we show 5 nm thick films with lateral sizes up to 1 mm composed of Al\(_2\)O\(_3\), HfO\(_2\), ZrO\(_2\) and multilayer metal oxides via this method. The quality of film growth depends on the surface of the NaCl substrate, where extended exposure to ambient environment promotes a transition to continuous growth from island growth, as observed for freshly cleaved crystal faces. Unlike some strong chemical etchants frequently used in nanomaterial synthesis, our aqueous dissolution of the NaCl substrate is compatible with many nanomaterials. In addition to large area films, we apply this approach to high surface area NaCl powder substrates to produce a large quantity of metal oxide nanomaterials with inexpensive substrates and gentle aqueous etching. We demonstrate the tunability of the surface chemistry by functionalizing films with organic self-assembling monolayers (SAMs), like alkanolic acids and fluorosilanes. The functionalization of the surface of the metal oxides contributes to the development of a new class of hybrid organic-inorganic amorphous 2D materials. The structure of amorphous 2D materials suggests future applications as membrane materials to with fast diffusion rates and control of ion selectivity.

QN02.08.05

Olivine Mn\(_2\)Si\(_3\)O\(_6\), So—Magnetic Frustration and Spin-Flop Transition in Triangular Sawtooth Lattice  
Harishan Hnalhi1, Raju Baral2, Adrian Cosio3, Bethuel Khamala1, Srinivasa Rao Singamaneni1, Magdalena Fitta1, Rajendra R. Zope1, Tunna Baruah1, Daniel Antonio1, Krzysztof Golfryk4, Bayrammurad Saparov2 and Haririkshnan S. Nair1; 1Department of Physics, The University of Texas at El Paso, El Paso, Texas, United States; 2Department of Chemistry and Biochemistry, The University of Oklahoma, Norman, Oklahoma, United States; 3Department of Magnetic Materials and Nanostructures, The Henryk Niewodniczanski Institute of Nuclear Physics -PAN, Krakow, Poland; 4Idaho National Laboratory, Idaho Falls, Idaho, United States.

Due to their profitable band structure features, olivines are potential candidates for thermoelectric and photovoltaic applications. In the present work we study the magnetic properties of sawtooth lattice olivine Mn\(_2\)Si\(_3\)O\(_6\) by replacing Si with Se progressively. We study the spin flop antiferromagnetic transition in the composition series, Mn\(_2\)Si\(_3\), Mn\(_2\)Se\(_3\), (x = 0 – 4). The magnetic phase transition occurred at 86 K for x = 0 compound and reduced almost linearly in magnitude as Se-doping increased. New magnetic anomalies below 20 K are identified for all these compounds through the present work, which might correspond to spontaneous spin re-orientations. The magnetic phase transitions characterized using specific heat revealed very low magnetic entropy at transition temperature for the x = 0 compound, which suggested that the underlying frustrated nature of the Mn\(^{2+}\) ions was in the sawtooth-like triangular arrangement. The spin-flop transition occurred at critical field of 2.7 T for x = 0 and evolved with the composition in a non-linear fashion. Our studies mark the maximally frustrated compound as the x = 4. Our density functional theory calculations point towards the existence of competing magnetic interactions in the triangular units of Mn as leading to frustration effects.

QN02.08.06

Magnetic Instabilities in Low-Dimensional Co\(_{0.75}\)Mg\(_{0.25}\)Ta\(_2\)O\(_6\) Trirutile  
Hector S. Fierro1, Raju Baral1, Baidyanath Sahu2, Bishnu Belbase3, Suji Bati4, Andre M. Strydom2, Thomas W. Heitmann2, Madhav Ghimire1,2, Haririkshnan S. Nair1,2 and Cristian Rueda1; 1Department of Physics, The University of Texas at El Paso, El Paso, Texas, United States; 2Physics, University of Johannesburg, Johannesburg, South Africa; 3Physics, Tribhuvan University, Kirtipur, Nepal; 4Condensed Matter Physics Research Center, Butwal, Nepal; 1Leibniz Institute for Solid State and Materials Research Dresden, Dresden, Germany; 4University of Missouri Research Reactor, University of Missouri, Columbia, Missouri, United States.

Using a combination of experiments and density functional theory (DFT) calculations, we probe the magnetic ground state of the low dimensional anisotropic ising-like system, Co\(_{0.75}\)Mg\(_{0.25}\)Ta\(_2\)O\(_6\) (x = 0, 0.1, 0.3, 0.5, 0.7, 1). Neutron diffraction data was collected at the high resolution neutron powder diffractometer (PSD) at MURR, Missouri. Co\(_{0.75}\)Mg\(_{0.25}\)Ta\(_2\)O\(_6\) adopts the tri-rutile space group P42/mnm in the whole composition range and does not undergo structural changes. Co\(_{0.75}\)Mg\(_{0.25}\)Ta\(_2\)O\(_6\) displays an antiferromagnetic ordering occurring below 6 K. For the x = 0 we observe additional low temperature magnetic transitions. With progressive Mg-doping the magnetic transition disappears and gives rise to short-range correlations with an enhancement in ferromagnetism. Our neutron and specific heat data neatly captures these features of low-dimensional magnetism. We performed DFT calculations with the full-potential local-orbital (FPLO) code using the generalized-gradient approximation (GGA) in the Perdew-Burke-Emzerhof (PBE) scheme. From DFT, the magnetic ground state is found to be ferromagnetic (FM) with the lowest energies among four different magnetic configurations within GGA. However, the small energy difference between the FM and first excited AFM state (\(\pm 15\) meV) is indicative of competing ground state. Here we report results for the FM state where band gap of 0.4 eV was found between the \(d_{xz}\) states in spin-down channel within GGA while that with U = 5 eV for Co, gap rises to ~3.0 eV. Further work is in progress to confirm the antiferromagnetic ground state as found in experiment.

QN02.08.07

Defect Dominated Trion Dynamics in Monolayer WS\(_2\)  
Paul D. Cunningham, Kathleen M. McCreary, Aubrey T. Hambicki and Berend Jonker; U.S. Naval Research Laboratory, Washington, District of Columbia, United States.

Weak screening of Coulombic interactions lead to strong many-body interactions in monolayer transition metal dichalcogenides (TMD). This gives rise to the formation of tightly bound excitons, many-body particles such as biexcitons, many-body scattering mechanisms such as exciton-exciton annihilation,\(^1\) and screening effects such as bandgap renormalization.\(^2\) Charged trions, where an exciton couples to a charge carrier, have been observed in the emission spectra of unintentionally doped TMDs and may form due to defect trapping of charge carriers in those materials. Recently, it was shown that adsorbed molecules can passivate defects in TMDs. Specifically, WS\(_2\)can be thermally or laser annealed in vacuum to remove atmospheric adsorbates and reveal trion emission;\(^3\) excitonic emission is restored under dry air flow. This is likely due specifically to adsorbed oxygen,\(^4\) which may bind to defect sites in the crystal lattice and neutralize their net charge. It is possible that these defect sites are the same sites responsible for regions of weak emission that have been universally observed in WS\(_2\).\(^5\) Interestingly, this annealing process can only be done for transferred monolayers indicating that strain in as-grown layers prevents this process.\(^1\) Here, we report the ultrafast dynamics of the trions in WS\(_2\). We use the aforementioned annealing process to remove atmospheric adsorbates from defect sites, effectively doping
the WS$_2$ and allowing for excitation of trions. We show that after annealing the trion absorption resonance appears in the ground state absorption spectra in addition to the typical A-exciton peak. We estimate the trion binding energy as 32 meV. In dry air, we see only the A-exciton resonance, which shows that oxygen and water vapor is responsible for neutralizing defect sites. Ultrafast transient absorption spectroscopy shows that excitons dissociate rapidly into trions. The decay of the photoexcited trions does not appear consistent with many-body Auger mechanisms, but instead appears to be dominated by trapping. We discuss the prospects for using annealing as a methodology for preparing trions states for studies targeting their valley polarization and valley lifetime. We conclude that while this is an effective means of creating trions for fundamental studies that ultimately the trap-limited lifetime may limit the usefulness of such states.

Electrical Conductivity of Stabilized Bilayer Graphene Jesús R. González Martínez$^1$, Jesús Ramiro Aragón Guajardo$^2$, Rogelio Gámez Corrales$^3$, Luis Ivan Serrano Corrales$^4$, Keren Hapuc Gutiérrez Acosta$^5$ and Anna Bertha López Oyarzá$^6$; 1Departamento de Investigación en Física, Universidad de Sonora, Hermosillo, Mexico; 2Ciencias Básicas, Instituto Tecnológico de Hermosillo, Hermosillo, Mexico; 3Departamento de Física, Universidad de Sonora, Hermosillo, Mexico; 4Departamento de Ingeniería Química y Metalurgia, Universidad de Sonora, Hermosillo, Mexico; 5Departamento de Matemáticas, Universidad de sonora, Hermosillo, Mexico; 6Conacyt, CICATA IPN, Altamira, Mexico.

In this paper an experimental study comparing the electrical conductivities of stabilized bilayer graphene with different organic materials is presented. To carry out this work we used a variant of the graphene synthesis method by mechanical graphite exfoliation, this method allows us to stabilize graphene with different materials, in this work we present the results of bilayer graphene stabilized with Bromide of hexadecyltrimethylammonium (CTAB), as well as with the biopolymers: xanthan gum and mezquite gum, and with the conductive polymer Polyvinylpyrrolidone (PVP). To perform the electrical conductivity tests, the Kelvin method or four-point method was used. The results presented are related to how the electrical conductivity of the graphenes varies in relation to the stabilizer, as well as in relation to the compaction pressure.

Grain Growth in Nanocrystalline MoS$_2$—An Experimental and Computational Investigation Aman Haque, Kehao Zhang, Joshua Robinson and Zahabul Islam; The Pennsylvania State University, University Park, Pennsylvania, United States.

In this present study, we investigate electron wind force driven recrystallization phenomenon in nanocrystalline Molybdenum disulfide (MoS$_2$) using in-situ Transmission Electron Microscope (TEM). We use a custom made micro electro-mechanical system (MEMS) device to bias the sample inside TEM. To investigate the effect of electron wind force as well as Joule heating on recrystallization phenomenon in MoS$_2$, we apply DC current at varying current density keeping it below the electro-migration failure limit. For low temperature (400 °C) chemical vapor deposited MoS$_2$, our electrical annealing scheme resulted in 3x decrease in electrical resistivity. Inside the TEM, we observed changes in selected area aperture diffraction (SAED) pattern at a current density of 1.0×10$^{-3}$ A/cm$^2$. This is an indication of grain growth phenomenon in MoS$_2$.

To comprehend the growth mechanism observed in TEM, we employ classical molecular dynamics (MD) simulation to investigate the underlying mechanism of grain growth using Reactive empirical bond-order (REBO) potential implemented in LAMMPS. In our present study, we build single layer polycrystalline MoS$_2$ with a grain size of 2.5nm using vonoroi-tessellation method. After building the model we checked overlapping of atoms at the grain boundaries. To incorporate both Joule heating and electron wind force effect, we conduct the experiment at different temperatures with an additional imparted electron wind force on each atoms. Grain boundaries of MoS$_2$ contains different types of ring defects such as 6|8, 5|7, 4|6, 4|8 as well as vacancy. 6|8 ring defects can be generated from 5|7 ring defects by inserting one Molybdenum (Mo) or 1 pair of Sulfur (S) atoms. On the other hand, 4|6 defects can arise from 5|7 defects by deleting one Mo or 1 pair of S atoms. In addition to this 6|8 ring defects can be healed to two perfect 6 rings and one 4 ring defects 4|6. In our present simulation, we also notice the similar ring defects recombination phenomena at the GBS of polycrystalline MoS$_2$. To investigate the defect annihilation at the grain boundaries of nanocrystalline MoS$_2$, we performed Nudged Elastic Band (NEB) simulation with 192 atoms containing 6|8, 4|6 and vacancy defects. Based on calculation, a defective sample containing these ring defects requires approximately 0.8 eV/atom additional energy to overcome the energy barrier. This additional energy could be provided during the electrical annealing of the sample in terms of Joule heating as well as imparted electron wind force. It is well-known that both electron wind force and Joule heating are concurrent phenomena during electrical annealing. Both Joule heating and electron wind force effect is beneficial for atomic/defect mobility. Due to the disorders and misorientations at the GBS, electron wind force are dominant at these defective sites and contributes pronounced scattering. In addition to the Joule heating, electron wind force could induce high atomic mobility at the GBS and annihilates defects to favor recrystallization. To investigate the effectiveness of annealing on mechanical properties we also conducted tensile testing of pre-annealed and post-annealed sample.

A Novel 2D Material—Long-Range Ferrimagnetic Order in a Two-Dimensional Supramolecular Kondo Lattice Jan Girovsky$^1$, Jan Nowokowski$^1$, Md. Ehesan Ali$^2$, Milos Baljozovic$^1$, Harald Rossmann$^1$, Thomas Nijs$^3$, Elise Aeby$^2$, Sylvia Nowokowska$^2$, Dorota Siewert$^4$, Gitika Srivastava$^1$, Christian Waeckerlin$^1$, Silvio Decurtins$^4$, Shi-Xia Liu$^5$, Peter Oppeneer$^1$, Thomas A. Jung$^6$ and Nirmalya Ballav$^7$; 1Paul Scherrer Institute, Villigen, Switzerland; 2Fondazione CRT, Pavia, Italy; 3Department of Physics, Swiss Nanoscience Institute, Univ. Basel, Basel, Switzerland; 4Institute of Nanoscience and Nanotechnology, Mohali, India; 5Department of Chemistry and Biochemistry, University of Bern, Bern, Switzerland; 6Department of Physics, University of Uppsala, Uppsala, Sweden; 7Chemistry, IISER, Pune, India.

Supramolecular assemblies of spin-bearing molecules on conducting substrates represent a rich platform to investigate the interplay of fundamental magnetic interactions and the emergence of novel properties in low-dimensional materials. Here we demonstrate the direct observation of long-range ferri-magnetic order emerging in a two-dimensional supramolecular Kondo lattice. The lattice consists of paramagnetic hexadeca-fluorinated iron phthalocyanine (FePhC) and manganese phthalocyanine (MnPc) molecules co-assembled into a checkerboard pattern on single-crystalline Au(111) substrates. Spectro-microscopy correlation experiments comprised by X-ray magnetic circular dichroism (XMCD) experiments and scanning tunneling microscopy and spectroscopy (STM/S) provide unambiguous evidence for the long range and local magnetic ordering. After magnetization at high magnetic fields (B > 6.5 T), remarkably, the remnant magnetic moments are oriented in out-of-plane direction containing significant orbital moment contributions. First-principles calculations reveal that the FePhC-MnPc antiferromagnetic nearest neighbour coupling is mediated by the Ruderman–Kittel–Kasuya–Yosida (RKKY) exchange interaction via the Au substrate electronic states.

Realization of long-range magnetic order in surface-supported two-dimensional systems has been challenging, mainly due to the competition between fundamental magnetic interactions such as the long-range Kondo effect and spin-stabilizing magnetic exchange interactions. The 2D ferrimagnetism in our case emerges from the high spin moment of the Fe and Mn atoms in the porphyrins, the precise 2D architecture and next nearest neighbor interactions mediated by the RKKY interaction. Our findings provide a prominent example of the supramolecular engineering of a 2D spin architecture with a weak nearest neighbor and next nearest neighbor interaction. Such systems invite for the local modification of individual spin systems e.g. by chemical ligation[2] and the investigation of the local response in the 2D array. Such novel, tunable and configurable "quantum breadboard"[3] materials allow for novel and insightful experiments directing towards their application in molecular quantum devices.

Role of Non-Covalent Interactions in Tuning Magnetic Properties of Two-Dimensional Materials Wei Ji; Renmin University of China, Beijing, China.

We theoretically show a symmetry breaking of magnetic moments in geometricaly equivalent Fe cations in Fe$_x$GeTe$_{2-x}$ few-layers using density functional theory calculations. The moments of two outermost Fe$^{2+}$ in a Fe$_x$GeTe$_2$ layer differ by 0.1 µB, which is a result of strongly inter-sub-layer coupled Fe cations. Such broken symmetry is exceptionally and
QN02.08.12
Disentangling the Oxygen and Water Vapor Effects on Optoelectronic Properties of Monolayer WS$_2$
Hanyu Zhang, Jeremy Dunklin, Obadiah Reid, Sanjini Nanayakkara, Jeffrey Blackburn and Elisa Miller; National Renewable Energy Laboratory, Lakewood, Colorado, United States.

Monolayer transition metal dichalcogenides (TMDCs) are perturbed by the atmosphere; therefore, optoelectronic measurements may vary from day to day and lab to lab. Thus, we quantify changes to the optoelectronic properties of WS$_2$ monolayers with careful environmental control, namely inert gas, dry air, and humid nitrogen. Our WS$_2$ monolayers are prepared by chemical vapor deposition, where defects are present. To probe changes to the optoelectronic properties, we employ state-steady photoluminescence, transient absorption, and time-resolved microwave conductivity measurements to monitor the different phenomena resulting from dry air and water vapor. We determine that oxygen and water molecules have disparate impacts on the photoluminescence, exciton dynamics, and photogenerated carriers of monolayer WS$_2$. Our work disentangles the oxygen and water contributions and how these molecules passivate the WS$_2$ monolayer surface, which leads to differences in the optoelectronic properties. These effects introduced by water or oxygen molecules can be reversed and the original pristine WS$_2$ recovered. The conclusion of this work can further develop the interface charge transfer dynamics as well as photocatalysis applications of TMDCs.

QN02.08.13
Transferrable Polymeric Carbon Nitride/Nitrogen-Doped Graphene Films for Solid–State Optoelectronics
Xin Gan, Feiyu Kang and Runuo Lyu; Tsinghua University, Beijing, China.

Polymeric carbon nitride (PCN) is a stable semiconducting material with an intermediate band gap (2-3 eV), which is efficient for catalysis and optoelectronics. However, it is still a big challenge to synthesize large-area and transferrable PCN films for applications in solid state optoelectronics. In this work, by using nitrogen-doped graphene (NG) as a van der Waals epitaxial substrate, centimeter-size PCN films are synthesized via polymerization of melamine molecules. As-grown PCN/NG films can be then transferred onto other substrates (e.g. SiO$_2$/Si wafers, quartz slides, polymer substrates). Structural characterization reveals a polymerized structure of PCN films with nitrogen-containing heterocycles. By stacking PCN/NG films with graphene films, it is possible to construct a photodetector responsive to near-UV and UV illumination under ambient conditions. The responsivities of the photodetector are 0.59 mA/W and ~30 μA/W towards 365 nm lamp and 488 nm laser, respectively. Our PCN photodetectors also show fast response times (e.g., ~0.29 s to 488 nm laser illumination). Furthermore, our PCN photodetector can be fabricated on polymer substrates. As-obtained flexible photodetectors can maintain its photo-response after 100 times bending. Our results clearly demonstrate the possibility of employing large-area carbon-based semiconductors to meet the increasing demands of wearable and portable electronics.

QN02.08.14
Long Valley Relaxation Time of Free Carriers in Monolayer WSe$_2$
Siyuan Yang, Tengfei Yan and Xiaodong Cui; The University of Hong Kong, Hong Kong, Hong Kong.

Monolayer transition metal dichalcogenides (TMDCs), known as two-dimensional semiconducting materials, exhibit unique features like strong spin-orbit coupling and spin-valley locking. The exotic natures have attracted more and more research interests of new physics in TMDCs such as spintronics and valleytronics. However, a critical problem that limits the application is the relaxation time of spin and valley polarization. In this work, we use time-resolved Kerr rotation spectroscopy to probe the valley dynamics of excitons and free carriers in monolayer tungsten diselenide. Our result shows that the valley relaxation time of free carriers is found around 2 ns at 70 K, about three orders of magnitude longer than the excitons of about 2 ps, and 15 times larger than that of trions (130 ps).

QN02.08.15
Probing the Exciton k-Space Dynamics in Monolayer Tungsten Diselenides
Tengfei Yan and Siyuan Yang; The University of Hong Kong, Hong Kong, Hong Kong.

The dynamics of bright excitons in monolayer tungsten diselenides is studied, by pumping at exciton ground state and probing at higher energy, where excitonic excited states can be identified from the pump-probe spectroscopy. Remarkably, the rise time of the differential reflection signal increases significantly with the index of the excited states, which we attribute to the phase-space filling effect that probes the momentum distribution of ground state exciton. Our results reveal fast exciton momentum relaxation as a signature of the strong Coulomb interaction in 2D TMDCs.

QN02.08.16
On the Electronic Properties of 2D Transition Metal Carbides and Nitrides (MXenes)
Kanit Hantanasisirakul, James L. Hart, Yizhou Yang, Mitra Taheri, Steven J. May and Yury Gogotsi; Drexel University, Philadelphia, Pennsylvania, United States.

2D transition metal carbides, carbonitrides, and nitrides, known collectively as MXenes, have been receiving a great deal of attention in several scientific communities due to their outstanding properties such as high electrical conductivity, versatile transition metal chemistry, tuneable surface chemistry, and hydrophilicity. They have shown promise in many applications including electromagnetic interference shielding, energy storage, transparent conductors, catalysis, photothermal therapy, and photonics. To date, about 30 MXenes such as Ti$_2$C, Ti$_3$C$_2$, Ta$_2$C$_2$, Mo$_2$C, Mo$_2$TiC$_2$, Mo$_2$Ti$_3$C$_2$, Nb$_2$C, and Nb$_2$C$_2$, have been experimentally synthesized and a dozens more predicted to be stable with interesting electronic properties. In this talk, an overview of electronic properties of this large 2D materials family is presented and discussed. Transport and magnetoelectric properties of free-standing MXene films were studied by temperature-dependent resistivity measurements from 2-300 K with and without external magnetic field up to 9 Tesla. Control over MXenes' electronic properties was achieved by controlling their intercalation and surface termination via high-temperature annealing in inert atmosphere.

QN02.08.17
Control of MXenes’ Electronic Properties Through Termination and Intercalation
James L. Hart, Kanit Hantanasisirakul, Andrew Lang, Babak Anasori, David Pinto, Yevheniy Pivak, J. Tijn van Ommer, Steven J. May, Yury Gogotsi and Mitra Taheri; Drexel University, Philadelphia, Pennsylvania, United States; DENSolutions, Delft, Netherlands.

MXenes are an emerging class of 2D transition metal carbides, nitrides, and carbonitrides which show promise for applications in energy storage, electromagnetic interference shielding, and catalysis. For these applications, MXenes’ excellent performance is largely due to their high metallic conductivity, and as such there is motivation to better understand and control their electronic properties. In this talk, we will discuss how the MXene surface termination and molecular intercalation can be engineered to maximize conductivity. Specifically, we will discuss in situ annealing and electrical biasing measurements of Ti$_2$C$_2$, Ti$_3$CN, and Mo$_2$TiC$_2$ performed within the TEM. With annealing, we observe molecular de-intercalation and surface de-functionalization via in situ annealing and ex situ TGA-MS. We show that intercalants strongly influence the inter-flake MXene resistance, and that intercalation can cause macroscopic negative dR/dT for multi-flake MXene samples which display metallic (positive dR/dT) intra-flake conductivity. We also show that high temperature annealing leads to the desorption of surface termination species, and that termination loss increases the MXene conductivity. This work furthers our fundamental understanding of MXene electronic properties and provides clear guidelines for optimizing the MXene conductivity for specific applications.
Surface-enhanced Raman spectroscopy (SERS) has been widely used for the analysis of ultra-low concentration bio and chemical molecules. Moreover, the SERS signals can be amplified to 10^{15} to 10^{17} times through highly localized surface plasmonic oscillations, enabling the possibility of single molecule detection. Two major theories such as chemical and electromagnetic enhancement theories are widely accepted in order to understand the enhancement mechanisms although the exact enhancement mechanism is still under debate in the literature. Among these, the electromagnetic enhancement is the first and major contributor for the SERS enhancement, which generally originates from the magnification of the electric field by the excitation of localized surface plasmons of underlying SERS active material. The second significant chemical enhancement of SERS relies on the charge transfer between chemisorbed species and the metal surface. In order to achieve both the enhancements, we developed a reliable SERS-active substrate by gold nanoparticles (Au NPs) decorated on defect-engineered CVD graphene. It is well known that the local electric field enhancement depends on the particle size, shape and also the gap between the particles in order to get the Raman signal enhancement in SERS. To achieve the Raman signal enhancement and to control the deposition density of the Au NPs, we have used a plasma treatment strategy. Experimentally, it has been observed that Au NPs are stabilized at defect sites. In an appreciation of the above, we have performed a plasma treatment of the monolayer graphene to create the defects. Control of in-plane defects in graphene was achieved by controlling the Ar/H₂ flow rates and plasma power, and post-growth functionalization was performed using electrochemical deposition. Quantitative analysis of the defect density and nature of the interaction of Au with graphene was performed using several analytical tools. As compared to the pristine graphene, higher Au NPs density and coverage is observed for plasma modified graphene samples. The intensity ratio of the D to the G band (I_D/I_G) for graphene was 1.30. However, the I_D/I_G ratio in the case of 15-sec sample was 2.31, indicating that the plasma exposure process has altered the structure of graphene with more structural defects. After gold deposition, there is a red shift in G and 2D peaks and enhancement in I_D/I_G ratio which indicates the functionalization of graphene with Au NPs. The morphological features of plasma treated graphene samples were investigated from the STEM. STEM data shows vacancy-type defects and extended line defects, which are formed during the plasma treatment. These substrates show high SERS activity toward the Rhodamine B probe molecules. The observed enhancement in SERS might be due to the structural disorder induced generation of local defects and the strong resonant energy transfer between Au NPs and graphene. Moreover, we also observed a strong quench in the background fluorescence signal from the Au and probe molecules due to the graphene. Hence, the defect-mediated efficient gold functionalization and easy charge transfer at the graphene gold interface is expected to be suitable for biosensing and Raman imaging applications.

Two dimensional materials have shown great promise in a variety of electrochemical energy conversion and storage applications, and their further developments require an improved understanding of the atomistic mechanisms and effective design principles. I will discuss how the electronic structure of 2D materials controls atoms adsorption, and use this understanding to explain a number of puzzles, including: why structurally similar C forms/defects have distinct binding energies with Li [1], and why graphite has a low Na capacity while a high capacity for other alkaline metals [2]. This understanding also leads us to new catalysts for water splitting [3]. Finally, I will discuss the effects of varying charge and fixed potential in electrocatalysis of 2D materials [4], which are often neglected in modeling but are important for 2D materials due to their peculiar electronic structure, calling for re-evaluation of their electrocatalytic mechanisms by incorporating these effects into simulations.

Mo-S coordination number and role of V$_2$ with extended X-ray absorption fine structure (EXAFS) and density functional theory (DFT) calculation. The polymorphic transition induced through gas-solid reaction could be applied regardless of form factor and TMD type, even when the MoS$_2$ layer was incorporated into the carbon matrix. It enabled the fabrication of 1T-MoS$_2$-carbon nanofillers as HER electrolytocalyst and its superior catalytic performance is discussed.

Magnetic Properties of Proton Irradiated MnSiTe$_3$ Single Crystals Luis M. Martinez$^1$, Christian Saj$^1$, Adrian Cosio$^1$, Rubayn Olmos$^1$, Hector Iturriaga$^1$, Yu Liu$^2$, Cedomir Petrovic$^2$, Lin Shao$^3$ and Srinivasa Rao Singamaneni$^3$; $^1$University of Texas at El Paso, El Paso, Texas, United States; $^2$Brookhaven National Laboratory, Upton, New York, United States; $^3$Texas A&M University, College Station, Texas, United States.

In the recent past, van der Waals crystals have garnered much attention due to their unique and interesting properties, putting them in the spotlight for current and future research. This attention is due to their unique and interesting properties such as cleavability and tuneable magnetism. In this study, we explore the magnetic properties of Mn$_2$Si$_2$Te$_3$ (MST), a less-studied analog of Cr$_2$Si$_2$Te$_3$, after proton irradiation, which has been used as a tool to tune the magnetic properties of various materials. MST is a ferrimagnet below ~78 K, with its moments lying along the ab plane. Here, single crystals were grown using the self-flux method [1]. Crystals were irradiated with a 2 MeV proton beam with a fluency of 10$^{16}$ cm$^{-2}$. Magnetic measurements, as well as heat capacity (HC) measurements, were performed using a Versalab Vibrating Sample Magnetometer (VSM) with a temperature range of 50 – 350 K and a magnetic field of ±3 T. From M(T) curves, an estimated Curie temperature (T$_C$) ~74.35 K ±0.05 K [1]. From HC curves, it is apparent that there is a phase transition at ~71.67 K. After proton irradiation, a decrease in magnetization is observed from 14.01 emu/g to 11.78 emu/g in the ab plane. It is believed that proton irradiation may have caused a break in the ordering of magnetic ions, which reduces the exchange interaction in the system, thus causing the decrease in magnetization [2]. The magnetic anisotropy in the H/c direction is also reduced, setting the ab-axis as the easy axis. To corroborate these results, temperature dependent electron spin resonance (ESR) measurements have also been performed before and after proton irradiation. Additional measurements such as X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), and Raman spectroscopy are in progress to gain deeper insights.

SESSION QN02.10/QN01.11/QN03.12: Joint Session: Materials Science with Two-Dimensional Atomic Layers

Thursday Morning, April 25, 2019

PCC North, 100 Level, Room 129 A

11:30 AM *QN02.10.01/QN01.11.01/QN03.12.01

Materials Science with Two-Dimensional Atomic Layers Pulickel Ajayan; Department of Materials Science and NanoEngineering, Rice University, Houston, Texas, United States.

There has been tremendous interest in recent years to study two-dimensional (2D) atomic layers which form building blocks of many bulk layered materials. This was started by the spectacular discovery of graphene. This talk will focus on the materials science of the emerging field of 2D atomic layers of various compositions. Several aspects that include synthesis, characterization of defects, doping and manipulation will be explored with the objective of achieving functional structures with atomic layer building blocks. The concept of nanoscale engineering and the goal of creating new artificially stacked van der Waals solids and 3D constructs will be discussed through a number of examples including graphene and other 2D layer compositions. The talk will explore the emerging landscape of 2D materials systems that include hybrid compositions and multi-component 2D alloys. Some of the anticipated applications of these materials will also be discussed.

2:00 PM QN02.11.02

Antiferromagnetic van der Waals Materials TMPS3 and Its Potentials Je-Geun Park; Seoul National University, Seoul, Korea (the Republic of).

Magnetic van der Waals materials has been fast emerging as a new exciting field just over the last few years. Among one of the few known examples, TMPS3 with TM=transition metal elements have attracted significant attentions as it can exhibit the three fundamental magnetic model of Ising, XY and Heisenberg Hamiltonian depending on the TM elements. In this talk, I will demonstrate how we can use this unique magnetic property of these materials to learn of the old physics.

Surface Termination Dependent Work Function and Electronic Properties of Ti\textsubscript{2}C\textsubscript{2}T. MXene Thorsten Schultz\textsuperscript{1}, Nathan Frey\textsuperscript{2}, Kanit Hantanasirisuk\textsuperscript{1,4}, Soohyung Park\textsuperscript{1}, Steven J. May\textsuperscript{2}, Vivek B. Shenoy\textsuperscript{3}, Yury Gogotsi\textsuperscript{1,4} and Norbert Koch\textsuperscript{1}; \textsuperscript{1}Department of Physics, Humboldt University Berlin, Berlin, Germany; \textsuperscript{2}Department of Materials Science and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; \textsuperscript{3}A.J. Drexel Nanomaterials Institute, Drexel University, Philadelphia, Pennsylvania, United States; \textsuperscript{4}Department of Materials Science and Engineering, Drexel University, Philadelphia, Pennsylvania, United States.

MXenes, an emerging family of 2D transition metal carbides and nitrides, have shown promise in various applications, such as energy storage, electromagnetic interference (EMI) shielding, conductive thin films, photonics, and photothermal therapy to name a few. Their metallic nature, wide range of optical absorption, and tunable surface chemistry are the key to their success in those applications. The physical properties of MXenes are known to be strongly dependent on their surface terminations. In this study we investigated the electronic properties of Ti\textsubscript{2}C\textsubscript{2}T for different surface terminations, as achieved by different annealing temperatures, with the help of photoclectron spectroscopy, inverse photoelectron spectroscopy and density functional theory calculations. We find that fluorine occupies a single adsorption site, whereas oxygen occupies at least two different adsorption sites. The band structure of Ti\textsubscript{2}C\textsubscript{2}T was measured and found to be largely in agreement with calculated band structures. We further measured the work function of Ti\textsubscript{2}C\textsubscript{2}T as a function of annealing temperature and found that it is in the range of 3.9-4.8 eV, depending on its surface composition. Comparing it to detailed DFT calculations shows that it is not simply obtained by averaging the work functions of uniformly terminated Ti\textsubscript{2}C\textsubscript{2} surfaces, but that the interplay between the different surface-terminates plays a crucial role.

Epitaxial Growth of Transition Metal Dichalcogenides—The Route to Wafer-Scale Single Crystal Monolayers Xiaotian Zhang\textsuperscript{1}, Tanushree H. Choudhury\textsuperscript{2}, Mikhail Chubarov\textsuperscript{2} and Joan M. Redwing\textsuperscript{1,4}; \textsuperscript{1}Materials Science and Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States; \textsuperscript{2}2D Crystal Consortium, The Pennsylvania State University, University Park, Pennsylvania, United States.

Transition metal dichalcogenides (TMDs, MoS\textsubscript{2}, WS\textsubscript{2}, etc.) possess a range of intriguing optical and electronic properties at the single layer limit including direct bandgap, high exciton binding energies and valley polarization. While significant scientific advances have been achieved using TMD flakes exfoliated from bulk crystals, continued interest remains for the development of wafer-scale processes for TMD films. The synthesis of large area single crystal monolayers requires an epitaxial technique where the substrate provides a template for orientation and lateral growth of TMD domains that merge with minimal grain boundary formation. This is challenging, however, due to rotational symmetry in TMDs which gives rise to twins and anti-phase domains in coalesced films.

Our studies have focused on the epitaxial growth of binary TMD monolayers (MoS\textsubscript{2}, WS\textsubscript{2}, WS\textsubscript{2}, and MoSe\textsubscript{2}) by gas source chemical vapor deposition (CVD) using metal hexacarbonyl and hydride chalcogen precursors. A multi-step precursor modulation method was developed to independently control nucleation density and the lateral growth rate of monolayer domains on the substrate. Using this approach, atomically coalesced monolayer and few-layer TMD films were obtained on 2” sapphire substrates at growth rates on the order of ~1 monolayer/hour. In-plane X-ray diffraction demonstrates that the films are epitaxially oriented with respect to the sapphire with narrow X-ray full-width-at-half-maximum. Post-growth transmission electron microscopy carried out on monolayers transferred from the sapphire reveals that the films consist of micron-sized single crystal regions formed from merging of clusters of 0° and 180°oriented domains which are bounded by anti-phase grain boundaries (APBs). A significant reduction in the density of APBs was observed for WS\textsubscript{2} grown on hBN transferred onto sapphire. In this case, single atom vacancies in the hBN surface, which act as preferred sites for WS\textsubscript{2} nucleation, break the surface symmetry leading to a preferred domain orientation. WS\textsubscript{2} monolayers epitaxially grown on hBN also exhibit increased photoluminescence intensity and improved transport properties (as measured in field-effect devices) compared to comparable layers grown on c-plane sapphire. The results demonstrate hBN as a superior substrate for epitaxial growth of single crystal TMD films with a reduced density of APBs and improved properties and motivate continued efforts in the development of high quality hBN templates for wafer-scale films.

Growth and Characterization of Monolayer WS\textsubscript{2}-ferromagnet Heterostructures for Spintronics Nguyen M. Vu\textsuperscript{1}, Steve Novakov\textsuperscript{1}, Bhakti Jarwala\textsuperscript{2}, Azimkhan Kozhakhmetov\textsuperscript{2}, Joshua Robinson\textsuperscript{1} and John Heron\textsuperscript{1}; \textsuperscript{1}University of Michigan, Ann Arbor, Michigan, United States; \textsuperscript{2}Pennsylvania State University, State College, Pennsylvania, United States.

Transition metal dichalcogenide (TMD) monolayers, such as WSe\textsubscript{2}, WS\textsubscript{2}, MoSe\textsubscript{2}, and MoS\textsubscript{2}, possess distinct physical properties due to the strong coupling between spin and valley degrees of freedom.\textsuperscript{(1, 2)} As monolayer TMDs have a direct bandgap lying in visible range, they have been studied extensively by optical methods.\textsuperscript{(2, 3)} Heterostructures of monolayer TMDs with other functional materials are currently attracting significant attention due to the opportunities to access and utilize their spin-valley degrees of freedom through electrical means.\textsuperscript{(4)} For instance, TMD-ferromagnet heterostructures have been employed recently to study spin current generation in TMDs. \textsuperscript{(4, 5)} The quality of atomically thin TMDs, however, is strongly affected by deposition techniques of metallic layers and have not been fully investigated.\textsuperscript{(6)} In this work, we report the fabrication of Pt/Co multilayer using pulsed laser deposition (PLD) on monolayer WSe\textsubscript{2} grown by metalorganic chemical vapor deposition (MOCVD) on single crystalline (0001)-oriented Al\textsubscript{2}O\textsubscript{3} substrates. PLD is a plasma based deposition technique capable of tuning of kinetic and thermodynamic conditions over an expanse range to elucidate and control fundamental structure-property relationships across a wide variety of material classes.\textsuperscript{(7)} Using Raman Spectroscopy, we monitor deposition induced damage on monolayer WSe\textsubscript{2}. The pressure of Argon process gas is found to suppress deposition induced defects in WSe\textsubscript{2}, which indicates that the primary source of defect generation comes from ion bombardment. Further, we report on magnetometry and spin torque measurements of our WSe\textsubscript{2}-ferromagnet heterostructures and demonstrate the generation of spin current from TMD layer. We anticipate that our results will advance the electrical investigation of spin-valley and spin generation phenomena in 2D hybrid heterostructures for spintronics.

We performed comprehensive measurements of the structural, magnetic and electronic properties of layered van-der-Waals ferromagnet VI$_3$ down to low temperatures. Despite belonging to a well-studied family of transition metal trihalides such as CrI$_3$, a-RuCl$_3$ and TiCl$_3$, this material has received very little attention. We outline, from high-resolution powder x-ray diffraction measurements, a corrected room-temperature crystal structure to that previously proposed and uncover a structural transition at 79 K, also seen as a peak in the heat capacity. Magnetization measurements confirm VI$_3$ to be a hard ferromagnet (9.1 kOe coercive field at 2 K) with a high degree of magnetic anisotropy, and the pressure dependence of the magnetic properties provide evidence for the two-dimensional nature of the magnetic order. Optical and electrical transport measurements show this material to be an insulator with an optical band gap of 0.67 eV - the previous theoretical predictions of d-band metallicity then lead us to believe VI$_3$ to be a correlated Mott insulator. Our latest band structure calculations support this picture and show good agreement with the experimental data. We suggest VI$_3$ to host great potential in the thriving field of low-dimensional magnetism and functional materials, together with opportunities to study and make use of low-dimensional Mott physics.

**Mobility Fluctuation Induced Linear Positive Magnetoresistance in 2D Semiconductor Bi$_2$O$_5$Se Nanoplates**

Peng Li$^1$, Ali Han$^2$, Chenhui Zhang$^2$, Xiaoxing Mao$^1$; Institute for Quantum Computing, University of Waterloo, Waterloo, Ontario, Canada; 2Physical Science and Engineering, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

Bi$_2$O$_5$Se is a promising 2D semiconductor with ultrahigh mobility and excellent stability in ambient conditions. We report the observation of positive and linear magnetoresistance in both types of chemical vapor deposited Bi$_2$O$_5$Se nanoplates, which have different underlying mechanism. In Se rich Bi$_2$O$_5$Se samples, the transport mobility is typically smaller than 300 cm$^2$/Vs, and they show a smaller linear magnetoresistance that is proportional to the mobility. In Se poor Bi$_2$O$_5$Se nanoplates, the pronounced Shubnikov-de Hass oscillations lie in the linear magnetoresistance background. The Bi$_2$O$_5$Se nanoplates show a typical 2D conduction feature with small effective mass, i.e. 0.02m0. The average transport Hall mobility, i.e. less than 5500 cm$^2$/Vs, is significantly reduced, compared to the ultrahigh quantum mobility that is as high as 16200 cm$^2$/Vs. The spatial mobility fluctuation induced by Se vacancies between conducting (Bi$_2$O)$_2$ layers gives rise to the linear magnetoresistance, which are strongly supported by Hall transport and Shubnikov-de Hass oscillation analyses. Our finding expands the understanding of this 2D semiconductor and explores its potential magnetoresistive device application.

1Physics Department, Politecnico di Milano, Milan, Italy; 2Institute of Condensed Matter and Nanoscience (IMCN), Université Catholique de Louvain, Louvain, Belgium; 3Institute of Materials Science, University of Valencia, Valencia, Spain; 4Cambridge Graphene Center, University of Cambridge, Cambridge, United Kingdom; 5CNR-ISM, Division of Ultrafast Process in Materials (FLASHit), Monterotondo Scalo, Italy; 6Université du Luxembourg, Luxembourg, Luxembourg.

Single layer Transition Metal Dichalcogenides (1L-TMDs) are 2D direct bandgap semiconductors that have recently received significant attention for their potential suitability in photonic and optoelectronic applications. Due to the strong quantum confinement, the optical response of 1L-TMDs is strongly renormalized by excitonic effects. In the electronic bandstructure of single layer MoS$_2$ we can distinguish A, B and C excitonic peaks at 1.9eV, 2.05eV and 2.87eV, respectively.

The phonon bandstructure of single layer MoS$_2$ identifies two Raman active optical phonon branches, A$_1$ (out-of-plane) and E' (in-plane). Raman spectroscopy is extensively used to determine the number of layers in TMD samples, according to the layer-dependent frequency shift of the characteristic optical phonon frequency. Although vibrational modes of TMDs have been largely investigated by continuous wave Raman scattering, their behaviour in the time domain is almost unexplored. For instance, the generation mechanism of coherent optical phonons is still unclear. A$_1$ and E' modes have characteristic frequencies of 378cm$^{-1}$ and 406cm$^{-1}$, respectively, and the corresponding coherent oscillation period in time domain is 86 fs for the E' mode and 82 fs for the A$_1$ mode.

Here we use visible femtosecond pump-probe spectroscopy to detect impulsively excited coherent optical phonons in single layer MoS$_2$, in order to track the electron-phonon coupling across A, B and C transitions, and to understand what is the fundamental generation mechanism of coherent phonons. A frequency tunable sub-20fs pump pulse excites electron-hole pairs in the system, while a time-delayed broadband probe pulse, covering A, B and C excitonic spectral region (1.8-3.1eV), monitors the transient optical response. We find that optical phonons coherently modulate the transient optical response across all the three excitonic transitions, but predominantly across the C peak. Superimposed on the coherent electronic relaxation, we can clearly distinguish coherent oscillations, which have a period of 82fs, an amplitude of 2% of the signal peak, and a dephasing time of 2ps. The Fourier transform of this oscillating signal is peaked at the frequency of the A$_1$ mode (406cm$^{-1}$), while no signature of the coupling with the E' mode is detected.

The oscillation amplitude, i.e. electron-phonon coupling strength, which is maximum across the C peak, significantly lowers approaching B and A transitions. These observations are quantitatively supported by *ab initio* calculations computed in the framework of finite-differences of the dielectric function, also including excitonic effects. The proposed mechanisms for the generation of coherent optical phonons are Impulsive Stimulated Raman Scattering (ISRS) and Displacive Excitation of Coherent Phonons (DECP). In case of ISRS, femtosecond laser pulses impulsively activate all the Raman modes, if the laser pulse is shorter than the period of the phonon oscillation. Instead in DECP as carriers are photoexcited a sudden change in the energy potential surface acts as a kick for the generation of coherent optical phonons. Different from ISRS, DECP requires a preserved lattice symmetry, therefore only the A$_1$ mode (out-of-plane) can be excited. This strongly calls for the exclusive coupling with the A$_1$ mode and the absence of the E' mode, which is exactly what we observe.

The generation mechanism can be also deduced by the trend of the optical amplitude with the pump photon energy. As it is tuned from 2eV (A-B peaks) towards 3eV (C peak) the A$_1$ oscillations amplitude has a dramatic increase, and it lowers again for higher pump photon energies (4.3eV). *Ab initio* calculations also confirm that this trend tracks the imaginary part of the Raman susceptibility tensor, as required in DECP process.

All these observations reveal that in single layer MoS$_2$ the fundamental mechanism which is responsible for the generation of coherent optical phonons is the displacive excitation.
Neuromorphic computing systems using electronic synapses and neurons have been extensively studied in recent years due to its ability to perform analog computing for artificial intelligence. It is also expected to overcome the high energy and various limitations of today’s computing systems. Most of all analog switching device based on the two-terminal memristor, such as conductive bridging random access memory (CBRAM) and oxide based resistive random access memory (RRAM). The memristors are operated by movement of anion vacancies or forming of metal filament, which exhibit relatively good retention and endurance for neuromorphic circuits. However, since the anion vacancies or metal ions must move within the oxide by an electric field, these devices necessarily require high operating voltages of several V or more even few-nm switching oxide. The high operating voltage causes problems such as reduced overall device stability and increased device operation energy.

On the other hand, TMDC (transition metal dichalcogenide) materials have been of much attention as a kind of two dimensional (2D) material, due to its high carrier mobility and compressibility. The TMDC materials effectively block metal ion transport due to the high bonding energy and the close packing structure of atoms within the single layer. However, the metal ions can be transported through defect sites such as grain boundaries and vacancies, thus enabling the operation of the TMDC memristor. In particular, the bi-layer TMDC, in which the defect site is effectively controlled through transfer process, has the advantage of significantly improving the device-to-device uniformity and endurance. This is because the transfer process with rotation converts most of the defect sites to point defects. In contrast, the mono-layer TMDC has high possibility of line defect such as grain boundary, so that the uniformity and endurance of memristor are not secured.

Finally, we fabricated the memristors of metal / 2L-MoS\textsubscript{2} / metal structure using MOCVD technique and rotated transfer method. These devices show bipolar memristor behavior with a lower set/reset voltage of \(0.5 \text{V} \sim 0.47 \text{V}\) than the conventional oxide based memristor. The resistance changes of the device from tens of to hundreds of ohms-um\textsuperscript{-2}\ is found to occur mainly in 2D materials through external voltage measurement. It also shows the possibility of analog memory whose resistance varies linearly with bias applied from 0.3 \text{V}. Also, we confirmed STDP (spike-timing-dependent plasticity) operation in a single device, and tested various applications using a cross-bar structure. This work is an important foundation for developing devices physics to understand the memristive characteristics of 2D material-based memristor and providing neuromorphic computing systems based on such memristors.

**Synergistic Gating of Electro-Iono-Photoactive 2D Chalcogenide Neuristors—Co-Existence of Hebbian and Homeostatic Synaptic Metaplasticity**

Rohit A. John, Arindam Basu, Zheng Liu and Nripan Mathews; Nanyang Technological University, Singapore, Singapore.

Emulation of brain-like signal processing with thin-film devices could lay the foundation for building artificially intelligent learning circuitry in future. Encompassing higher functionalities into single artificial neural elements will allow the development of robust neuromorphic circuitry emulating biological adaptation mechanisms with drastically less neural elements, mitigating strict process challenges and high circuit density requirements necessary to match the computational complexity of the human brain. Here, 2D transition metal dichalcogenide (TMDC) (MoS\textsubscript{2}) neuristors are designed to mimic intracellular ion endocytosis-exocytosis dynamics / neurotransmitter-release in chemical synapses using three approaches: (i) electronic-mode: a defect modulation approach where the traps at the semiconductor-dielectric interface are perturbed, (ii) ionotronic-mode: where electronic responses are modulated via ionic gating and (iii) photoactive-mode: harnessing persistent photoconductivity or trap-assisted slow recombination mechanisms. Exploiting a novel multi-gated architecture incorporating electrical and optical biases, this incarnation not only addresses different charge-trapping probabilities to finely modulate the synaptic weights, but also amalgamates neumodulation schemes to achieve “plasticity of plasticity-meta-plasticity” via dynamic control of Hebbian spike-time dependent plasticity and homeostatic regulation. Co-existence of such multiple forms of synaptic plasticity increases the efficacy of memory storage and processing capacity of artificial neuritors, enabling design of highly efficient novel neural architectures.

Recent Progress on 2D Monolayer Memory Devices

This work advances the down-scaling progress of memristive devices without sacrificing key performance parameters such as power consumption (< 20 nW) or applicability to lateral on-dielectric memtransistors from monolayer molybdenum disulfide (MoS2) utilising a focused helium ion beam.

Site-specific localised irradiation with the focused probe of a helium ion microscope (HIM) allows for the creation of charged defects in the MoS2 lattice, confining the damaged region to ~5 nm. The reversible drift of these locally-seeded defects in the applied electric field changes the resistance of the semiconducting channel, opening up versatile memristive functionality due to additional tuning by the field effect. The device can reliably retain its resistance ratios and SET voltages for hundreds of switching cycles at sweep frequencies of up to 2.9 V/s. High-resolution Raman and PL spectroscopy mapping has been employed to reveal the role of mobile defective sites in the switching mechanism of the device by proxy monitoring of adsorbate-enhanced luminescence.

Cryogenic charge transport studies down to 1.5 Kelvin have revealed the impact of defect drift on device operation; parametrised by large differences between the low and high resistance states in: threshold voltages, electron mobility scaling, carrier localisation lengths, Schottky barrier heights, amplitude of 1/f noise and current density saturation. In addition, an early onset metal-insulator transition occurs in the low resistance state of the memtransistor due to the high degree of reversible doping brought about by the drift of mobile n-type donors. Moreover, we demonstrate long term potentiation and depression with sharp habituation that promises rich applications in future neuromorphic architectures, as well as the ability to tune device conductance by cross-terminal stressing with perpendicular contacts.

This work advances the down-scaling progress of memristive devices without sacrificing key performance parameters such as power consumption (< 20 nW) or applicability to synaptic emulation. In addition, we push forward the understanding of resistive switching in atomically thin devices and demonstrate the utility of field-controllable dopant drift in facilitating exotic phenomena in two dimensions.

Two-dimensional layered semiconductors have recently emerged as attractive building blocks for next-generation low-power non-volatile memories. However, challenges remain in the controllable sub-micron fabrication of bipolar resistively switching circuit components from these novel materials. Here we report on the scalable experimental realisation of lateral on-dielectric memtransistors from monolayer molybdenum disulfide (MoS2) utilising a focused helium ion beam. This work advances the down-scaling progress of memristive devices without sacrificing key performance parameters such as power consumption (< 20 nW) or applicability to synaptic emulation. In addition, we push forward the understanding of resistive switching in atomically thin devices and demonstrate the utility of field-controllable dopant drift in facilitating exotic phenomena in two dimensions.

This work advances the down-scaling progress of memristive devices without sacrificing key performance parameters such as power consumption (< 20 nW) or applicability to synaptic emulation. In addition, we push forward the understanding of resistive switching in atomically thin devices and demonstrate the utility of field-controllable dopant drift in facilitating exotic phenomena in two dimensions.

Monolayers of 2D materials have ultrahigh mechanical strength, which enables application of very large elastic strains (e.g., ~11% for MoS2 and 25% for graphene). The ability of sustaining such large elastic strain offers unprecedented opportunities to engineer the physiochemical properties by applying mechanical strain. In this talk, I will present two examples on the effect of strain on the properties of MoS2 layer. The first example shows that elastic tensile strain reduces the bandgap of MoS2. When a gradient strain field is applied to MoS2 monolayer, the created bandgap gradient acts as an efficient funnel of photogenerated excitons that leads to enhanced photoluminescence. The second example shows that when elastic strain is applied to the sulfur vacancy on the basal planes of monolayer 2H-MoS2, the strain modifies the local electronic structure and catalytic activity.

This talk will present the latest research progress on 2D memory materials and devices, otherwise known as atomristors. In particular the talk will highlight our work on fundamental research on switching mechanisms, performance limits, and the new application of zero-power non-volatile radio-frequency (RF) switches. The fundamental understanding is enabled by in-situ scanning tunneling microscopy studies, materials characterization, and first principles modeling. The monolayer memory devices offer fast switching below 15ns, relatively high retention and the prospects of high endurance with further studies. From an application perspective, the non-volatile RF switches offer superior scalability compared phase-change memory RF switches.
Liquid exfoliation has become an important production technique to give access to large quantities of two-dimensional nanosheets in colloidal dispersion. Importantly, this is a highly versatile technique that can be applied to numerous layered materials. In this talk, recent advancements in the liquid-exfoliation and optical characterization of a range of 2D-materials will be summarized. Unifying principles among various classes of materials in both centrifugation and optical properties were identified recently. Materials under study include various commercially available TMDs, GaS, InSe, h-BN, hydrides, and more exotic candidates such as RuCl$_3$, PdSe$_2$, LaSeTe$_2$, NiPS$_3$ or even novel synthetic organic sheet stacks (2D polymers and COFs).

All materials can be exfoliated and size-selected in a similar way yielding nanosheet dispersions with well-defined changes in their lateral dimensions and thickness. This allowed us to develop a model to understand the exfoliation in high energy processes in greater depth. In brief, the "exfoliation efficiency" (defined by the combination of layer number and lateral size that can be produced) is dependent on both interlayer and intralayer interactions. In addition, similar to the effects previously observed for MoS$_2$ and WS$_2$, the optical extinction and absorbance spectra show systematic changes across all material classes. This is of great practical importance as it allows for a rapid size determination via optical spectroscopy which can be used for further optimization of the sample preparation. For example, centrifugation can be designed in such a way to enrich dispersions in monolayers without significantly changing their lateral dimensions. In addition, we show that liquid-exfoliated nanosheets and the fundamental understanding of their optical properties is an ideal foundation to track potential degradation due to reaction with water and oxygen at time and temperature dependent optical measurements of the dispersions. This in turn allows us to elaborate ways to chemically passivate defect sites and quantify the efficiency of various passivation pathways.

Germanium- and Tin Chalcogenides—Growth, Heterostructure Formation, Devices, Nanoscale Light-Matter Interactions

Peter Sutter and Eli Sutter, University of Nebraska—Lincoln, Lincoln, Nebraska, United States.

Two-dimensional group IV (Ge, Sn) monochalcogenides – compound analogues of phosphorene – are of fundamental interest due to their anisotropic crystal structure and predicted characteristics such as large exciton binding energies, tunable band offsets and charge separation in heterostructures, selective valley polarization, and multiferroic order in semiconductors with bandgaps in the visible and near-infrared range. To access these predicted properties and pave the way for applications of this family of 2D semiconductors, robust approaches toward single-layer group IV chalcogenides are required. However, realizing monolayers of this class of materials has proven challenging, both by top-down (exfoliation) and bottom-up (growth) approaches.

Here, we discuss results from in-situ low-energy electron microscopy that shed light on the fundamental growth mechanisms and identify the factors that complicate the synthesis of monolayers. We have used this insight to determine avenues for growing ultrathin crystals with thickness down to a single layer, as well as few-layer heterostructures, e.g., between mono- and dichalcogenide phases involving the same metal species. The functional properties of these materials are explored through charge transport in devices, and in particular via measurements of light-matter interactions with nanometer resolution using cathodoluminescence spectroscopy in scanning transmission electron microscopy (STEM-CL). Using a tightly focused electron beam as an excitation source, STEM-CL provides spectroscopy and mapping of light emission far below the diffraction limit to address band-edge luminescence, excitonic effects, charge separation in heterostructures, and confined photonic modes in monochalcogenide mesostructures.

Electromagnetic Response of Large-Area Graphene Films

Byung Hee Hong, Seoul National University, Seoul, Korea (the Republic of).

Magnetism of graphene has attracted much attention because of its combined charge and spin manipulation useful for futuristic spintronic devices. In addition, the magnetism of carbon-based materials is particularly important for lightweight actuator/sensor devices and electromagnetic wave shielding in flexible electronics. The previous studies on graphene’s magnetism were mainly focused on paramagnetism and ferromagnetism that are related to electron spins, but the diamagnetism induced by the orbital motion of two-dimensional electron gas has been studied only by theoretical approaches due to the lack of measurable amount of samples. Recent advances in large-scale synthesis of graphene enabled a facile preparation of massive graphene samples by multiple stacking and transfer. Here we report a giant orbital diamagnetism in ultra-thin, lightweight, flexible, and transparent graphene films grown by chemical vapor deposition (CVD), where the diamagnetic susceptibility in perpendicular direction is measured to be ~100 times greater than the strongest diamagnetic materials such as bismuth. As a result, the graphene film also exhibits two orders stronger electromagnetic interference (EMI) attenuation characteristics normalized to the thin film thickness than conventional EMI shielding or absorbing materials over wide frequency ranges. The EM wave induces an oscillating magnetic moment generated by the orbital motion of moving electrons, which efficiently absorbs the EM energy and dissipate it as a thermal energy. In this case, the mobility of electron is more important than the conductivity, because the EM-induced diamagnetic moment is directly proportional to the speed of electron in an orbital motion. To control the charge carrier mobility of graphene we functionalized substrates with assemblies of monolayers (SAM). As the result, we find that the graphene showing the Dirac voltage close to zero can be more efficiently heated by EM waves. In addition, the temperature gradient also depends on the number of graphene. We expect that the efficient and fast heating of graphene films by EM waves can be utilized for smart heating windows and defogging windshields.

Tailoring Commensurability of hBN/Graphene Heterostructures Through Substrate Morphology and Epitaxial Growth Conditions

Daniel J. Pennachio, Chance C. Omelas-Skarin, Nathaniel S. Wilson, Elliot C. Young, Anthony P. McFadden, Tobias L. Brown-Heft, Kevin M. Daniels, Rachael L. Myers-ward, D. K. Gaskill, Charles R. Eddy and Chris Palmstrom, Materials Department, University of California, Santa Barbara, California, United States; Electrical Engineering and Computer Science, University of California, Irvine, Irvine, California, United States; Electrical and Computer Engineering, University of California, Santa Barbara, California, United States; U.S. Naval Research Laboratory, D.C., District of Columbia, United States.

Many of the intriguing properties of single-crystal 2D devices rely on the relative rotational alignment between layers. For instance, in the graphene/hBN system, substantial band structure modulation can occur at specific interlayer alignments [1], but a misalignment may be beneficial if innate graphene properties are to be examined, as in the case with near-commensurate bilayer graphene showing superconductivity [2]. To allow for scalable graphene/hBN heterostructure formation, this work investigates hBN growth on single-crystal epitaxial graphene (EG) on macroscopically aligned SIC(0001) substrates. The presented results suggest that the EG/SiC(0001) macrosteps influence hBN epitaxy such that a metastable, 30° in-plane hBN/EG rotational alignment is more favorable in certain growth regimes than the fully commensurate hBN/EG alignment, despite their similar crystal structures.

Plasma-enhanced chemical beam epitaxy (PE-CBE), an ultra-high vacuum (UHV) compatible process, was utilized to provide a clean environment for examination of the hBN structural, electrical, and chemical properties via in-situ and in-vacuo characterization methods. To determine the effect of substrate macrostep morphology, SIC(0001) substrates with a 4° offset toward <1120> and nominally on-axis substrates were used. The alignment of the hBN/EG/SiC(0001) heterostructure was studied by relating in-situ electron diffraction to nuclei edge directions found using ex-situ atomic force microscopy (AFM). Preferential alignment of the hBN nuclei edges to the SIC macrosteps was found in growths with a lower precursor flux (~1 nm/hr. growth rate), while far lower preference was found for higher-flux depositions (16 nm/hr growth rate). In addition, cross-sectional TEM confirmed the registry and rotational alignment of the hBN to the EG/SiC substrates for both growth conditions, while plan-view TEM showed a single crystal alignment.

Energy dispersive X-ray spectroscopy (EDS) during scanning TEM showed the graphene layers remained after the growth process and an atomically sharp hBN/EG interface was present. No hBN/EG intermixing between the layers was detected in either EDS or X-ray photoelectron spectroscopy (XPS). High-resolution topographic measurements and electrical measurements confirming the dielectric integrity of the hBN layer were performed using in-vacuo scanning tunneling microscopy (STM) and conducting AFM. The macrostep-directed epitaxy of hBN on EG highlighted in this work shows how different levels of commensurability can be achieved solely by tuning growth parameters during van der Waals epitaxy, thus reducing the reliance on manual rotation during film transfer and increasing the viability of scalable, single-crystal heterostructure growth.
Two-dimensional (2D) layered 3-rhombobedral (3R) phase transition metal dichalcogenides (TMDs) have received significantly increased research interest in nonlinear optical applications due to their unique crystal structures and the broken inversion symmetry. However, controlled growth of 2D 3R phase TMDs still remains a great challenge. In this work, we report a universal growth method for large area TMDs atomic layers with controllable crystal phases via a developed temperature selective physical vapor deposition route. Large area triangular 3R phase TMDs (e.g. WS\textsubscript{2} and WSe\textsubscript{2}) layers are synthesized at a lower deposition temperature. Steady state and time-resolved photoluminescence (PL) spectroscopy and Raman spectroscopy have been used to study the unique properties of 3R phase layers due to different layer stacking and interlayer coupling. Moreover, with broken inversion symmetry, 3R phase layers show a quadratically increased second harmonic generation (SHG) intensity with respect to layer numbers. Furthermore, by polarization-resolved SHG, we observe a uniform polarization preference in bilayer and trilayer 3R phase WS\textsubscript{2}, which could be a benefit for practical applications. Our results not only contribute to the controlled growth of 2D TMDs layers with different phases but also pave the way to the promising nonlinear optical devices.

Chemical Vapor Deposition Synthesis and Characterization of Ultra-Thin Single-Crystal Metallic Molybdenum Dioxide Nanosheets

Anup Chakraborty, Sandhya Susarla, Anand B. Puthirath and Pulickel Ajayan; Rice University, Houston, Texas, United States.

Two-dimensional materials such as graphene and transition metal dichalcogenides (TMDs) show intriguing properties compared to their bulk counterparts. Most of these materials crystallize in hexagonal systems with covalent bonding in two dimensions and weak van der Waals' bonding in the out-of-plane direction. Recently, two-dimensional transition metal oxides have attracted enormous attention due to their unique differences compared to the other chalcogenides in terms of structure, properties, and chemistry which are important for potential applications. Most syntheses so far have been achieved via exfoliation and sol-gel methods which result in good yield but lack size and quality control. In this work, we explore the synthesis of ultra-thin molybdenum dioxide (MoO\textsubscript{2}) nanosheets using chemical vapor deposition. Unlike Mo-based chalcogenides, MoO\textsubscript{2} crystallizes in a monoclinic structure with anisotropy. We achieve single-crystal flakes with lateral size of tens of microns and thickness of ~5 nm as confirmed via atomic force microscopy. The crystal structure is verified with high resolution transmission electron microscopy and grazing incidence X-ray diffraction whereas Raman, FTIR, and X-ray photoelectron spectroscopies reveal the intricate changes in the bond vibration and binding energy shifts. The flakes show strong optical absorption at ~550 nm and high metallic conductivity as verified by transport measurements. The structural anisotropy of the as-synthesized MoO\textsubscript{2} flakes was verified with polarized Raman spectra for vibration modes at 205 cm\textsuperscript{-1} and 745 cm\textsuperscript{-1}. Experiments for hydrogen evolution reaction showed catalytic properties of the as-synthesized MoO\textsubscript{2} nanoflakes at 0.4V. The mechanical properties of the flakes were investigated with nanoindentation and nanoscratch experiments. The work shows a facile way of synthesizing metallic nanosheets with potential optoelectronic, catalytic, and mechanical applications.

4:30 PM QN03.02.08

Oligothiophene-Bridged Conjugated Covalent Organic Frameworks

Niklas Keller, Derya Bessinger, Stephan Reuter, Mona Calik, Laura Ascherl, Fabian Hanusch, Florian Aurual and Thomas Bein; LMU Munich, Munich, Germany; University of Cambridge, Cambridge, United Kingdom.

2-Dimensional covalent organic frameworks (2D-COFs) are crystalline porous materials comprising aligned columns of π-stacked building blocks. Regarding potential applications of COFs in organic electronics and optoelectronics, access to oligothiophene-based COFs would be of great interest. However, the realization of such materials has remained a challenge, in particular concerning the laterally conjugated imine-linked COFs. We have developed a new building block design, implementing an asymmetric modification on an otherwise symmetric backbone that allows us to obtain a set of highly crystalline quaterthiophene (4T)-derived COFs with tunable electronic properties. Studying the optical response of these materials, we have observed for the first time the formation of a charge transfer state between the COF subunits across the imine bond.

In this work, we have developed the first quaterthiophene-based 2D covalent organic frameworks comprising ordered π-stacked columns of 4T and pyrene moieties. Applying an asymmetric functionalization strategy of the otherwise C2-symmetric 4T backbone allowed us to incorporate alkyl chains for optimized solubility while still retaining the ability of the building blocks to stack in close-packed face-on thiophene columns. We also demonstrate that this approach provides a facile route for modifying the electronic properties of the 4T backbone via incorporation of electron-deficient subunits, thus forming donor-acceptor type chromophores. The absorption and emission spectra confirm that the 4T-based building blocks are electronically integrated into the framework. Spectral features below the energy of the π-π* transition and the analysis of the corresponding emission decay time traces reveal the fast and efficient formation of a charge transfer state between the imine-linked pyrene and quaterthiophene subunits. We believe that our new asymmetric building block design provides a general strategy for the synthesis of well-ordered COFs from various extended building blocks. This will greatly expand the range of applicable molecules for realizing frameworks with tailor-made optoelectronic properties.

4:45 PM QN03.02.09

Bottom-Up Synthesis of Ultrathin PdSe\textsubscript{2} Crystals with High Electron Mobility

Yixi Qin\textsuperscript{1, 2, 4}, Yiling Yu\textsuperscript{1}, Chenze Liu\textsuperscript{1}, Hui Cai\textsuperscript{2}, Akino Odo\textsuperscript{2}, Anna N. Hoffman\textsuperscript{1}, Yu-Chuan Lin\textsuperscript{1}, Alexander A. Puretzky\textsuperscript{2}, Gerd Duscher\textsuperscript{2}, Philip D. Rack\textsuperscript{1, 2}, Christopher M. Rouleau\textsuperscript{1}, David B. Geonhgan\textsuperscript{1} and Kai Xiao\textsuperscript{1}; Key Laboratory of Photochemical Conversion and Optoelectronic Materials, Technical Institute of Physics and Chemistry, Chinese Academy of Sciences, Beijing, China; Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; Department of Materials Science and Engineering, The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; University of Chinese Academy of Sciences, Beijing, China.

PdSe\textsubscript{2} is a high-mobility 2D material that has an unusual pentagonal structure, leading to buckled and puckered layers. Its strong interlayer coupling results in highly interesting and asymmetric optoelectronic properties and makes it difficult to exfoliate. However, to date it has not been directly synthesized on substrates. In this work, we report the bottom-up, vapor transport growth of few-layer PdSe\textsubscript{2} crystals that are rectangular and tens of microns in size. The high quality of the PdSe\textsubscript{2} crystals were confirmed by low-frequency Raman spectroscopy, atomic force microscopy (AFM), and high resolution annular dark field scanning transmission electron microscopy (ADF-STEM). Second-harmonic generation (SHG) mapping analysis of the PdSe\textsubscript{2} flakes was used to characterize their strong optical anisotropy. Field-effect transistors made from the few-layer PdSe\textsubscript{2} crystals revealed tunable ambipolar charge carrier conduction with a high electron mobility of ~78 cm\textsuperscript{2}V\textsuperscript{-1}s\textsuperscript{-1}, which is comparable to that of exfoliated PdSe\textsubscript{2}, indicating the promise of this anisotropic 2D material for electronics.

Synthesis science was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences (BES), Materials Sciences and Engineering Division and characterized were performed at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.
The continuous miniaturization of electronic devices has propelled modern technologies to higher performance and efficiency, but future progress requires a shift from traditional semiconductors towards new multifunctional systems and integration technologies. The development of two-dimensional (2D) van der Waals (vdW) crystals has led to the discovery of new phenomena and the realization of several functional devices. Among these vdW crystals, the metal chalcogenide InSe compound represents a promising semiconductor [1-6]. Our recent demonstration of fast broad-band photodiodes [1], field effect transistors (FETs) with electron mobility higher than in Si-FETs [3], and quantum devices [4, 6] has revealed the great potential of this material. From the growth and fundamental studies to the demonstration of prototype devices, this talk will describe how these systems can provide a platform for scientific investigations and new routes to 2D electronics and optoelectronics.

Hexagonal Boron Nitride as a Buffer Layer in Monolayer Molybdenum Disulfide Transistors

*Alexander L. Mazzoni*1,2, Sina Najmaei1, Katherine Price1,2, Robert Burke2, Michael D. Valentin1,2, Matthew Chin1,2 and Madan Dubey2; 1University of Maryland, Adelphi, Maryland, United States; 2U.S. Army Research Laboratory, Adelphi, Maryland, United States; 3Duke University, Durham, North Carolina, United States; 4University of California, Riverside, Riverside, California, United States.

One current problem with the fabrication of devices using two-dimensional (2D) materials as the semiconducting channel is the formation of a high-quality semiconductor-dielectric interface. Seeding for atomic layer deposition (ALD) films is notoriously difficult on van der Waals (vdW) layers due to the absence of dangling bonds. One method to improve the seeding on vdW materials is to use plasma-enhanced atomic layer deposition (PEALD). However, PEALD often damages the top-most layers which prevents the use of PEALD on monolayer materials.

Here we investigate the use of few-layer hexagonal boron nitride (h-BN) as an interfacial buffer layer transferred on top of monolayer molybdenum disulfide (MoS2) before deposition of the top dielectric. Top-gated monolayer MoS2 transistors with various dielectric stacks are fabricated and the h-BN layers’ impact is characterized via optical and electrical measurements.

What Limits the Intrinsic Carrier Mobility of Two-Dimensional Metal Dichalcogenides?

Yuanyue Liu; The University of Texas at Austin, Austin, Texas, United States.

Two-dimensional (2D) metal dichalcogenides (MX2) are the most common type of 2D semiconductors and have shown great potential for a wide range of chemical and physical applications. However, they are limited by a low electron/hole mobility, which has been recognized as one of the major challenges impeding their further developments, and urges efforts to understand the mobility-limiting factors and discovery of higher-mobility alternatives. Here using density functional perturbation theory and Wannier interpolation of the electron-phonon matrix to study a wide range of MX2, we find that the intrinsic carrier mobility, in contrast to common belief, neither correlates with the effective mass nor can be assessed by the widely used deformation potential theory; instead it is limited by the longitudinal optical (LO) phonon scattering for most MX2, while for MoS2 and WS2, the mobility is limited by the longitudinal acoustic (LA) phonon scattering. Furthermore, we find that the LO scattering strength is strongly correlated with the magnitude of the Born effective charge, suggesting that the carrier transport is greatly affected by the electric polarization change induced by the atomic vibration. This finding enables us to use the Born effective charge to rapidly screen the 2D MX2 database for high-mobility semiconductor candidates. Our work reveals the underlying factors governing the intrinsic carrier mobility of 2D MX2, and offers a practical descriptor for discovering high-mobility candidates.

Enhancement and Control of Circularly Polarized Emission in Monolayer Heterogeneous WS$_2$ with a Plasmonic Chiral Metasurface Wei-Hsiang Lin$^1$, Pin Chieh Wu$^1$, George. R. Rossman$^2$, Na-Chang Yeh$^3$ and Harry Atwater$^4$; 1Department of Applied Physics, California Institute of Technology, Pasadena, California, United States; 2Department of Physics, California Institute of Technology, Pasadena, California, United States; 3Division of Geological and Planetary Science, California Institute of Technology, Pasadena, California, United States.

Controlling the circular polarization of light is a key aspect for the development of functional nanophotonics for emerging applications. Monolayer transition metal dichalcogenides (TMDCs) are excellent candidates for spintronic, valleytronic and optoelectronic devices because the two inequivalent valleys in the Brillouin zone can give rise to valley-polarized photoluminescence (PL) under excitation with circular polarized light (CPL). However, the atomic monolayer thickness is a significant challenge for WS$_2$ photoluminescence emission due to its weak light-matter interaction. We investigated the feasibility of enhancing the light-matter interaction in monolayer WS$_2$ by means of the exciton-plasmon interaction with spin-orbit coupling of light. This objective was achieved by designing and fabricating plasmonic spiral rings with subwavelength dimensions on a hybrid substrate for WS$_2$, and by synthesizing high-quality WS$_2$. Specifically, we developed controlled growth of heterogeneous domains in CVD-grown monolayer WS$_2$ single crystal on SiO$_2$/Si substrate using tungsten oxide and sulfur precursors at T=850 degree C. Spatially resolved PL, Raman, X-ray photoelectron spectroscopy and Kevin probe force microscopy images revealed the formation of homojunctions in these single crystals which imply a direct correlation between the chemical stoichiometry and optoelectroheterostructure. The WS$_2$ were integrated with a plasmonic spiral ring metasurface with subwavelength sized elements, designed to enhance the light-matter interaction. Our plasmonic chiral metasurface consisted of a gold back reflector, a 20-nm-thick SiO$_2$ dielectric layer followed by a monolayer heterogeneous WS$_2$ layer on which we fabricated a gold spiral array. By optically pumping the plasmonic chiral metasurface/WS$_2$ heterostructure with CPL and measuring the resulting spatially resolved PL emission (P$_{CPL}$) at room temperature and low temperature (80K), we found the optical chirality of WS$_2$ was enhanced by more than 10 times relative to WS$_2$ layers. Additionally, by proper designs of the dimensions of the chiral metasurface structure, a linearly-polarized incident light can be converted to circularly-polarized light. These results suggest a new pathway of manipulating the valley-polarized PL emission in 2D materials via plasmonic chiral metasurfaces, which may be further applied to the development of valley-polariton optoelectronic devices.

Photoluminescence Enhancement at Heterojunction in WS$_2$-MoS$_2$ Lateral Heterostructures Revealed by Tip Enhanced Optical Spectroscopy Andrey Krayev$^1$, Sourav Garg$^2$, Seongsin M. Kim$^3$ and Patrick Kung$^2$; 1Horiba Scientific, Novato, California, United States; 2The University of Alabama, Tuscaloosa, Alabama, United States.

2D semiconductors such as transition metal dichalcogenides (TMDCs) recently attracted significant attention of the research community due to large number of fascinating optoelectronic and photocatalytic properties of these materials originating from their 2D nature. Defect engineering in these materials and defect-bound excitons are of particular importance due to their potential use as qubits for quantum computing. Lateral heterostructures of different TMDCs is one of possible ways of creating controlled defects. Tip enhanced optical spectroscopy (TEOS) which encompasses tip enhanced Raman scattering (TERS) and tip enhanced photoluminescence (TEPL) is a fast developing method that allows spectroscopic characterization of 2D materials with nanoscale spatial resolution and cross-correlation of this optical information with various properties revealed by scanning probe microscopy. Here we report observation of strongly enhanced PL from WS$_2$ at the grain boundary in CVD-grown monolayer of WS$_2$–MoS$_2$ lateral heterostructures transferred onto gold. Scanning Kelvin probe microscopy revealed strongly profiled saw-tooth-like junction between the MoS$_2$ and WS$_2$ sub-crystals with typical size of the features being from few hundreds to over 1000 nm. TEPL measurements showed that PL peak corresponding to WS$_2$ gets strongly enhanced within approximately 100nm next to the heterojunction. TERS spectra suggested alloying within few tens of nanometers away from formal boundary between MoS$_2$ and WS$_2$. We argue that observed strongly localized nanoscale enhancement of the WS$_2$ PL is associated with defects located at heterojunction and subsequently exciplexes bound to these defects. We’ll discuss prospective use of such structures as single photon emitters with prospective application as qubits for quantum computing.

Optically Active Defects in Tunable 2D Materials A.W. Holleitner; Technical University-Munich, Garching, Germany.

Atomically thin two-dimensional layered materials receive great interest because of their unique physical properties. Particularly, monolayers of semiconducting transition metal dichalcogenides, such as MoS$_2$, excel due to their strong light-matter interaction that is dominated by exciton phenomena [1-3]. Key to the integration of monolayer 2D materials into atomistic circuits is the possibility to tune and engineer their properties on demand and on-chip e.g. by defects, dielectric environment and local doping [4-8]. We will introduce a methodology based on silicon ion microscopy (SIM) to controllably realize single optically active emission centers in MoS$_2$, which show clear indications of quantum dot-like behavior. Our results demonstrate the potential of optically controlled ion beams to engineer the optical properties of semiconducting 2D materials at the nanometer scale [5,9].

We thank J. Klein, A. Kue, F. Siggter, F. Merbler, J. Wierzbowski, M. Altzschner, F. Kneipl, K. Muller, M. Kaniber, M. Florian, M. Lorke, M. Knap, R. Schmidt, J.J. Finley, and U. Wurstbauer for a fruitful collaboration and the DFG via NIM, eConversion, and project HO3324/9-1 for financial support.

Emerging photoluminescence from MoS$_{2(1-x)}$Se$_x$, MoS$_2$-MoSe$_2$ and MoS$_x$-WS$_x$: Layered Semiconductor Atomic Layered Materials Ravi K. Birje$^1$, Rahul Sharma$^2$, Krishna R. Sahoo$^3$, Balakrishna Annathoju$^4$, Tharangattu N. Narayanan$^5$, Robert Dyef$^6$ and Wolfgang Theis$^7$; 1Nanoscience Physics Research Laboratory, School of Physics and Astronomy, University of Birmingham, Birmingham, United Kingdom; 2Tata Institute of Fundamental Research, Hyderabad, India; 3School of Chemistry, National Graphene Institute, University of Manchester, Manchester, United Kingdom.

Two dimensional (2D) layer semiconductor atomic layered materials, such as transition metal dichalcogenides (MX$_2$, where M= Mo, W, and X=S, Se, Te) and their heterostructures have attracted considerable interest. Heterostructures with atomically sharp interfaces and alloyed versions of these exhibit widely tunable band gaps as a function of composition and stacking sequence. In the present work, we demonstrate the direct physical vapour deposition (PVD) growth of MoS$_{2(1-x)}$Se$_x$, MoS$_2$-MoSe$_2$ and MoS$_x$-WS$_x$: van der Waals (vdW) heterostructures using individual TM and chalcogen precursors (MoO$_3$, WO$_3$, S and Se powders) and their enhanced optical properties in the visible light. The morphology of as-grown MoS$_2$-MoSe$_2$ and MoS$_2$-WS$_x$; and MoS$_{2(1-x)}$Se$_x$:vdW heterostructures on Si/SiO$_2$ substrates evolves from triangular to hexagonal domain shapes with decreasing coverage. It is found that the domain size in MoS$_{2(1-x)}$Se$_x$:few-monolayer alloys is larger than for MoS$_2$-MoSe$_2$, MoS$_2$-WS$_x$. The crystallinity of the atomic layers and Se composition in MoS$_{2(1-x)}$Se$_x$:MoS$_2$-MoSe$_2$ and MoS$_{2(1-x)}$Se$_x$:MoS$_2$-WS$_x$: are determined by micro-Raman spectroscopy (µRaman) and XPS, respectively. In the present case, Se composition in the MoS$_{2(1-x)}$Se$_x$: is found to be around 40:60 (i.e x=0.41, MoS$_{2(1-x)}$Se$_{0.41}$) from XPS analysis, which is consistent with the previous reports. Interestingly, we found the tunable photoluminescence fromMoS$_2$-MoSe$_2$, MoS$_2$-WS$_x$: and MoS$_{2(1-x)}$Se$_x$:in-correlation with density functional theory (DFT) calculations of modified band structure and bandgap in these monolayer heterostructures as a function of Se to S atomic percentage. Thus establishing that these few-monolayer structures are excellent candidates for optoelectronics and visible light photocatalysis applications which cover a large window of the visible wavelength.

Light Emitting Optoelectronic Devices Based on van der Waals Heterostructures

Two-dimensional (2D) materials are promising due to unique optical and electrical properties. New physics observed only in 2D materials allow for development of new-concept devices by using their valleys, tunneling effect, engineered band offset, and strong light-matter interaction. Recently, van der Waals heterostructures (vdWH) have been achieved by putting these 2D materials onto another, in the similar way to build Lego blocks. Assembled 2D blocks provide a big playground for engineers and physicists to investigate unprecedented properties of 2D materials and fabricate multi-functional optoelectronic devices. In this talk, I introduce our recent achievement in optoelectronic devices based on van der Waals heterostructures. By engineering band alignment of the stacked 2D materials and utilizing work function tunability of graphene, light emitting devices with exceptional multi-functions were fabricated. The electrically tunable light emitting transistors and tunnel devices can emit a strong light with modulation of charge (or trion) density. So, wavelength and intensity of emitted light can be controlled by electric field. Further, light emission from interlayer exciton generated in the stacked 2D semiconductors was demonstrated in device operation for the first time. Our work shows a great promise of van der Waals heterostructures for optoelectronic applications. I will also introduce our recent progress in high integration of graphene devices (or graphene leads). We developed a novel patterning technique by using XeF2 gas and fluorographene via contacts for graphene interconnects embedded in a van der Waals heterostructure. Our via contacts can be useful for 3D integration of 2D devices for future 2D electronics.

High Photoresponsivity Ultrathin Lateral Stacking WS2—Graphene Photodetectors Made by Direct CVD Growth

Graphene is an ideal material for optoelectronic applications. Its photonic properties give several advantages and complementarities over Si photonics. I will show that graphene-based integrated photonics could enable ultrahigh spatial bandwidth density, low power consumption for next generation datacom and telecom applications. Heterostructures based on layers of atomic crystals have a number of properties often unique and very different from those of their individual constituents and of their three dimensional counterparts. I will show how these can be exploited in novel light emitting devices, such as single photon emitters, and tunable light emitting diodes.

High Photoreponsivity Ultrathin Lateral Stacking WS2—Graphene Photodetectors Made by Direct CVD Growth

Two dimensional transitional metal dichalcogenides (TMDs) have been widely investigated in recent years for their electronic, optical and catalytic properties as well as specific mechanical properties. In addition, the characteristics of TMDs would be determined by the layer numbers or layer stacking configurations. Thus, it is essential to design a method for developing new 2D-architecture by tailoring the properties of the material. In this work, we provided a sub 10nm localized thinning technique of atomic layers WS	extsubscript{2} via in-situ scanning transmission electron microscopy (STEM/TEM). The entire process was visualized at atomic scale and conducted at high temperature. In the beginning, we shortly presented a methodical CVD system to synthesize the crystalline atomic-layers WS	extsubscript{2}, followed by transferring the as-grown samples onto specialized TEM chips. Subsequently, evidenced by the TEM results, we successfully shaped the WS	extsubscript{2} layer by partially peeled off each WS	extsubscript{2} monolayer. Additionally, during the thinning process, the exclusive 2D-behaviors such as nanolayers migration, coalescence and etching were observed. Finally, we utilized atomic resolution STEM images to identify layer variation and structural configuration, which helped us deduce the exact atomic stacking sequence. Further EDS/EELS analysis provide elemental information to elucidate the sulfur depletion mechanism. This sculpting technique allows for sub-10nm thinning features while preserving the crystallinity, and also paves the way for the rational design of WS	extsubscript{2}-based quantum and optoelectronic devices.

Solution Processed Transition Metal Dichalcogenides for Printed Electronics Applications

Joe Neilson; The University of Manchester, Manchester, United Kingdom.

Semiconducting 2D materials, such as the Transition Metal Dichalcogenides (TMDs), have been widely explored for use in the fabrication of devices such as: field-effect transistors (FETs), sensors, and light emission devices, due to their attractive and size tuneable electrical properties. In particular, FETs manufactured around single mechanically exfoliated flakes with mobilities greater than 700 cm	extsuperscript{2}/V·s	extsuperscript{-1} have been widely reported. TMDs can also be handled as liquid phase dispersions, enabling the formulation of inks for use in high throughput and low cost printed electronic devices. Liquid dispersions of TMDs therefore represent an attractive alternative to current organic semiconductor technology, as mobility and on/off ratio enhancements may be possible.

However, current literature demonstrates that FETs manufactured using solution processed TMDs suffer from low mobilities and on/off current ratios. The reason for the observed shortcomings in such devices is unknown, but possible reasons can be broadly narrowed down to contamination/oxidation of the flakes, surface defects, or poor flame-flake contacts within a film of solution processed TMD material.

Here, we will present results which elucidate possible mechanisms for the poor electronic performance of solution processed TMD thin film devices. First, we have developed new methods of thin film assembly from solution processed few layer 2D material dispersions including; liquid/liquid interfacial assembly, and Langmuir-Blodgett assembly via a Pickering emulsion intermediate phase. This has resulted in average film thicknesses of less than 5 nm. Subsequently, photo and field-effect transistors were assembled around the resultant thin films. Considerable improvements to the electrical properties were achieved by the application of dielectric polymer passivation layers and careful separation of monolayer enriched material from the liquid dispersions. Alternate exfoliation routes such as chemical and electrochemical exfoliation and the effects on resulting thin film transistors have also been explored.

Revealed herein are examples of FET devices manufactured around thin films of TMDs assembled utilising various simple, low cost, and highly scalable assembly methods. This work provides insights into the manufacturability of solution processed 2D FETs by elucidating and resolving some of the failure modes associated with solution processing methods. Finally, a robust and simple all-solution processed manufacture technique for high performance thin film devices made from dispersions of 2D TMD material is demonstrated.

Deterministic Folding of 2D Materials for Electronic Device Applications

Huan Zhao, Beiwei Wang, Xiaodong Yan, Haozhe Wang, Jing Kong, Aiichiro Nakano, Rajiv Kalia and Han Wang; 1Ming Hsieh Department of Electrical Engineering, University of Southern California, Los Angeles, California, United States; 2Collaboratory for Advanced Computing and Simulations, University of Southern California, Los Angeles, California, United States; 3Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Atomically-thin two dimensional (2D) layered materials have exceptional mechanical flexibility. Therefore, 2D nano-sheets can be strained, stretched and folded into various origami structures and superlattices. 2D material origami structures possess unprecedented physical properties emerged from the folded edge, the interface, and the rotational angle of crystal lattices induced by the highly controllable folding direction.

In this talk, we will introduce a deterministic folding technique for creating controllable 2D material origami structures. This technique allows us to accurately fold a 2D atomic sheet at any position and direction pre-defined by standard electron beam lithography. 2D origami structures of layer-by-layer stacked heterostructure of 2D materials and large-scale CVD monolayer array will be demonstrated as examples of the scalability and controllability of this technique. We also looked deep into the molecular-level dynamics to understand the fundamental interactions underlying the folding process. Through simulation, we found the free energy of graphene increased after folding while the entropy of graphene decreased.

In addition, we will demonstrate various applications of our origami technique. 2D superlattice with controlled rotational angle can be prepared using the folding approach, which can be a powerful platform for exploring a rich array of physical phenomenon. For example, we found a pronounced Raman enhancement in a twisted graphene sample prepared by folding, suggesting the existence of Van Hove singularities. In addition, we were able to reconfigure the functionalities of 2D material electronics through folding. I will introduce a novel flash memory device built with this approach.

In summary, we developed a technique to deterministically fold 2D materials. Not only can this technique serve as a platform for studying nano-mechanics and exploring emerging physical phenomenon, but also it could be promising for realizing foldable and adaptive electronics, nano-actuating, and bio-nano interfaces.

Graphene–Si–Graphene Bipolar Junction Transistor with Tunable Gain

Ze Liu, Wenzhe Wang, Jie Huang, Audrey Rose M. Gutierrez and Zhaozhi Zhong; University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

Traditional silicon bipolar junction transistor (BJT) is widely used in current amplification and high power circuits. With its compatibility to planar process, BJTs with different parameters such as doping level and base width are dedicatedly designed and fabricated to achieve large desired gains. For traditional silicon BJT, gain is determined intrinsically by the base width. The gain can be tuned by the doping concentration of the emitter, but this is a limited approach, as the doping concentration is usually limited by the maximum sheet carrier density in the emitter. For graphene, this constraint does not exist, and the gain can be tuned by the doping or the Fermi level of the emitter graphene.

Graphene–Si–Graphene BJT can also be readily applied to other type of two dimensional material–Si hybrid devices for better control and performance.

2D Materials as Emerging Sensing Platforms

Raman Singh, 1CSIR-CSIO, Chandigarh, India; 2AcSIR-CSIO, Chandigarh, India.

It is believed that 2 D materials have evolved from astonishing properties of graphene and are in spotlight date back to 2004 when techniques of exfoliation of graphene were discovered. Since then both layered and non-layered 2D materials have gained momentum due to their some eye catchy properties which are ascribed to the dimensionality effect
and modulation in their band structure. In recent years, these 2D materials have been used for various emerging applications viz catalysis, opto-electronic devices for sensing, high performance electrodes and nanocomposites.

Among various 2D materials, atomically layered transition metal dichalcogenides (TMDs) have been used as promising two-dimensional materials for their wide applications. Their properties like an intrinsic band gap varying with the number of layers, a direct band gap and strong spin-orbit coupling in monolayers, have attributed to their immense consideration by researchers for varied applications.

In our research, nanoscaled layered transition metal dichalcogenides have been synthesized using simple synthesis method and are used as platform for fabrication of immunosensor for diagnostic applications.

**An Investigation of Carrier Mobility in MoS2 Grown by Chemical Vapour Deposition in a 300nm reactor**

Emma Coleman,1 Paul Hurley,1 Scott Monaghan,1 Jun Lin,1 Farzam Gity,1 Michael Schmidt,1 James Connolly1, Lee Walsh,1 Karim Cherkaoui1, Katie O Neill1, Niall McEvoy2,Corneac OColleain2, Colm O'Dwyer3, Georg Duesberg4 and Ian M. Povey1

1Tyndall National Institute, Ballincollig, Ireland; 2CRANN, Trinity College Dublin, Dublin, Ireland; 3Chemistry, University College Cork, Cork, Ireland; 4Universität der Bundeswehr München, Munich, Germany.

Two dimensional (2D) van der Waals materials bonded exhibit a range of electronic properties spanning from semi-metals through to wide bandgap semiconductors. Potential applications include electronics, sensors and display technologies [1]. In relation to practical device applications, research is focused on large area growth [2 – 6], stable approaches to doping and contacting [7,8]. We report on the optical properties and carrier mobility in thin films (2-10nm) of MoS2 grown in a commercial 300nm atomic layer deposition reactor. The MoS2 films are grown on sapphire and SiO2/Si substrates at temperatures in the range of 350°C to 550°C by a chemical vapour deposition process using Mo(CO)6 and H2S precursors.

Analysis of the films with Raman, X-ray photoelectron spectroscopy and electron backscattered diffraction all confirm the films as MoS2. The carrier concentration, carrier type and carrier mobility are studied with Hall measurements. Excellent ohmic behaviour is achieved on MoS2 (10nm, 550°C with no post growth annealing) deposited on sapphire and a-Al2O3/sapphire substrates. Room temperature Hall analysis of the MoS2 films indicates that the non-intentionally doped MoS2 films are n-type with very low carrier concentrations of ~10^4cm^-3. Comparison of the free carrier concentrations in the grown films (~10^4cm^-3) to Hall analysis of natural and synthetic MoS2 crystals (1x10^6 to 1x10^7 cm^-3) [9], with the presence of electrically active defect states in the energy gap of the MoS2 for the polycrystalline CVD grown films [10]. MoS2 films grown at 550°C and subsequently annealed at 550°C in a H2/Ar ambient indicate a significant increase in the electron concentration (~8x10^5 cm^-3).

The electron mobility is in the range of 3 to 17 cm^2/Vs for films grown at 550°C (with comparable values for MoS2 films grown at 350°C and subsequently annealed at 550°C in a H2/SiH4). Electron mobility values up to ~17 cm^2/Vs for a MoS2 grain size in the 5nm to 20nm range in this work, compared to values in the range of 25 to 30 cm^2/Vs reported by K. Kang et al. [3] for monolayer MoS2 with a grain size around 1μm [11]. This motivates the need to investigate scattering mechanisms and the influence of grain size on electron mobility in CVD grown MoS2 and preliminary results will be shown on the temperature dependence of electron concentration and electron mobility in the CVD grown MoS2 films.

**Self-Limiting Growth of High-Quality 2D Monolayer MoS2 by Direct Sulfurization Using Precursor-Soluble Substrates**

Yang Lu and Jamie Warner; University of Oxford, Oxford, United Kingdom.

Monolayer transition metal dichalcogenides (TMDCs) have demonstrated great potential in next-generation electronics due to their unique optical and electronic properties. Considerable efforts have been made to achieve large-scale synthesis of high-quality TMDC monolayers. However, it remains challenging to produce uniform high-quality monolayer TMDCs over large scale. Vapor phase deposition methods have been known to produce high quality TMDCs suitable for large-scale device fabrication, but the nucleation and growth of 2D crystals is significantly affected by the gas flow and the geometric effect of chamber in these systems. Direct sulfurization method holds great promise in achieving large-scale synthesis, but the obtained materials suffer from small grain size and multilayer regions.

In this work, low-cost glass substrate is used to address the issues in direct sulfurization method. The synthesized monolayer MoS2 single crystals possess the largest average crystal size (~100 μm) ever reported for MoS2 grown by direct sulfurization method, with large-area uniformity which is only limited by the size of the substrate. We confirm that the ability of glass to incorporate pre-deposited precursors into its molten state is the key to the facile production of high-quality monolayer MoS2 crystals. A combination of low-cost, uniformity, scalability, simplicity and high quality is achieved in our method which showed great promise for the development of wafer scale electronic devices based on 2D materials. Our work also provides a new look at the role substrates could play in the synthesis and the possibilities of using other glass or liquid substrates for the growth of high-quality 2D materials.

**QN03.06.08**

**Tunable Plasmons in Few-Layer Graphene Anti-Dot Lattices**

Kaci L. Kuntz, Elena R. Kovalik and Scott Warren; University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

The low carrier concentration (n ~ 10^13 cm^-3) and linear band dispersion at the fermi energy E_F of graphene enable tunable optoelectronic responses with small changes in the carrier concentration, demonstrating shifts of the plasma frequency in the THz (*Nat. Nanotech.*, 6 (2011), 630-634) and mid-infrared (ACS Nano, 7 (2013), 2388-2395) regions. However, there have been limited observations of plasma shifts in the near infrared (NIR) and visible spectra, which would enable opportunities for graphene-based plasmonic sensors with high sensitivity to local dielectric environments (*Analyst*, 140 (2015), 386–406), optical tunability for fast telecommunications (*ACS Photonics*, 1 (2014), 135–152), and photovoltaics with reduced dimensions (*Nat. Mater.*, 9 (2010), 205–213). Most commonly, graphene plasmons have been tuned by (1) altering the carrier concentration through electrostatic doping (*Nature*, 471 (2011), 617–620) or (2) reducing the dimensions (*ACS Photonics*, 1 (2014), 135–152). Through electrostatic techniques, the E_F can be shifted as much as in eV (*Nature*, 471 (2011), 617–620); therefore, the plasmonic response of doped-graphene has been limited by the placement of the charge carriers attainable within the Dirac cone in the band structure, where interband transitions are minimized (e.g. THz and mid-IR). The second approach is reducing dimensions, demonstrated in dot (*ACS Nano*, 7 (2013), 2388–2395), ring (*ACS Nano*, 7 (2013), 2388–2395), ribbon (Nat. Nanotech., 6 (2011), 630-634), and tapered (Nature, 487 (2012), 77–91) structures; these have enabled graphene plasmons to be shifted to the mid-IR, as low as 3.7 μm (ACS Nano, 7 (2013), 2388–2395). Although graphene plasmons are generally studied in arrays, there is limited research in anti-dot (e.g. hole or nanomesh) lattices (Nano Lett., 13 (2013), 2541–2547). Here, through simulations, we investigate hexagonal anti-dot lattices, where electrostatic doping and structure parameters (i.e. radius, periodicity, number of layers) can tune the plasma frequency. We employ a finite-difference time-domain suite (FDTD Solutions in Lumerical, Inc.) to simulate the optical properties of anti-dot structures with diameter D, periodicity P, one to six layers, and bias doping up to 0.8 eV. The graphene is modeled using 2D surface conductivity (*J. Appl. Phys.*, 103 (2008), 064302) with a temperature of 300 K and a scattering rate of 0.001 eV.
Additionally, as the number of layers increases, the plasmon frequency also blue-shifts. For example, for an array with $D = 40$ nm and $P = 120$ nm, as the electrostatic doping increases from 0.2 to 0.7 eV, the plasmon of the monolayer shifts from $\sim 13900$ nm (THz) to $\sim 7300$ nm (mid-IR), respectively. For 6-layer graphene, the plasmon shifts from $\sim 6700$ nm (mid-IR) to $\sim 3090$ nm (close to NIR), respectively. By decreasing the diameter and periodicity, the plasmon frequency of these few-layer, anti-dot lattices can be blue-shifted into the NIR—opening new opportunities for graphene in tunable NIR plasmonics, beyond what has been achieved with dot arrays (ACS Nano, 7 (2013), 2388–2395).

Furthermore, we evaluate the plasmon frequency dependence on carrier concentration, fermi energy, and the dimensions of a graphene structure using the Drude model for metals and the scaling law for graphene dot structures (ACS Photonics, 1 (2014), 135–152).

With this work, we employ simulations to identify few-layer graphene nanomesh structures with broadly tunable optoelectronic responses from the THz to NIR, informing future experimental investigation of graphene as a NIR plasmonic material (Manuscript in preparation). Finally, we use the observed relations to provide design parameters for scaling the structure and propose schemes to further shift the plasmon response to shorter wavelengths.

**Elasto-Optic Properties of Co, Cu, Mo and Sn Intercalated α-MoO₃ as Measured by Brillouin Spectroscopy**

Daniel Williams, Bryan P. Moser, Nicholas Lundgren and Kristie Koski; University of California, Davis, Davis, California, United States.

Molybdenum trioxide ($\alpha$-MoO₃) is a 2D layered oxide that has shown suitability in electrochromic and photochromic devices owing to the tunability of its optical properties. Through reversible intercalation of zero-valent metals, the color of $\alpha$-MoO₃ can be altered from transparent white to dark blue. In this study we show how intercalation also changes the elasto-optic properties of $\alpha$-MoO₃ via intercalation of Sn, Cu, Mo, and Co. Brillouin spectroscopy is a non-invasive, non-contact, laser-based technique that can be used to measure the elastic properties of a material. We determine the full elastic stiffness tensor of $\alpha$-MoO₃ and show how intercalated metals alter the elastic properties.

**QN03.06.10**

**Chemically Tunable Acoustic Phonons in Intercalated Bi₂Se₃**

Nicholas Lundgren, Kristie Koski, Daniel Williams and Bryan P. Moser; Koski Group, University of California, Davis, Davis, California, United States.

Bismuth selenide is a 2D layered material with acoustic, optical, and electronic properties that can be chemically tuned through intercalation. Using Brillouin laser light scattering, we measure the acoustic phonons of metal-intercalated Bi₂Se₃. We show that the entire elastic stiffness tensor can be chemically tuned through intercalation of metals into this host. Acoustic attenuation, elasticities, and sound velocities are presented.

**QN03.06.11**

**Pressure-Dependent Raman of Mn-Intercalated 2D Layered Materials**

Virginia L. Johnson, Daniel Williams, Gabriella Lahti, Bryan P. Moser and Kristie Koski; University of California, Davis, Davis, California, United States.

Two-dimensional layered materials (2DLM), Bi₂Se₃, MoSe₂, Si₂Te₃, and GeSe were intercalated with atomic manganese and investigated to 7 GPa using a diamond anvil cell and Raman spectroscopy. There have only been a few studies of intercalation experiments at high pressure. Of those, most have focused on the effects of staging. The behavior of a specific intercalant in different hosts remains unexplored. These studies demonstrate that intercalation of manganese into 2DLMs can result in the appearance of new Raman peaks with pressure, and a change in the initial Raman frequency coincident with no change in the frequency shift with pressure.

**QN03.06.12**

**High-Pressure Study of Vibrational Structure in Phosphorene Samples**

Jacek B. Jasinski, Meysam Akhtar, Congyan Zhang, Manthilia Rajapakse, Rajib Musa, Ming Yu and Gaminu Samanasekera; University of Louisville, Louisville, Kentucky, United States.

In recent years, phosphorene, a two-dimensional (2D) form of elemental black phosphorus, has attracted a great deal of attention because of its unique properties and numerous potential applications. This material exhibits a highly tunable bandgap, high carrier mobility, and strong in-plane anisotropy. Its potential applications extend onto various fields, including electronic, optoelectronic and spintronic devices, sensors and actuators, as well as different energy conversion and storage technologies. Here, we report our recent study on the fabrication, characterization, and high-pressure properties of phosphorene samples. We used a diamond anvil cell and conducted a series of in-situ Raman spectroscopy measurements at pressures up to $\sim 10$ GPa. Simultaneous theoretical calculations, performed using the density functional theory (DFT) framework, as implemented in the Vienna Ab-initio Simulation Package (VASP), were also conducted. We used a short transport growth method for obtaining bulk black phosphorus, followed by the liquid mechanical exfoliation to produce flakes of phosphorene of different layer number thickness. These samples were thoroughly characterized using an array of structural and optical methods. For the in-situ high-pressure Raman experiments, two types of flakes, one with a few layers and the other with many layers, were selected. In both cases, systematic shifting of the primary Raman modes, i.e. $A_{1g}$, $E_{2g}$, and $A_{1g}$, with increasing pressure was observed. Such shifts were also found in our theoretical calculations. The detailed behavior and the magnitude of Raman shifts directly reflect the anisotropic nature of phosphorene, as well as the difference in the number of layers. Our study provides a better understanding of the relationship between the strain and the vibrational structure in phosphorene. Together with similar studies, it can enable rational strain engineering towards additional functionalities and device applications of phosphorene and other 2D materials.

**Magnetic Field Driven Metal Insulator Transition in Bi₂Te₃Se Topological Insulators**

Roshan Irfan; Physics, Aligarh Muslim University, Aligarh, India.

Topological insulators (TIs) are a new phase of matter with bulk insulating and conducting surface states. In three dimensional topological insulators such as Bi₂Se₃, large numbers of selenium vacancies push the Fermi level inside the conduction band; due to which the charge transport is generally dominated by the bulk current in this crystal and the as grown crystals of Bi₂Te₃ are p-type because of Te-Bi exchange defects. In order to extract the surface properties of topological insulators, it is necessary to have insulating bulk state in the TI material. Thus, among the known topological insulators, Bi₂Te₃Se with basic quintuple layer as Te-Bi-Se-Bi-Te, emerged as a promising material for studying the topological insulating properties. Bi₂Te₃Se is the hybrid material in which the selenium ion occupies the innermost layer in each quintuple. This will suppress both vacancy formation and Te-Bi exchange defects. In this report we study the surface properties of topological insulators Bi₂Te₃Se thin films grown by physical vapor deposition using Bi₂Te₃Se single crystals as a precursor. Pure phase of Bi₂Te₃Se are investigated using x-ray diffraction. Raman spectroscopy of Bi₂Te₃Se thin film showed strong intensity of $A_{1g}$, $E_{2g}$ and $A_{1g}$ modes in addition with $A_{1g}$ modes. The surface studies on these thin films were carried out using scanning electron microscopy and atomic force microscopy and the elemental analyses is done using x-ray photoelectron spectroscopy. The $R_{s}$ variation with temperature in the range 2 K to 350 K at different magnetic field shows a bump at high temperature and as we increase the magnetic field there is increase in resistance at high temperatures. The magneto-resistance measurements on Bi₂Te₃Se thin film shows a weak antilocalization effect that arises due to quantum interfering nature of topological insulators and the measured weak anti-localization effect is fitted using Hikami-Larkin-Nagaoka (HLN) model.

**Morphological Engineering and Site-Specific Positioning of MoS₂ Layered Structures—The Role of Au Seeding**

Xinqi Chen and Yuan Li; Northwestern University, Evanston, Illinois, United States.

Molybdenum disulfide (MoS₂), a semiconductor in the family of transition metal dichalcogenide (TMD) materials, has recently drawn great research interest in a wide range of applications such as electronic transistors, light sensing, batteries, and hydrogen production. However, the limited control over the geometry, location, yield, and size distribution of the products using current synthesis methods has severely limited their large-scale applicability. Herein, we identify the ability to use metal (e.g., Au) nanoparticles to seed the growth of MoS₂ layered structures (including lateral monolayer and vertical wings) and thereby provide a means to achieve programmable and controllable synthesis. In this study, pre-patterned Au seeds are used as heterogeneous nucleation sites to induce the formation of desired geometries of MoS₂ layers via chemical vapor deposition. Our experimental and theoretical results shed light on the growth mechanism driving the formation of MoS₂ monolayers at these sites, revealing that the “seeding effect” originates from the favorable formation energy of MoS₂ on the Au surface. A field-effect transistor with a pre-designed MoS₂ monolayer channel exhibits electronic performance that compares nicely with previously reported MoS₂ monolayer devices. The vertical wing-like MoS₂ layers, with an abundance of edge-terminated active sites, are found to exhibit dramatically
improved electrocatalytic activity for the hybrid evaporation reaction. We believe this study contributes fundamental insights into controlled synthesis of layered TMDs, making integration of these materials into emerging electronic and energy systems more attainable.

**QN03.06.15 Diversified Magnetoelectric Coupling in 2D Multiferroics** Qing Yang and Menghao Wu; Huazhong University of Science and Technology, Wuhan, China.

Multiferroic materials with coupled magnetism and ferroelectricity, even though scarcely exist in nature, are highly desirable for efficient “electric writing + magnetic reading”. Currently, the polarization and magnetization of traditional multiferroics with strong magnetoelectric coupling are all too weak for practical applications. Here we show first-principles evidences that strong magnetoelectricity can be realized in a series of 2D multiferroics: in some intercalated bilayer systems, their “mobile” magnetism can be controlled by ferroelectric switching upon external electric field, exhibiting either “on” state with spin-selective and highly p-doped channels, or “off” state insulating for both spin and electron transport, which renders efficient electrical writing and magnetic reading; vertical polarization can be maintained against depolarizing field, rendering high-density data storage possible; moreover, all those functions can be directly integrated into a 2D wafer, like n/p channels by doping in a silicon wafer. In some 2D systems, the magnetization can be switched by 90 or even 180 degree upon ferroelectric switching.

**QN03.06.16 Selective Growth of Bi$_2$Te$_3$/WS$_2$ Heterostructures with Emergent Properties** Ethan L. Kahn$^1$, Michael Lucking$^1$, Fu Zhang$^1$, Yu Lei$^2$, Kory Beach$^3$, Tomotaroh Granzier-Nakajima$^4$, Ana Laura Elias$^5$, Humberto Terrones$^1$; 1The Pennsylvania State University, University Park, Pennsylvania, United States; 2Physics, Rensselaer Polytechnic Institute, Troy, New York, United States.

To create complex, scalable device structures from 2D materials, it is necessary for patterned growth techniques to be developed. While several methods have been developed for the seeding or exclusion of 2D nucleation on conventional substrates (e.g. SiO$_2$ mica, sapphire), to date there have been few reports of patterned growth of one atomically thin material on top of another. Here, we demonstrate a low temperature (< 260 °C) and generalizable deposition technique for the selective-area growth of few-layer Bi$_2$Te$_3$ on chemical vapor deposition (CVD)-grown WS$_2$ single crystalline monolayers. These heterostructures are observed to grow with an epitaxial registry despite considerable lattice mismatch, and display both electronic and optical properties distinct from their constituent layers. These results are explained by Density Functional Theory calculations, which confirm that Bi$_2$Te$_3$/WS$_2$ possesses an electronic structure unique from the layers from which it is comprised. The nature of the interlayer electronic coupling in this novel system is explored further through computation of its band structure upon variation of both the interlayer distance and orientation.

**QN03.06.17 Increasing the Coverage of Functional Groups on Exfoliated Molybdenum Disulfide** Ellen X. Yan and Nathan S. Lewis; California Institute of Technology, Pasadena, California, United States.

Two-dimensional layered transition-metal dichalcogenides (TMDs) containing a Group V1 metal (MoS$_2$, MoSe$_2$, WS$_2$, WSe$_2$) have been explored recently for use in a variety of devices and applications, including transistors, ultra-thin flexible electronics, sensors, drug delivery, and bio-imaging. A variety of methods have been developed for covalent and non-covalent functionalization of the relatively inert basal plane of TMDs to improve their application-specific suitability. We are investigating the use of reductant-activated functionalization to increase the coverage of functional groups on covalently modified surfaces of 1T MoS$_2$ relative to existing methods, where one-electron reductants are used as sacrificial electron donors that can transfer negative charge to the MoS$_2$. The reduced MoS$_2$ can then react with electrophiles, similar to the transfer of negative charge from freshly intercalated and exfoliated MoS$_2$.

Our results for reductant-activated addition of methyl and propyl groups to 1T MoS$_2$ show that we are able to increase the coverage of these groups by 50-100% and facilitate functionalization with weak electrophiles using strong one-electron reductants. We also observe that the rate of reaction increases with increased reduction potential, resulting in higher coverages under the same conditions. Coverage of functional groups was quantified using XPS and TGA, and the covalent C-S bond and carbon species observed through FTIR and solid-state 13C-CPMAS NMR. By enabling greater coverage and facilitating reactions with weak electrophiles, reductant-activated functionalization is a promising method to broaden the set of obtainable functionalized TMD materials.

**QN03.06.18 Tuning the Opto Electronic Properties of Ultrasmooth Large Area rGO Films Grown via Pulsed Laser Deposition (PLD) Technique** Muhammed I. Manojittachali$^{1,2}$, M. S. Ramachandra Rao$^1$ and Venkatesan Thirumalai$^2$; 1Physics, IIT Madras, Chennai, India; 2NUSNRI, National University of Singapore, Singapore, Singapore.

We present the growth of large area ultrasmooth reduced graphene oxide (rGO) thin films on a four inch wafer via beam scanning mode of Pulsed laser deposition technique. With the versatility of the PLD technique, the easy tuning of optoelectronic properties is achieved on rGO thin films without employing any buffer layers. The conventional growth mechanism of rGO films involves hazardous chemicals, whereas this physical vapour deposition technique gives high quality rGO films with tunable optoelectronic properties. This wafer-scale growth mechanism of rGO films can potentially employ in various optoelectronic applications due to its high transparency and p-type conductivity. We illustrates the optoelectronic tunability of large area rGO films and its use through the evaluation of transparent conducting films, where our rGO films shows highest performance as compared to existing p-type transparent conducting films.

**QN03.06.19 Chemical Vapor Deposition of Bernal-Like Stacked Graphene with Built-in Vertical Electric Field** Minseek Yoo, Hyo Chan Lee and Kilwon Cho; Chemical Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of).

Multilayer graphene has been considered as a promising material for various optoelectronic devices because of its tunable electronic structure under an vertical electric field (E-field). Introduction of desired E-field inside the multilayer graphene is essential to fully exploit its intriguing electronic properties. However, applying desired E-field inside multilayer graphene has been remained challenge because external E-field is mostly screened by the outer graphene layer. Here, we report a one-step chemical vapor deposition for the synthesis of Bernal-like stacked graphene that S atoms are gradiently-doped in c-axis. The thickness and built-in E-field of synthesized graphene can be simultaneously controlled in wide range at the growth stage. We demonstrated tunability of electronic structure of synthesized graphene by dual-gate field-effect transistor and infrared absorption measurement. Taking advantage of built-in E-field, we fabricated barristor-type graphene photodetectors that has both high phororesponsivity and on/off current ratio.

**QN03.06.20 Quantum-Confined Stark Effect and Electric-Field Tuning of Excitons in 2D Ferroelectric α-InSe Layers** Jingqi Qiao$^1$ and Su Ying Quak$^{1,2}$; 1Centre for Advanced 2D Materials and Graphene Research Centre, National University of Singapore, Singapore, Singapore; 2Department of Physics, National University of Singapore, Singapore, Singapore.

The Stark effect in quantum-confined nanostructures can lead to electric field tuning of exciton energies and dissociation rates, and is important for applications in optoelectronic devices. Two-dimensional (2D) α-InSe has recently been demonstrated theoretically [1] and experimentally [2] to be a 2D ferroelectric material with out-of-plane polarization. However, the Stark effect in this ferroelectric material is largely unknown. Here, we perform first principles density functional theory and many electron perturbation theory GW-BSE (Bethe-Salpeter equation) calculations to investigate the effect of out-of-plane electric fields on the optical properties of 2D α-InSe. We find that the magnitude of the Stark shift depends sensitively on the direction of applied electric field, which results from the spontaneous polarization in the material. When the direction of the electric field is antiparallel to the intrinsic dipole moment, the exciton energies and band gaps decrease significantly even for the monolayer, at a rate that is comparable to that previously found
for interlayer excitons in 2D materials [3]. Our results will motivate experimental studies of the Stark effect in the 2D ferroelectric, α-InSe1.

QN03.06.21
2D Graphene Oxide Based Metal Hybrid Systems for Sensing and Catalysis Hadi Kelami and Mary Sajjini Devadas; Department of Chemistry, Towson University, Towson, Maryland, United States.

Graphene oxide (GO) serves as a precursor to various technologies, which include batteries, biosensors, solar cells, and supercapacitors. Metal hybrids of GOx enhance the sensitivity and electrical conductivity for sensing and catalytic applications. In this project we use silver and palladium nanoparticles independently to modify the surface of GOx. Silver nanoparticles exhibit optical properties that play a role in bacterial resistance, demonstrating its role in various biomedical sensors. Palladium nanoparticles are highly sensitive and functional in room temperature; making it an ideal metal for catalytic applications. Here we report the synthesis of functional graphene oxide from graphite flakes, followed by both successful carboxylation and reduction. In this experiment, carboxylation of GOx was followed by insertion of silver nanoparticles through an oleylamine ligand. Reduction of GOx resulted in a highly conductive, monolayer graphene quantum dot, which will be coated with palladium nanoparticles and utilized in catalytic applications, primarily Suzuki cross-coupling reactions. The Pd-GOx will serve as a cheaper and stable alternative as compared to traditional palladium-based catalysts used in these reactions. Initial results of our experiment will be presented.

We acknowledge funding from NSF MRI 1626326.

QN03.06.22
Ferrimagnetism of Ti-Adsorbed Graphene Zhenzhen Qin1 and Xu Zuo2; 1Zhengzhou University, Zhengzhou, China; 2Nankai University, Tianjin, China.

Using the first-principles calculations, we investigate the magnetism of isolated Ti-adsorbed graphene and the magnetic ground state of Ti adatoms at various concentrations. For isolated Ti adatom on graphene, we analyze the localization of magnetic impurity states and moment formation that can be understood in terms of hybridization between C-pz and Ti 4s-3d orbitals. To examine the magnetic ground state of Ti adatoms, we construct graphene cells with Ti adatom at various concentrations and set up the magnetic configuration for a triangle lattice. It is found that a ferrimagnetic (FI) phase is the most stable in a wide range of Ti concentration by comparing the total energies of different magnetic states. In addition, the exchange integrals between the nearest neighbor and next-nearest-neighbor Ti adatoms are calculated by applying a classical Heisenberg model. The prediction of a graphene-based FI metal monolayer will open the door to applications of spintronics, given that Ti obeys a 2-D growth mechanism on graphene.

QN03.06.23
Negative Poisson's Ratio in Two-Dimensional Honeycomb Structures Zhenzhen Qin1, Guangzhao Qin1 and Ming Hu1; RWTI Aachen University, Aachen, Germany; 2Zhengzhou University, Zhengzhou, China; 3University of South Carolina, South Carolina, South Carolina, United States.

Negative Poisson's ratio (NPR) in auxetic materials is of great interest due to the typically enhanced mechanical properties, which enables plenty of novel applications. In this paper, by employing first-principles calculations, we report intrinsic NPR in a class of two-dimensional honeycomb structures (graphene, silicene, h-BN, and h-GaN), which are distinct from all other known auxetic materials. They share the same mechanism for the emerged NPR despite the different chemical composition, which lies in the increased bond angle θ. However, the increase of bond angle θ is quite intricate and anomalous, which cannot be explained only in the point of view of the geometry structure and mechanical response, such as in the framework of classical molecular dynamics (MD) simulations based on empirical potential. We attribute the counter-intuitive increase of θ and the emerged NPR fundamentally to the strain modulated electronic orbital coupling and hybridization. Furthermore, we propose that the NPR phenomenon can also emerge in other nanomaterials or nanostructures with similar honeycomb structure. The physical origin as revealed in our study deepens the understanding on the NPR and would shed light on future design of modern nanoscale electromechanical devices with special functions based on auxetic nanomaterials and nanostructures.

QN03.06.24
Graphene-MoS2 Heterostructures for Infrared Photodetection Audrey Rose M. Gutierrez, Dehui Zhang, Zhe Liu and Zhaozhong Zhong; University of Michigan, Ann Arbor, Michigan, United States.

Infrared imaging has applications in multiple fields, including point-of-care diagnostics in medical care and gas sensing in air quality monitoring. While solutions for these applications exist, commercially available technologies are expensive due to reliance on costly materials. Here we report an inexpensive and scalable device for infrared sensing, implemented using chemical vapor deposition (CVD) grown two-dimensional materials. A MoS2 field-effect transistor (FET) is combined with a graphene photoactive layer, allowing transport of charges through a tunable Schottky barrier. The MoS2 FET has a lower dark current and higher on-off current ratio than graphene alone, while the graphene component permits detection of light beyond the natural absorption spectra of MoS2. The resulting heterostructure device is capable of broadband detection. Detailed mechanism, device sensitivity, and viability for photodetector array applications will be discussed in the presentation.

QN03.06.25
Synthesis, Structure and Stability of Siloxetine Nanosheets Tuahit Shah1, Karalee Jarvis1, Pengyi Tang2, Eric Prestat1, Jordi Arbiol1, Quentin Ramasse1 and Brian A. Korgel1; 1McKetta Department of Chemical Engineering and Texas Materials Institute, The University of Texas at Austin, Austin, Texas, United States; 2Catalan Institute of Nanoscience and Nanotechnology (ICN2), CSIC and BIST, Campus UAB, Bellaterra, Spain; 3SuperSTEM Laboratory, Daresbury, United Kingdom; 4Texas Materials Institute, The University of Texas at Austin, Austin, Texas, United States.

Silicene, a buckled honeycomb structure of Si atoms, has received increased interest in recent years because of its exotic properties and compatibility with existing semiconductor technology. Theoretical studies have predicted silicene to be thermodynamically stable, but its synthesis remains a challenge due to the high reactivity of sp2 hybridized Si structures. So far, silicene has been synthesized on a metal substrate under ultra-high vacuum. The major drawback of this method is the high reactivity of silicene surface and its strong coupling with the metal substrate. A promising alternative is the synthesis of functionalized silicene that can preserve the honeycomb structure of silicene and reduce its surface reactivity. Functionalized silicene can be synthesized using a top-down method starting with siloxene. Siloxene is a layered, honeycomb silicon structure with hydride and hydroxide functionalization. Previous research has focused on the hydrosilylation reaction of siloxene as an exfoliation method. In our work, we show that stable dispersions of siloxene nanosheets can be synthesized via liquid-assisted exfoliation without hydrosilylation and conduct a detailed study of their structure and stability.

Electronic Energy Loss Spectroscopy (EELS) and Electron Diffraction show that the structure of siloxene nanosheets is sensitive to air exposure. The nanosheets synthesized in ambient environment show amorphous silica-like characteristic while in the inert synthesis they retain the hexagonal crystalline structure. Our in-depth EELS study shows that crystalline nanosheets have a signature distinct from pure Si and SiO2. We have also identified a method for the large-scale synthesis of these nanosheets which enables size-selection. This study, conducted in ambient environment, shows a blue shift in the band-gap and luminescence decrease in size of the nanosheets likely due to a combined effect of oxidation and size. This method can be potentially extended to the synthesis in inert environment to yield size-selected dispersions of crystalline siloxene nanosheets. In this work, we provide the first EELS study of siloxene nanosheets to understand its structure and stability in different environments. We have also identified a unique solution-based synthesis method and the conditions under which crystalline siloxene nanosheets can be obtained. This provides a feasible synthesis for silicon-based nanosheets and opens up the possibility of integrating them with the existing silicon technology.

QN03.06.26
Anomalously Temperature-Dependent Thermal Conductivity of Monolayer GaN with Large Deviations from the Traditional 1/T Law Guangzhao Qin and Ming Hu; University of South Carolina, Columbia, South Carolina, United States.

Efficient heat dissipation, which is featured by high thermal conductivity, is one of the crucial issues for the reliability and stability of nanodevices. However, due to the generally fast 1/T decrease of thermal conductivity with temperature increase, the efficiency of heat dissipation quickly drops down at an elevated temperature caused by the increase of work load in electronic devices. To this end, pursuing semiconductor materials that possess large thermal conductivity at high temperature, i.e., slower decrease of thermal conductivity with temperature increase than the traditional α ∼ 1/T relation, is extremely important to the development of disruptive nanoelectronics. Recently, monolayer gallium

Negative Poisson's Ratio in Two-Dimensional Honeycomb Structures Zhenzhen Qin1, Guangzhao Qin1 and Ming Hu1; RWTI Aachen University, Aachen, Germany; 2Zhengzhou University, Zhengzhou, China; 3University of South Carolina, South Carolina, South Carolina, United States.

Negative Poisson's ratio (NPR) in auxetic materials is of great interest due to the typically enhanced mechanical properties, which enables plenty of novel applications. In this paper, by employing first-principles calculations, we report intrinsic NPR in a class of two-dimensional honeycomb structures (graphene, silicene, h-BN, and h-GaN), which are distinct from all other known auxetic materials. They share the same mechanism for the emerged NPR despite the different chemical composition, which lies in the increased bond angle θ. However, the increase of bond angle θ is quite intricate and anomalous, which cannot be explained only in the point of view of the geometry structure and mechanical response, such as in the framework of classical molecular dynamics (MD) simulations based on empirical potential. We attribute the counter-intuitive increase of θ and the emerged NPR fundamentally to the strain modulated electronic orbital coupling and hybridization. Furthermore, we propose that the NPR phenomenon can also emerge in other nanomaterials or nanostructures with similar honeycomb structure. The physical origin as revealed in our study deepens the understanding on the NPR and would shed light on future design of modern nanoscale electromechanical devices with special functions based on auxetic nanomaterials and nanostructures.
nitride (GaN) with a planar hexoncomb structure emerges as a promising new two-dimensional material with great potential for applications in nano- and optoelectronics. Here, we report that, despite the commonly established 1/7 relation of thermal conductivity in plenty of materials, monolayer GaN exhibits anomalous behavior that the thermal conductivity almost decreases linearly over a wide temperature range above 300 K, deviating largely from the traditional $\kappa \sim 1/T$ law. The thermal conductivity at high temperature is much larger than the expected thermal conductivity that follows the general $\kappa \sim 1/T$ trend, which would be beneficial for applications of monolayer GaN in nano- and optoelectronics in terms of efficient heat dissipation. We perform detailed analysis on the mechanisms underlying the anomalously temperature-dependent thermal conductivity of monolayer GaN in the framework of Boltzmann transport theory and further get insight from the view of electronic structure. Beyond that, we also propose two required conditions for materials that would exhibit similar anomalous temperature dependence of thermal conductivity: large difference in atom mass (huge phonon band gap) and electronegativity (LO-T0 splitting due to strong polarization of bond). Our study offers fundamental understanding of phonon transport in monolayer GaN, and the insight gained from this study is of great significance for the design and search of materials superior for applications in nano- and optoelectronics in terms of high-performance thermal management.

QN03.06.27

Synthesis and Optoelectronic Applications of Heterostructures Based on Carbon Nanomaterials and MoS$_2$

Van Tu Nguyen and Ji-Yong Park; Ajou University, Suwon, Korea (the Republic of)

By employing 2-step chemical vapor deposition (CVD) method, we realize heterostructures of molybdenum disulfide (MoS$_2$) with carbon nanomaterials such as graphene and carbon nanotubes (CNTs). On the first CVD step, either highly aligned CNTs (HA-CNTs) or graphene is first synthesized. On the second CVD step, mono to few-layer MoS$_2$ is directly grown on previously grown carbon nanomaterials forming heterostructures. In the case of HA-CNTs, MoS$_2$ grows preferentially along CNTs, forming mixed-dimensional heterostructures, which become visible as line-like features under an optical microscope. Post-growth characterizations such as atomic force microscopy, Raman and PL measurements confirm the formation of heterostructures with mostly few-layer crystalline MoS$_2$ flakes along HA-CNTs with low defect densities. On the other hand, vertical heterostructures of graphene/MoS$_2$ are prepared by the CVD deposition of triangular MoS$_2$ flakes on the graphene surface. Efficient charge transfer from MoS$_2$ to carbon nanomaterials are found on both types of heterostructures. By utilizing efficient light absorption and charge transfer in MoS$_2$, with high mobility channels (CNT or graphene), we demonstrate photodetectors with high responsivities using both types of heterostructures. Strategies to improve the temporal responses of photodetectors will also be discussed.

QN03.06.28

Role of CVD-Graphene Layer Between Current Collector and Active Electrode Material Towards Equivalent Series Resistance in Supercapacitors

Sunil Kumar$^1$ and Yongho Seo$^2$

$^1$Graphene Research Institute, Sejong University, Seoul, Korea (the Republic of); $^2$Department of Nanotechnology and Advanced Materials Engineering, Sejong University, Seoul, Korea (the Republic of)

Graphene has been used in supercapacitors as an electrode material in recent times due to its high surface area. The reduced graphene oxide (rGO) has a high surface area, which is a key parameter for high capacitance. In addition, there is another parameter i.e. equivalent series resistance (ESR), which influences the performance of supercapacitors. ESR should be controlled, particularly at high scan rates, for the high capacitance of the electrical double layer capacitors (EDLC). The resistance at the interface between the current collector and the active electrode material is the major component of ESR. In this report, chemical vapor deposition (CVD) method grown graphene has been introduced between the rGO and Ni-foil to minimize this resistance. The GGO having the surface area, ~367 m$^2$/g, has been used as an active electrode material and Ni-foil as the current collector. The CVD-graphene, grown directly on Ni-foil at various cooling rates i.e. 20, 40 and 100 $^0$C/min. during the growth process, has been used between rGO and Ni-foil to fabricate electrodes for optimizing the supercapacitor properties. The electrodes with CVD-graphene grown at faster cooling rates exhibited better electrochemical characteristics even at high scan rates. The specific areal capacitance of electrodes with CVD-graphene grown at 40 $^0$C/min. cooling rate is 58.3 F/cm$^2$ (213.8 $F$/$g$) and 39.1 F/cm$^2$ (143.3 $F$/$g$) at scan rates 0.05 and 10 $V$/$s$, respectively. The electrodes with CVD-graphene grown at 100 $^0$C/min. exhibit better stability, and low voltage drops at various current densities while maintaining quasi-rectangular shapes in C-V characteristics. The introduction of CVD-graphene between the rGO and Ni-foil reduced the ESR significantly from 0.8 $\Omega$ to ~0.38 $\Omega$ at high frequencies.

Integration of Partially Suspended Monolayer Graphene into a Strain-Based Polymer Chemiresistor

Annelise C. Thompson, Kyra Lee and Nathan S. Lewis; California Institute of Technology, Pasadena, California, United States.

Graphene has been used in supercapacitors as an electrode material in recent times due to its high surface area. The reduced graphene oxide (rGO) has a high surface area, which is a key parameter for high capacitance. In addition, there is another parameter i.e. equivalent series resistance (ESR), which influences the performance of supercapacitors. ESR should be controlled, particularly at high scan rates, for the high capacitance of the electrical double layer capacitors (EDLC). The resistance at the interface between the current collector and the active electrode material is the major component of ESR. In this report, chemical vapor deposition (CVD) method grown graphene has been introduced between the rGO and Ni-foil to minimize this resistance. The GGO having the surface area, ~367 m$^2$/g, has been used as an active electrode material and Ni-foil as the current collector. The CVD-graphene, grown directly on Ni-foil at various cooling rates i.e. 20, 40 and 100 $^0$C/min. during the growth process, has been used between rGO and Ni-foil to fabricate electrodes for optimizing the supercapacitor properties. The electrodes with CVD-graphene grown at faster cooling rates exhibited better electrochemical characteristics even at high scan rates. The specific areal capacitance of electrodes with CVD-graphene grown at 40 $^0$C/min. cooling rate is 58.3 F/cm$^2$ (213.8 $F$/$g$) and 39.1 F/cm$^2$ (143.3 $F$/$g$) at scan rates 0.05 and 10 $V$/$s$, respectively. The electrodes with CVD-graphene grown at 100 $^0$C/min. exhibit better stability, and low voltage drops at various current densities while maintaining quasi-rectangular shapes in C-V characteristics. The introduction of CVD-graphene between the rGO and Ni-foil reduced the ESR significantly from 0.8 $\Omega$ to ~0.38 $\Omega$ at high frequencies.

Annealing Effects on Direct Bandgap Emission from Atomically Thin MoS2 via NB Ion Implantation

Gourav Bhuyan$^1$ and Mengbing Huang$^1$; $^1$Colleges of Nanoscale Science and Engineering, SUNY Polytechnic Institute, Albany, New York, United States; $^2$University at Albany, State University of New York, Albany, New York, United States.

The emergence of 2D materials has led to increased attention on correlating the structural, optical, and optoelectronic properties of atomically thin transition metal chalcogenides like MoS$_2$. We demonstrate the tunability of the photoluminescence (PL) properties of bulk MoS$_2$ via implantation of Nb ions. Raman spectroscopy is used to confirm the p-type doping. The PL intensity of MoS$_2$ is drastically enhanced by the adsorption of p-type dopants. X-ray photoelectron spectroscopy (XPS) is used to study the change of MoS$_2$ structure after annealing in oxygen. We also demonstrate a stronger PL enhancement through defect engineering and oxygen bonding realized by oxygen anneal. Our results provide a new route for modulating the optical properties of two-dimensional semiconductors. The strong and stable PL from defects sites of MoS$_2$ may have promising applications in optoelectronic devices.

QN03.06.31

Novel Graphene Functionalization Approach Leading to Ultrasensitive, Robust and Fast Sulfur Contaminants Detection in Aviation Fuels

Evelynia Lock$^1$, Keith Perkins$^1$, Joseph Prestigiacomo$^1$, Anthony Boyd$^1$, Anindya Nath$^1$, Mike Ososky$^1$, Rachael L. Myers-Ward$^1$, Pratibha Deb$^1$, Thomas Reinecke$^1$ and D. K. Gaskill$^1$; Naval Research Laboratory, Washington, District of Columbia, United States; $^2$George Mason University, Washington, District of Columbia, United States; $^3$Howard University, Washington, District of Columbia, United States.

In this work we demonstrate novel functionalization approach allowing for increased reactivity of epitaxial graphene with no deterioration of electrical properties. In particular, we show that these functionalized samples exhibit the Quantum Hall Effect and possess Shubnikov-de
Haas oscillations, which are typical for high quality exfoliated graphene flakes. We did not observe these phenomena on the initial pristine epitaxial graphene films. From first principle calculations, these results are likely due to reduced sheet charge density after functionalization, derived from charge transfer from the chemical molecules to the epitaxial graphene. For practical application, this means that graphene is amenable to attachment of other moieties (molecules, biomolecules, quantum dots, etc.). In this work, we show graphene films and sensors functionalization with ITO, ZnO, CuO, and Fe3O4 nanoparticles. We use these sensors for detection of sulfur contaminants in aviation fuel to prevent catalyst poison that rapidly degrades fuel cell performance. We demonstrate fast (≤ 30 seconds) response, with ppb levels of sensitivity and selectivity towards various sulfur compounds in synthetic S8 fuel mixtures (Figure 1). Furthermore, we show a path towards development of sensor arrays allowing chemical fingerprinting of complex mixtures. In addition, we perform principle component analysis allowing identification of unknown sulfur compounds based on developed library of responses. This work is partially supported by the Office of Naval Research through Naval Research Laboratory Base Program.

QN03.06.32
Double Gate Single Layer MoS2 FETs for Low Noise Frequency Modulation
Michael A. Rodder and Ananth Dodabalapur; University of Texas at Austin, Austin, Texas, United States.

Before the discovery and creation of molecularly thin, stable, semiconducting transition metal dichalcogenide (TMD) sheets, FETs with multiple independent gates were realized mostly by use of ultra-thin SOI channels. Due to the van der Waals attraction between a single layer sheet of TMDs (e.g. MoS2) and atomically smooth, defect free, insulating hexagonal boron nitride (h-BN), single layer MoS2 FETs with two gates (above and below the channel), to independently control the charge concentration in the channel, can be fabricated using standard dry transfer techniques developed for the construction of van der Waals bonded FETs made from TMDs and h-BN [1-2]. The functionality of these devices as circuit elements is of great interest.

In this work, we focus on fabricating single layer MoS2 FETs with two independent gates for use as front-end single transistor mixers to up-convert weak, low frequency input signals to a higher frequency of around 5 kHz. Chopper stabilization is a circuit technique that uses frequency modulation to up-convert a low frequency input signal, such as a brainwave, to a higher frequency (> 5kHz) where there is a reduction in 1/f noise before further amplification (i.e. using an op-amp). We show that a single layer, double gate MoS2 FET can be used as a chopper amplifier. The input signal of around 100Hz is applied to one of the two gates of the MoS2 FET. A modulation frequency of a few kHz is applied to the second gate. Heterodyning is observed albeit with a low conversion gain due to linearity created by large contact resistance. We improve the non-linearity ($I \sim V^2$ saturation characteristics) by increasing the channel length of our FETs so that the contact resistance does not dominate the total resistance. We note that a differential pair of double gate MoS2 FETs requires less overall FETs (two) as compared to the traditional chopper consisting of four silicon FETs. The pristine interfaces between MoS2 and h-BN could result in less noise caused by interface states as compared to traditional semiconductors. We also note that due to the van der Waals bonding of MoS2 and h-BN, these two-dimensional materials can be fabricated on a variety of substrates, making them of interest for front-end input signal frequency modulation. A biomedical signal may be acquired by use of an electrode gel sticking to a part of the body. Along with using two traditional metal gates to modulate the charge of the MoS2 channel, we will show results of an single transistor MoS2 chopper amplifier in which one of the gates is a traditional metal gate while the other is replaced with an ion-gel for charge modulation via ion-gating. By applying a low frequency input signal to the ion-gel gate while applying a few kHz signal to the traditional metal gate to show up-conversion of the input signal, we demonstrate the double gate MoS2 FET’s broader applications as a chopper amplifier to up-convert biomedical signals. Additionally, we present a new double gate MoS2 FET device structure for reducing contact resistance. From the necessity for electrostatic gating to reduce source/drain contact resistance in intrinsically low doped TMD FETs, we fabricate a double gated FET in which MoS2 is both on top and bottom of the source and drain metal, thereby resulting in electrostatic doping of the contact regions from both the top and bottom gate rather than only one gate as in the traditional double gate MoS2 FET structure. This new structure is made possible due to the van der Waals attraction between TMD and h-BN layers; such a structure could not be fabricated easily using conventional semiconductor materials.

QN03.06.33
High-Throughput Identification of Efficient Crystalline Solar-Cell Materials—Example of Screening 2D-Bulk Materials
Komal Choudhary; National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

We present the results of a density functional theory high-throughput screening approach for identifying potential solar cell materials. In order to evaluate a materials efficiency, we calculate spectroscopy limited maximum efficiency (SLME) using frequency dependent dielectric function data obtained using meta-GGA TBmBJ formalism. Additionally, we use effective carrier mass information to further screen candidate materials. Finally, we present the results of a specific example screening case for finding potential 2D-bulk solar materials with high-SLME. Out of 30000 materials in the JARVIS-DFT database, we have 15000 TBmBJ frequency dependent dielectric function data. The dielectric functions were used to calculate SLME. We further investigate the elements that contribute towards high efficiency solar cell materials. We find elements such as Pd, Cu, In, Se, S are some of them. Furthermore, we screened 58 2D-bulk materials with high-SLME, low effective mass, and energy above convex hull ~0.1 eV/atom.

QN03.06.34
Interfacial Charge Behavior Modulation in Perovskite Quantum Dot-Monolayer MoS2 0D-2D Mixed-Dimensional van der Waals Heterostructure for Ultrason-sensitive Photodetector
Hualin Wu1, Zhuo Kang1 and Yue Zhang2; 1 School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China; 2 Beijing Municipal Key Laboratory of New Energy Materials and Technologies, University of Science and Technology Beijing, Beijing, China.

Fundamental understanding of charge behavior inside heterostructures is of vital importance for advancing high-performance optoelectronic applications. However, photoexcited state charge behavior at 0D-2D mixed-dimensional van der Waals heterostructures (MvdWHs) remains elusive. In this work, energy band alignment protocol was adopted to realize effective energy band structure engineering inside 0D-2D MvdWHs of perovskite quantum dots (QDs) and MoS2 monolayer with precisely designed typical type I and II heterostructures. The interfacial photoinduced charge behavior was probed and in-depth understood based on such MvdWHs from two opposite perspectives. Sufficient comparison of a series of optical characteristics results, including Raman shift, quenched photoluminescence, visualized suppressed fluorescence intensity, and imaged shortened fluorescence lifetime, clearly verified that the interfacial charge behavior can be tailored by varied band alignment in 0D-2D MvdWHs. Furthermore, the photoreponse performance and the relatively stronger and weaker photogating effects of such MvdWHs based phototransistors also demonstrated the modulation of interfacial charge behavior in 0D-2D MvdWHs via energy band structure engineering is still practicable for optoelectronic performance optimization. These results are expected to shed light on designing novel functional devices and advancing the development of 0D-2D MvdWHs in the foreseeable future.

Electronic, Topological and Phonon Dispersion Behaviour in vdW Layered Two-Dimensional Heterostructures
Sushant K. Behera and Pritam Deb; Tezpur University, Tezpur, India.

Two-dimensional (2D) materials offer a platform that allows creation of heterostructures with a variety of properties [K. S. Novoselov et al. *Science*, 353 (2016) 461]. Modelled van der Waals (vdW) heterostructures constitute an emerging field promising to design systems with properties on demand. Besides, specific electronic, topological, phononic and optical properties are convenient for controlling the generation, transportation and recombination of charge carriers, excitons, photons which are beneficial for the design of unique electronic devices and catalysts [A. K. Geim et al. *Nature*, 499 (2013) 419]. To assemble the vdW heterostructures, which consist of atomically sharp interfaces and atomic layered structures, provides the chance for engineering a new device at quantum length scale, so as to invent the ultarhin, low-power and flexible device. Despite the relatively weak vdW interaction, which does not affect the electronic properties around the Fermi level, the first principle calculations show significant changes in electron-phonon interaction trends in...

**Aligned Growth of Millimeter-Size Hexagonal Boron Nitride Single-Crystal Domains and Its Application for Deep Ultraviolet Photodetectors**
Jinhua Meng, Xing Wang Zhang, Heng Liu and Menglei Gao; Key Lab of Semiconductor Materials Science, Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China.

Atomically thin hexagonal boron nitride (h-BN), a structural analogue of graphene, has received considerable special attention in recent years. As the unique insulator in the 2D family, h-BN has large optical band gap (5.97 eV), self-terminating surface, low dielectric constant, high thermal conductivity, superb mechanical strength and excellent chemical inertness, thus giving rise to a variety of applications, such as deep ultraviolet optoelectronic devices, dielectric substrates, or protective coatings. For both device applications and fundamental studies, high quality and large-area h-BN layers are certainly desirable. Although, numerous efforts have been devoted to synthesize h-BN domains, the lateral dimensions of single-crystal h-BN domains is still very small, only about one hundred micrometers. In this work, we demonstrated the aligned growth of millimeter-size single-crystal h-BN domains on the epitaxial Ni (111)/sapphire substrates by ion beam sputtering deposition. Under the optimized growth conditions, the single-crystal h-BN domains up to 0.6 mm in edge length were obtained. The formation of large-size h-BN domains results mainly from the reduced Ni-grain boundaries and the improved crystallinity of the Ni film. Furthermore, due to the close lattice match between h-BN and Ni (111), these h-BN domains exhibit well-aligned orientation. The merged h-BN layer exhibits quite uniform and excellent dielectric behavior. In addition, a high-performance deep ultraviolet (DUV) photodetector were fabricated based on the transferring h-BN layers on SiO$_2$/Si substrates, and the corresponding photodetectors exhibited high performance with an on/off ratio of $>10^4$ under DUV light illumination at 212 nm and a cutoff wavelength around 225 nm. This work provides an effective approach for synthesizing large-scale high-quality h-BN layers for electronic applications, especially for the construction of high-performance solar-blind photodetectors.

QN03.06.37
**ZnO/rGO Heterostructures as Potential Photomemristor**
Surinder P. Singh and Manjit Singh; CSIR-National Physical Laboratory, New Delhi, India.

The quest towards miniaturization and smart futuristic technologies in electronic, optoelectronic, healthcare and environmental technologies has fuelled research in material science and engineering. The memristive/ resistive switching devices are a promising candidate for upcoming innovations in electronics with high packing density. Recently, it is being envisioned that an optical control over memristors may open new paradigms in optoelectronic devices for photonic integrated circuits, optical fibre telecommunications, neuromorphic computing and artificial intelligence. Graphene and ZnO nanostructures as optically active semiconductors have already been studied in designing memristor/ resistive switches as well as photodetectors, individually. This encouraged us to further design a photomemristor using the two. We have prepared ZnO/rGO heterostructure using wet chemistry and spin coating the materials on ITO coated glass substrate. In heterostructure device, ZnO acts as a photoconducting layer, whereas, rGO film serves as a light absorbing material and an efficient (top) transport layer that facilitates the movement of charge carriers across the interface. The device showed a resistive switching behaviour with $I_{ON}/I_{OFF}$ ratio of $\sim 10^4$ and photoswitching with $I_{ON}/I_{OFF}$ ratio of $\sim 10^4$ under 370 nm illumination. The results indicate that ZnO/rGO heterostructures may form promising photomemristors.

8:00 AM QN03.07.01
**Quantum Calligraphy—Writing Single Photon Emitters in a Two-Dimensional Materials Platform**
Matthew R. Rosenberger$^2$, Chandrikier K. Dass$^2$, Hsun-Jen Chuang$^1$, Saujan Sivaram$^1$, Kathleen M. McCready$^1$, Joshua Hendrickson$^1$ and Berend Jonker$^1$; U.S. Naval Research Laboratory, Washington, District of Columbia, United States; $^1$Air Force Research Laboratory, Wright-Patterson AFB, Ohio, United States; $^2$KBRWyle, Beavercreek, Ohio, United States.

We present a paradigm for encoding strain into two dimensional materials (2DM) to create and deterministically place single photon emitters (SPEs) in arbitrary locations with nanometer-scale precision. Our material platform consists of a 2DM placed on top of a deformable polymer film. Upon application of sufficient mechanical stress using an atomic force microscope (AFM) tip, the polymer layer plastically deforms. While the AFM tip is in contact with the sample, the AFM tip forces the 2DM to deform with the polymer layer, resulting in tensile strain build-up in the 2DM. When the AFM tip is removed, the adhesive interaction between the polymer and the 2DM prevents the 2DM from relaxing back to its original, strain-free geometry, resulting in a permanent and highly localized strain field in the 2DM. We demonstrate control of indent size by modifying the applied load. Also, we show excellent repeatability of both indent shape and size. We show that SPEs are created and localized at nanodots in a WSe$_2$/PMMA structure, as confirmed by antibunching measurements. The SPEs exhibit single photon emission up to 60 K, which is the highest temperature reported for SPEs in WSe$_2$. This *quantum calligraphy* allows deterministic placement and real time design of arbitrary patterns of SPEs for facile coupling with photonic waveguides, cavities, and plasmonic structures. In addition to enabling versatile placement of SPEs, these results present a general methodology for imparting strain into 2DM with nanometer-scale precision, providing an invaluable tool for further investigations and future applications of strain engineering of 2DM and 2DM devices.

**Tuning Thermal Transport in Two-Dimensional Ferromagnetic CrI$_3$ by Spin-Lattice Coupling**
Guangzhao Qin and Ming Hu; University of South Carolina, Columbia, South Carolina, United States.

Recently, two-dimensional monolayer chromium triiodide (CrI$_3$) with intrinsic magnetism was experimentally discovered, which shows promising applications in many technologies ranging from sensing to data storage where thermal transport plays a critical role. However, so far, the effect of spin-lattice coupling on the thermal transport properties has not been explored yet. In this talk, I will present the giant effect of spin-lattice coupling on the lattice thermal conductivity ($\kappa_l$) of monolayer CrI$_3$. The lattice thermal conductivity is more than two orders of magnitude enhanced by considering the spin-lattice coupling. The effect is found to be especially stronger for the acoustic phonon modes, which dominates thermal transport with spin-lattice coupling. The mechanism lies in the weakened phonon anharmonicity by spin-lattice coupling. The bond angle and atomic position are changed due to the spin-lattice coupling, making the structure much stiffer and more symmetric, which lead to the weaker phonon anharmonicity, and thus the enhanced thermal conductivity. This study uncovers the effect of spin-lattice coupling on the thermal transport, which would deepen our understanding on thermal transport and shed light on future research of thermal transport in magnetic materials.

8:30 AM QN03.07.03
**The Effect of Layer-Coupled States on Charge Transfer in van der Waals Heterostructures**
Peyman Zarehski$^1$, Yaqing Wei$^2$, Run Long$^3$ and Hui Zhao$^1$; Department of
Using semiconductor van der Waals materials in the ultrathin limit as a foundation for engineering new function in electronic materials, we demonstrate the tunable properties provided by direct growth and/or assembly of 0-D materials (quantum dots and organic molecules) on 2D materials (transition metal dichalcogenides and metal monochalcogenides). We address the challenge of controlling nucleation and growth on a non-reactive (vdW) substrate by developing a range of substrate pre-treatments prior to initiating van der Waals epitaxy via metal organic vapor phase deposition. Furthermore, the alternate pulsing of precursors enables the realization of self-limited growth using physisorbed species. We use this approach to grow p-type SnS on n-type MoS2 in both 2-D/2-D and 0-D/2-D heterojunctions. To understand the role of shape, size, structure, and composition on the physical behaviors and device characteristics of mixed-dimensional heterojunctions, we employ Kelvin probe force microscopy, conductive atomic force microscopy, and scanning photocurrent microscopy to analyze the induced photovoltage and photocurrent generated by these mixed-dimensional van der Waals heterojunctions. Further chemical tunability of the photoresponse is enabled by the direct deposition and assembly of organic donor or acceptor molecules on 2-D n-type or p-type materials, respectively, with subsequent characterization by scanning probes. While the energies of molecular orbitals and band edges can in general be used to predict the response, we find that local electrostatic effects at these unusual interfaces also play a role. Finally, in operando studies of the effects of adsorbing dopant molecules and metal oxide precursors will be described to provide new insights into mechanisms that enable tunable doping.

References:
sulfur vacancies, which is evident of the existence of local magnetic states. In a device environment, interacting strongly with the local magnetic defects through the Kondo effect, most of the electrons anomalously scattered back to the hot side, leading to a large anomalous positive Seebeck coefficient in highly conducting n-type MoS₂. Furthermore, modulated by an external electric field, a record power factor of 50 mW/mK² was achieved. Our device is planar and compact and could become a viable option for high-performance thermoelectric devices.

10:00 AM BREAK

10:30 AM *QN03.07.08 Tunable Symmetries and Berry’s Phase in Few Layer Graphene Mandar Deshmukh; TIFR, Mumbai, India.

There have been extensive studies on monolayer graphene where unique properties result from the symmetry of the honeycomb lattice. Few layer graphene systems are of interest as they offer interesting opportunities to study effect of electronic interactions [1] due to flatter bands while monolayer graphene was largely understood in terms of independent electron picture. In addition, few layer graphene offer an opportunity to break simple symmetries and study their consequence [2].

Berry’s phase can be probed using magneto-transport measurements. These measurements can throw up interesting questions in multiband system of few layer graphene. I will briefly discuss our efforts to measure and understand Berry’s phase in a complex multiband system.

11:00 AM *QN03.07.09 Optically Addressable Spin Defects in Hexagonal Boron Nitride Lee C. Bassett; Quantum Engineering Laboratory, Department of Electrical & Systems Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Two-dimensional materials hosting optically addressable electronic states offer a unique platform for quantum engineering due to intrinsic spatial confinement and the ability to create multifunctional layered materials. Defect-related quantum emitters exhibiting room-temperature photoluminescence (PL) have been identified in the wide-bandgap van der Waals material hexagonal boron nitride (h-BN), although many questions remain regarding the defects’ chemical and electronic structure [1], and evidence for spin-related effects has so far been elusive. In this talk I will present new measurements of room-temperature, spin-dependent quantum emission in h-BN [2]. Select defects exhibit striking, anisotropic PL modulations in response to an applied magnetic field, with corresponding changes in the photon emission statistics consistent with an electronic model featuring a spin-dependent inter-system crossing between triplet and singlet states. The discovery of optically addressable spins in h-BN ushers in a new platform for spin-based quantum technologies with the potential for atom-scale engineering and versatile functionality.

This work was supported by the Army Research Office (W911NF-15-1-0589).

SESSION QN03.08/QN01.06/QN02.05: Keynote: Joint Session: 2D Magnets and Heterostructures

1:30 PM QN03.09.01 Highly Mechanosensitive Ion Channels in 2D Membranes Alex Smolyanitsky and Alta Fang; National Institute of Standards and Technology, Boulder, Colorado, United States.

The ability to tune aqueous ion conduction across nanoporous membranes is a key ingredient in a wide variety of applications in nanofluidics and is a critical function of protein ion channels, which control salinity in living cells for a myriad of biological processes. Unsurprisingly, the inspiration for achieving controlled ion flow in artificial ion channels historically came from biophysics. Here, we instead draw the initial inspiration from the chemistry of complex formation between crown ether molecules and dissolved metal ions to demonstrate strain-gated permeation across locally suspended sub-nanoporous graphene and hexagonal molybdenum disulfide (MoS₂) monolayers. Using extensive all-atom molecular dynamics simulations informed by density functional theory calculations, we investigate electrostatically driven aqueous ion permeation across precisely engineered sub-nanometer pores in two-dimensional (2D) membranes under the influence of tensile strain.

In graphene, highly strain-sensitive solid-state ion channels are achieved via membrane-embedded crown ether pores, which exhibit trapping of certain aqueous cation species in the pores due to ion-crown complexation at room temperature. The resulting highly mechanosensitive permeation of potassium ions is shown to arise from a strain-controlled competition between ion-crown and ion-solvent interactions, enabled by the atomic thinness of graphene [1]. Additionally, ion trapping in crown-porous graphene is demonstrated to enable strain-controlled sieving of salt mixtures. In MoS₂ monolayers, mechanosensitive sub-nanopores selective to either anions or cations can be achieved by precise multivacancy engineering, in principle not requiring additional chemical functionalization of the pore lining, because MoS₂ contains two atom species with significantly different electronegativities and thus considerable partial electrostatic charges. The high strain sensitivity in ion permeation across sub-nanoporous MoS₂ membranes is shown to arise from the reduction of ion-pore repulsive interactions upon pore dilation caused by lattice strain. For both graphene and MoS₂-based membranes, current modulation at the order-of-magnitude level per a few percent of lattice strain is demonstrated. Pore structures similar to those considered here have been reported experimentally and thus our results potentially lay ground for a new class of solid-state membranes with ion permeation properties sensitively controlled by externally applied tensile lattice strain.

Effect of Inhomogeneous Nanoscale Strain on Monolayer Tungsten Transition Metal Dichalcogenides Investigated by Nano-Photoluminescence Spectroscopy and Nano-Raman Scattering

Two-dimensional materials suitable for targeted missions with limited resources. Two dimensional material-based environmental sensors can be used for the

Multifunctional Sensor Platforms made of Two Dimensional Materials

Two dimensional materials offer a unique set of advantages as sensors for space applications. For instance, two dimensional materials such as graphene and molybdenum disulfide have high surface-to-volume ratio and low Johnson noise, resulting in highly sensitive gas sensors. In addition, great mechanical, thermal, and electrical stability, as well as radiation hardness due to minute cross-sectional area, make them useful in space applications. Furthermore, lightweight, low power consumption and small size make the two dimensional materials suitable for targeted missions with limited resources. Two dimensional material-based environmental sensors can be used for the *in situ* detection of neutrals, trace gases, volatile organics and environmental parameters in a number of disciplines, including Planetary Science, Earth Science and Heliophysics. For example, these nanosensors can detect gases that can fingerprint various biological and abiotic processes on outer planetary bodies. They can be used to simultaneously detect methane, ammonia and other gases difficult to detect using mass spectrometry due to mass interference issues, and thus can be used in tandem with mass spectrometers. In addition, these miniaturized sensors can be used for quick screening of samples in sample return missions without adding significantly to the mass and power of the payload. Furthermore, Human exploration missions can benefit from these highly sensitive sensors to detect leaks of toxic gases that are commonly onboard such as hydrazine, ensuring human safety and mission success. In this talk, we will discuss our work on developing a multifunctional sensor platform with a suite of environmental sensors fabricated with a variety of nanomaterials.

Making Use of Nano-Bubbles and Nano-Tents Formed by 2D Materials

Nanobubbles at room temperature. This extreme effect of nanobubble strain on both the Raman and photoluminescence signals shows dramatic heterogeneity over the nanobubbles. For both WSe$_2$ and WS$_2$, TEPL and TERS signals show large enhancement with increasing strain from the nanobubble. Additionally, longer wavelength bound exciton luminescence is observed in both WSe$_2$ and WS$_2$ nanobubbles at room temperature. This extreme effect of nanobubble strain on both the Raman scattering and photoluminescence shows the promise of using nanobubble strain to engineer the properties of excitons in monolayer TMDs for novel opto-electronic applications.
QN03.10.01

Two-dimensional (2D) materials provide a wide range of unique properties that enable light generation, modulation, and detection for photonic applications, and could offer an alternative solution for heterogeneous integration by the advent of sufficiently strong van der Waals (vdW) force combined with mature and low-cost CMOS fabrication technology [1]. Hence, it is important to understand the interaction of 2D materials with Silicon photonic platform since their real vs. imaginary part of the optical indices decay away from the exciton resonance have different impacts on the telecom-operating photonic structures [2]. In order to achieve, a detailed understanding of the loss and index change on Si photonics, as per example, the precise and cross-contamination free transfer of 2D materials is essential. In reality, the state-of-the-art of TMDs transfer techniques are not benign with taped-out chip technology due to the inability to place a single 2D material flake on the pre-fabricated photonic chip without incurring significant cross-contamination (e.g. transfer of undesired flakes). We recently provided a solution for this challenge developing a 2D material printer enabling cross-contamination-free transfers without impacting the underlying photonic waveguide structures [3,4]. Finally, we discuss our latest results on passive coupling tunability and index determination using a semi-empirical approach with heterogeneously integrating TMDs layer on Si micro-ring resonator for broadband-on-chip modulators and photodetectors with high-speed and high responsivity [5].

Our results indicate that 2D materials could be an essential building block for a fully integrated photonic circuit.

Large Single-Crystals Synthesis WSe2 Monolayer by Chemical Vapor Deposition Zhenfeng Zhang, Xiaole Xu, Jian Song, Yubao Zhang, Xuefei Li and Yanqing Wu; Wuhan National High Magnetic Field Center and School of Optical and Electronic Information, Huazhong University of Science and Technology, Wuhan, China.

The rich and diverse physics with novel electrical transport and optical properties of transition metal dichalcogenides (TMDs) offer unprecedented opportunities for electronics and optoelectronics applications. However, CVD growth of large-area TMDs film with high mobility is still a challenge. Here, we present an approach for growing monolayer WSe2 with high quality on c-plane sapphire substrate using a low pressure chemical vapor deposition (LPCVD) method. We can successfully obtain WSe2 monolayer with single domain size up to 144 μm in 15 minutes with clean and regular triangle morphology. This synthesis approach of high-quality large domain size of 2D TMDs film provides a pathway for high-performance 2D electronic devices.

The Route Toward Graphene-Metal Composites Kaihao Zhang and Sameh Tawfick; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

The pursuit of high quality multifunctional carbon-based composite materials is driven by a myriad of application lined-up for strongest synthetic structure ever produced. There have been extensive studies, over the past decades, incorporating low-dimensional materials such as carbon nanotube and graphene in metal matrix, whereas no rational design route of graphene-metal composites has been elucidated due to the lack of understanding of graphene-metal interacting at multiple length scales. To gain insights in graphene-metal interactions and to build a rational design route of strong graphene-based macroscopic assemblies and composites, we use a model system incorporating high quality monolayer graphene in single crystalline ultra-thin metal matrix via rapid chemical vapor deposition (CVD) processes.

The ultra-thin metal matrix having thickness less than 200 nm has been manufactured by beating and used extensively for gilding sculptures, precious furniture and building exteriors for over 3000 years. Palladium (Pd) leaf is used as a gilding material for its silver color and excellent anti-corrosion properties. We choose Pd leaf as the metal matrix for two additional reasons: (i) its high carbon solubility at elevated temperatures (~150-fold higher than that of copper at 1000 C). This helps to achieve high carbon segregation flux for graphene nucleation. And (ii) its high binding energy with graphene layer (~2.5-fold higher than that of copper). Graphene-metal interaction gives rich insights of strengthening/toughening mechanisms of graphene in macroscopic composites. In this work, the Pd leaf catalyst is made by hammer beating of a micrometer thick foil. During this process, Pd thickness is reduced to 150 nm while the average grain size exceeds 20 μm. The Pd leaves made by high strain rate beating are stable at synthesis temperature up to 1100 C for 30 s, resisting solid state dewetting owing to their extremely low grain triple junctions density (~ 0.017 μm-2). Mathematical models of low pressure CVD synthesis kinetics on ultrathin metal catalysts guide the development of extremely rapid graphene synthesis conditions, resulting in the formation of high quality uniform graphene monolayer on thin Pd films in less than one minute. Graphene grows rate is twice as fast as copper-catalyzed growth. Uniaxial strain testing with Raman spectroscopy reveals the excellent crystallinity of graphene by probing the stress-induced phonon shifts.

Notable enhancement in mechanical properties is observed in the as-grown Pd-Gr thin film composites. The pristine Pd leaves can be readily transferred to a slotted transmission electron microscopy (TEM) grid, then shaped into doubly-clamped freestanding strips via focused ion beam (FIB). We dope the Pd strip surface with monolayer graphene via the proposed rapid CVD synthesis. Using nanoindentation with a wedge indenter on the Pd-Gr strips, we demonstrate the graphene’s ability to significantly stiffen the Pd leaves by over 116 %. Moreover, indentation, activation and unloading on the nanostructured Pd-Gr strip enables the fracture toughness measurement of ultra-thin film materials. The Pd-Gr exhibits 289.5 J/m² fracture energy, which is over 3.7-fold of the pristine Pd. This new graphene-metal composite material could open exciting opportunities in harnessing superb properties of 2D materials.

Facile Fabrication of Freestanding Size Tunable Graphene Nanomesh for Plasmonics Vivek Garde1, 2, 3, Rakesh Motel2 and Jing Fu3; 1IITB Monash Research Academy, Mumbai, India; 2Indian Institute of Technology Bombay, Mumbai, India; 3Monash University, Melbourne, Victoria, Australia.

Graphene, owing to its excellent electron transport together with a high mechanical strength, has opened up a new pathway in electronics since its discovery. Device applications of graphene, owing to its zero band gap, however, have been limited, and significant efforts have been made to introduce a band gap by including defects in pristine graphene. Patterned graphene is also employed and graphene nanoribbons (GNR), quantum dots (GQD), nanomesh (GNM), etc. have been used for band gap opening and transform graphene from semi-metal to semi-conductor for potential applications in visible to infrared plasmonics. A sizeable band gap can be engineered based on quantum confinement induced by patterned graphene, making the patterning of graphene an important research area.

Lithographic techniques along with plasma etching are most commonly used for graphene nanopatterning. However, referring to the violent nature of plasma etching, graphene nanopatterning inaccuracies. The key challenges are precision, size tunability, high periodicity avoiding the lateral damage in nanopatterning.

In this work, a facile and systematic approach for graphene nanopatterning with ion beam is presented, and size tunable graphene nanomesh on a suspended single layer graphene is shown. The beam overlap function and step size in a gallium FIB are used for nanomesh fabrication with tunable size (30-100 nm) and period (50-100 nm). The fidelity of FIB milling for graphene patterning is demonstrated and revealed by SEM, TEM and AFM imaging. The effect of fabrication parameters is evaluated and graphene cutting conditions are optimized, in addition to patterning. This is important from a technological perspective and graphene device applications. Fabricated nanomesh is size tunable, offering...
potential graphene plasmonics applications. The versatile nature of proposed approach avoiding lateral damage for graphene nanopatterning allows flexibility, and we also demonstrate the fabrication of size tunable graphene nanoribbons. Gold-graphene nanomesh, based on the developed graphene nanopatterning approach, is further presented and illustrated for graphene plasmonics and optical modulation of visible light. The plasmonic response, calculated with finite-difference time-domain (FDTD) electromagnetic simulations, offered through composite graphene-gold nanomesh architecture is in the visible range, and is tunable through the geometrical parameters, providing an opportunity for FIB nanopatterning for graphene plasmonics. Gold-graphene nanomesh offers field enhancements through patterned nanomesh, which arises from localized surface plasmons at the nanostructures significantly, improve the performance of graphene plasmonic devices. In summary, a nanopatterning approach for freestanding size tunable single layer graphene nanomesh is developed and graphene plasmonics is further illustrated through the development of composite graphene-gold nanomesh for optical modulation in the visible spectrum. The demonstrated approach shows endeavour for graphene patterning and future applications of graphene for plasmonics, gas sensing, water desalination etc. with just one processing step.

Two dimensional (2D) layered materials are widely studied due to the exceptional physical properties they exhibit compared to bulk, with a promise to add new functionalities to the existing nanoelectronic devices. It is important to realize low resistance contacts to these 2D semiconducting materials for high performance devices without degrading the pristine quality of the underlying 2D semiconductor. This is difficult to achieve with conventional metal contact schemes. 2D layered metals fall in a less explored class of materials and are ideal candidates for contacting layers to semiconducting 2D layers as they create less defects on other 2D materials due to the innate layered structure. 2H-TaSe$_2$ is one such layered 2D metal that shows simultaneously strong electron-phonon coupling and spin-orbit coupling, which play a crucial role in charge density wave (CDW) driven transport properties [1-2]. It exhibits the highest CDW transition temperature among 2H TMDCs. Interestingly, there is a large gap above and below the bands around the Fermi energy in the normal metal phase of TaSe$_2$ and is expected to possess interesting optical properties, which remain largely unexplored[3]. We exploit this bandstructure in this work to show that due to inter-band transitions, TaSe$_2$ shows strong optical absorption and photoluminescence with a tunable peak position by changing the temperature and thickness of the flake. The perfect combination of excellent electrical transport and optical properties makes 2H-TaSe$_2$ a unique material for flexible, “all-2D” optoelectronic applications. In this context, we show several device applications of TaSe$_2$ in this work, demonstrating its versatile usage as nano-opto-electronic material, as discussed below.

(1) We show that TaSe$_2$ can be used as an efficient donor layer for non-radiative resonant energy transfer (NRET) to other semiconducting layered material[4], allowing us to enhance the photoluminescence intensity of multilayer - stack 2H-TaSe$_2$ heterojunction device, we have used an efficient hot electron injector with large carrier diffusion length (unlike conventional metals), (2) We demonstrate TaSe$_2$ as an efficient contact material for planar and vertical heterojunction devices. (3) Finally, we demonstrate a gated TaSe$_2$/MoS$_2$/graphene vertical junction for photodetection applications where TaSe$_2$ is used as a dual-purpose layer, namely as light absorber and as photocarrier collector. The photodetector exhibits a responsivity of 10 A/W with an operating speed of 0.1 MHz. The results will ignite studies on several device explorations of TaSe$_2$ in nanoelectronic and optoelectronic domain.

Electrical Properties of Quasi 1D Germanium Selenide (GeSe) Nanoflake Field-Effect Transistors

Sang-Kwon Lee, Soo-Young Kang, No-Won Park, Won-Yong Lee, Yo-Seop Yoon and Gil-Sung Kim; Department of Physics, Chung-Ang University, Seoul, Korea (the Republic of)

We report on the electrical properties of natural quasi 1D p-type GeSe nanoflakes, which were mechanically exfoliated from GeSe single crystals by the polydimethylsiloxane (PDMS) stamp method, using a back-gate field effect transistor (FET) measured in a vacuum probe station at room temperature. In this study, we used two contact metals, including Au and Cr metals, as the Ohmic contacts to the GeSe nanoflake FETs, resulting in an Ohmic behavior with the Au contacts, with a total resistance of 5.5×10$^4$ Ω. We also found that the 40-nm-thick GeSe nanoflake FET exhibits clear p-type semiconductor behavior with a field-effect mobility of ~1.0×10$^4$(cm$^2$/Vs) and a current on/off ratio of ~10$^4$ at 4K.

QNO3.10.11

Giant Photoluminescence Enhancement Through Non-Radiative Energy Transfer in 2D/2D Heterostructure

Medha Danda, Mehak Mahajan, Sangheen Kallatt, Sarthak Das and Kausik Majumdar; Indian Institute of Science Bengaluru, Bengaluru, India.

The photoluminescence (PL) emerging from monolayer transition metal dichalcogenides (TMD) with their direct bang gap nature [1] and high binding energies of excitons [2] is prospective for multitude of nanoscale optoelectronic applications. However, the impeded amount of light absorption imposed by the monolayer thickness impedes the realization of viable TMD based optoelectronic devices. Using a van der Waals (vdW) heterostructure of monolayer MoS$_2$stacked on top of multilayer SnSe$_2$, we demonstrate PL enhancement of MoS$_2$ by more than an order of magnitude over the entire overlap area. Counteracting the PL quenching from ultrafast charge transfer across the highly staggered conduction bands of MoS$_2$ and SnSe$_2$, PL of MoS$_2$ enhances by 14x with 633 nm excitation and 5x with 532 nm excitation at room temperature. Similar enhancement is observed with monolayer WS$_2$ stacked on multilayer SnSe$_2$. The enhancement factor is found to be a strong function of the thickness of SnSe$_2$ flake. The PL enhancement retains up to 5x even with the insertion of hBN as thick as 10 nm across MoS$_2$ and SnSe$_2$.

This kind of robust enhancement is facilitated through sensitization of PL of TMD by strongly resonant dipole-dipole coupled energy transfer [3] to monolayer TMD from SnSe$_2$ which acts as a scavenger of light unabsorbed by the monolayer. Multilayer SnSe$_2$ has a strong optical absorption with a direct bandgap of about 2 eV [4] that closely matches with $A_\text{h}$, exciton state energy in MoS$_2$ or WS$_2$. These kind of layered heterostructures are lucrative for exploiting the energy transfer mechanism because of efficient dipole-dipole coupling at the closest possible spaced in-plane dipoles that match in momentum and delay conservation enabled by energy transfer from free electron-hole pairs to highly luminescent $A_\text{h}$ exciton states. At low temperatures (from 200 K to 4 K), we observe a quenching of the PL instead of enhancement, due to suppression of SnSe$_2$ absorption upon reducing temperature. Quenching is also observed when the donor material is replaced from SnSe$_2$ to a weakly absorbing material like TaS$_2$ [5]. The mechanism is further confirmed by polarization resolved PL data and the effect of different parameters on the factor of PL enhancement is analyzed upon constructing a microscopic energy transfer model. Such large area, uniform, highly efficient photoluminescence enhancement through non-radiative energy transfer is promising for the design of optoelectronic devices with layered materials.

Role of Surface Induced Defect States on Thermoelectric Power Factor in MoS$_2$

Lakshmi Amulya Nimmagadda, Manjunath C. Rajagopal, Krishna V. Valavala, Jangyup Son, Sunphil Kim, Arend M. van der Zande and Sanjiv Sinha; Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Two-dimensional materials such as MoS$_2$ have been show to exhibit large Seebeck coefficient and are promising candidates for thermoelectric energy conversion [1]. The ab-initio calculations predict a high intrinsic thermoelectric power factor if the substrate effects are excluded [2]. But the overall power factor is typically limited by its low electrical conductivity. This is possibly due to localized states arising from the impurities and the adsorbates introduced from the substrate [2]. In this work, we measure Seebeck coefficient and electrical conductance of CVD grown MoS$_2$ flakes on Si/SiO$_2$ substrates [3]. We observe hopping transport from the localized states introduced by the substrate at low temperatures and low electrostatic doping. To reduce the observed defect states, we use 2D hexagonal boron nitride (hBN) as a substrate because it provides less charge inhomogeneity and atomically flat surface. The CVD grown MoS$_2$ monolayer is placed on top of hBN using a dry transfer printing process and a PDMS stamp [4]. We observe an enhanced thermoelectric power factor of from MoS$_2$ on hBN substrate over Si/SiO$_2$. However, we still find the localized states to be dominating the extended states from Seebeck measurements at low temperatures and high doping. We attribute these defect states observed in hBN/MoS$_2$ to arise from the dry transfer printing process that could introduce strain heterogeneity. We systematically characterize the defect states through electrical measurements and similarly transfer printed monolayer MoS$_2$ on Si/SiO$_2$ substrates. This work advances the understanding of substrate effects on transfer printed 2D materials for improved thermoelectric performance.

Graphene is a 2D allotrope of carbon with fascinating chemical and physical properties. Its unique electronic structure and surface sensitivity qualify this single layer of sp²-carbon atoms as a promising material for sensor applications in the form of field-effect devices. As descendants of the ion selective field-effect transistor (FET), graphene FETs have been developed in the past years as part of the future of sensing devices. During measurements, the Dirac point of graphene is tracked. Stuiklin on the surface of graphene influence the position of this point of minimal conductivity. Examples for this effect range from graphene’s pH-sensitivity [1], over charge transfer doping effects e.g. by gas molecules [2], to the detection of biomolecules based on changes in the electrostatic charge distribution on the surface [3]. Using covalent chemical functionalization the physical properties and selectivity of graphene can be tuned to realize selective sensor surfaces.[4] In this work, we focus on non-covalent interactions between redox active molecules and graphene.

Graphene has been applied as an electrode material as well. Being used as a working electrode in electrochemical studies, it shows high electron transfer rates for canonical redox couples such as [Fe(CN)₆]³⁻/⁴⁻.[5] The Marcus-Gerischer theory can be applied to describes the electron transfer between a redox active species and an electrode. Therein, the position of the occupied or unoccupied states of the redox active species relative to the electronic structure of the electrode material plays a key role. Due to its unique electronic structure, graphene is particularly interesting in this context being neither metal nor semiconductor, which separates it from other 2D materials beyond graphene. The Marcus-Gerischer theory has been successfully used to explain charge transfer doping of graphene by the O₂/H₂O redox couple.[6]

In this study, we have investigated the interfacial interactions of redox active molecules with graphene, based on measurements using electrochemically grafted graphene FETs and cyclic voltammetry. [Fe(CN)₆]³⁻/⁴⁻ was used as the main probe. The influence of different factors was tested including the pH of the electrolyte solution, the initial oxidation state of the probe as well as the position of the standard potential of the redox couple with respect to the Dirac point. We showed that, while the electrochemical activity is independent of the initial oxidation state of the redox-couple, only the oxidized form [Fe(CN)₆]³⁻ exhibits charge transfer doping onto graphene. In this presentation, we explore systematically the influence of several factors on the observed doping effect.

Light Emitting Devices Based on van der Waals Heterostructures with Plasmonic Nanocavities
Viktoria Shautsova, Yuewen Sheng, Qianyang Zhang, Linlin Hou, Yingqiu Zhou and Jamie Warner, University of Oxford, Oxford, United Kingdom.

Van der Waals heterostructures have recently emerged as promising materials for a new generation of optoelectronic devices. Due to dangling-bond-free surface of 2D materials, the constraints of lattice matching are lifted giving unprecedent flexibility for the device fabrication. Van der Waals heterostructures comprising semiconducting 2D layers are of particular importance, since monolayer materials, for example MoS₂ and WS₂ can be direct bandgap semiconductors in contrast to their bulk counterparts. Various van der Waals heterostructures have been explored for electrically induced light emission, where proof-of-principle devices were typically made of exfoliated materials drastically limiting reproducibility and scalability. Consequently, for practical device applications, large scale materials grown by chemical vapour deposition (CVD) technique are crucial. In this work, we study electrically induced light emission in vertical van der Waals heterostructures fully produced from CVD materials. Vertical graphene contacts are employed to facilitate efficient injection of both the electrons and holes in the active materials such as WS₂. Using hBN tunneling barriers between graphene contacts and active semiconductor materials, the current leakage is minimized for efficient electron-to-photon conversion. Next, the van der Waals heterostructures are combined with plasmonic nanocavities to enhance light emission efficiency and control emission spectrum.

Ultrafast Carrier Dynamics in Few Layer Colloidal Molybdenum Disulfide Probed by Broadband Transient Absorption Spectroscopy
Pieter Schiettecatte, Pieter Geiregat and Zeger Hens; Ghent University, Gent, Belgium.

Ultrathin two-dimensional (2D) group VI transition metal dichalcogenides (TMDs) such as molybdenum disulfide (MoS₂) have attracted much attention in opto-electronics due to their extraordinary properties. As bulk materials, they feature a layered crystal structure consisting of stacked monolayers weakly bound by Van der Waals interactions. The combination of these weak out-of-plane forces with strong in-plane chemical bonds enable ultrathin mono-and few-layered TMDs to be produced using top-down exfoliation methods, vacuum deposition approaches and, more recently, solution-based wet-chemistry methods. Vacuum deposition approaches have arisen as key methods to produce large area monolayer films, yet their high cost and substrate dependence, still remain critical concerns. In this respect could colloidal synthesis offer an inexpensive and scalable alternative as the production and processing of materials in solution opens ample possibilities for large-area device fabrication with a high degree of tunability. [1]

Over the past years, much work has been devoted to understanding photophysical processes occurring in MoS₂ flakes made by exfoliation or CVD. Using a series of spectroscopic techniques it was shown that their physics is being largely governed by enhanced many-body Coulomb interactions which result from quantum confinement and reduced screening. [2] These effects have shown to give rise to pronounced exciton binding energy and band gap renormalization effects. Such studies have not only contributed to a broader fundamental knowledge but were also pivotal for advancing the use of MoS₂ in a broad range of applications. To date, few, if any, studies have addressed the photophysical properties of MoS₂ produced by colloidal synthesis. An overview study is therefore relevant and timely as these materials are produced through an entirely different chemistry - low temperature solution phase versus high temperature gas phase (cf. CVD) and bottom-up versus top-down (cf. exfoliation). In addition would the knowledge obtained in this study undoubtedly pave the way for a more rational fine-tuning of emerging synthetic protocols.

In this contribution, we address the relaxation dynamics of few layer colloidal MoS₂ sheets after photoexcitation by means of femtosecond transient absorption (TA) spectroscopy at visible and near infrared wavelengths. We show that the transient absorbance after photoexcitation results from the joint effect of (a) a reduced oscillator strength of the so-called A and B exciton and (b) a redshift of the entire absorbance spectrum; features we assign to state filling and band-gap renormalization, respectively. Both components exhibit a close to first order decay, yet their rate constants differ markedly. All signatures of state filling disappear from the transient absorbance at a rate of 4 ps⁻¹. In line with the work by Cunningham et al. [3], we attribute the loss of state filling to the trapping of charge carriers - electrons in this case - in midgap states. The bandgap renormalization decays at a rate of 0.1 ps⁻¹, which reflects the rate of the eventual non-radiative charge-carrier recombination. Although being made by an entirely different chemistry, colloidal MoS₂ nanosheets have shown a great resemblance to the state-of-art CVD grown flakes. These results are promising for the future development of colloidal TMDs and their rational fine-tuning according to state-of-the-art post-treatment techniques which would undoubtedly pave the way for their incorporation in device applications.

Passivation of Black Phosphorus using Plasma-Enhanced Atomic Layer Deposition High-k Dielectrics Katherine Price1, 2, Sina Najmaei2, Madan Dubey2 and Aaron D. Franklin1
1Duke University, Durham, North Carolina, United States; 2U.S. Army Research Laboratory, Adelphi, Maryland, United States.

The growing research interest in black phosphorus (BP) as a remarkable material with applications in electronics and optoelectronics has made the study and development of device fabrication and integration processes an essential research area. Specifically, the weak material integrity and oxidation chemistry of BP makes the development of robust passivation techniques vital to preventing degradation in BP. The rapid interactions of BP with O and H2O in air leads to formation of oxides and quick degradation of its electrical and optical properties. An approach, compatible with electronic and optoelectronic device fabrication, that can protect and preserve BP properties is the dielectric capping of the 2D crystal. In this work we will explore and develop scalable (~10 nm) processes for deposition of high-k dielectrics as capping layers on BP using plasma-enhanced atomic layer (PEALD). We demonstrate how the high energy chemical processes and minor defect formations at the interfaces in the PEALD process can enhance the nucleation of the high-k dielectrics on the surfaces of the BP to enable high quality thin film deposition. We are currently developing carrier-selective Schottky-type photovoltaic devices that utilize this new high performance BP capping layer and will fabricate photodetectors with external quantum efficiency up to 0.2% that show good uniformity and homogeneity over multiple layers.
Anomalous Valley-Selective Optical Stark Effect in Monolayer WS

Converse flexoelectricity induces mechanical stress under an inhomogeneous electric field in all dielectrics. Although this electromechanical behavior has great potential as an efficient and low-cost electronics, including solar cells, touchscreens, displays, and printed electronics. So far, there have been several thin film materials with such potentials, such as graphene-like state, known as reduced graphene oxide (rGO). Subsequently, GO is treated in reducing condition to remove oxygen containing functional groups gained during the oxidation, thus, reverting it back to graphene-like state, known as reduced graphene oxide (rGO).

Valley pseudo-spin and broken inversion symmetry leads to valley-specific optical selection rules in monolayer transition metal dichalcogenides (TMDC). Specifically, the degenerate K and K' valleys can be selectively populated with right- and left-hand circularly polarized light. This control of the band edge states has fueled interest in the potential of TMDCs for Valleytronics applications, where the momentum state is manipulated to perform computational and/or logical operations.

Recently, it was discovered that intense circularly polarized light fields can be used to break the degeneracy between the K and K' valley, allowing the energy levels of each valley to be independently tuned via a valley-selective form of the well-known optical Stark effect\(^1\)\(^2\) and lesser-known Bloch-Siegert\(^2\) effects. For high-intensity sub-resonant illumination with right-hand circularly polarized light, the K-valley A-exciton absorption band will blue-shift to higher energies. In the past, this has been described by the dressed-atom picture, which predicts that the effect reverses to a red-shift for above-resonant illumination. Additionally, application of Floquet theory to describe those observations has led to the prediction of topologically protected chiral edge states for above-resonant light fields. We do not see a Stark shift associated with intervalley biexcitons.

We do not see a Stark shift observed for the opposite (i.e. K') valley, confirming the valley-selective nature of the optical Stark effect in TMDCs. For near-resonant pumping of the K-valley, no Stark shift is observed for the opposite (i.e. K') valley, confirming the valley-selective nature of the optical Stark effect in TMDCs. For low-dimensional semiconductors, we suggest that exciton-exciton repulsion needs to accounted for to predict the near-resonance behavior of the optical Stark effect. Our results may have implications in the search for topologically protected chiral states in TMDCs.

Converse Flexoelectric MoS\(_2\) Thin-Film Actuator

Converse flexoelectricity induces mechanical stress under an inhomogeneous electric field in all dielectrics. Although this electromechanical behavior has great potential as an actuation mechanism, flexoelectric actuators have not been widely studied, which is mainly attributed to the fact that the effect of flexoelectricity is considerably small in general bulk dielectrics. Two-dimensional (2D) materials can be a practical candidate as an active material due to the scaling effect of flexoelectricity. Here, we report a molybdenum disulfide (MoS\(_2\)) thin-film actuator driven by the converse flexoelectric effect under electric field gradient. To fabricate an actuator device, single-layer chemical vapor deposition (CVD)-grown MoS\(_2\) was transferred on the substrate with an insulator on the bottom electrode, followed by comb-shaped top electrode deposition for the electric field gradient through fringe fields. To characterize the actuators, we measured out-of-plane displacements at the first harmonic resonance frequency of the input AC signal using a laser vibrometer. When we characterized the actuation performance, we measured the displacement relative to the active layer thickness of our MoS\(_2\) actuator showed more than an order of magnitude higher performance compared to other existing flexoelectric actuators. In addition, in a cyclic test, the MoS\(_2\) device exhibited consistent performance after 10\(^8\) cycles of actuation, which suggests stable operation in air conditions. The converse flexoelectricity combined with distinct properties of 2D materials will open up unique opportunities in the field of nanoelectromechanical systems (NEMS).
Non-destructive inspection of features or materials buried beneath dielectrics is highly sought after for diagnostics of micro- and nanoelectronics, and is a long lasting technical challenge. Optical microscopy allows for imaging beneath an insulator, while its lateral resolution is limited to the micron scale. Scanning electron microscopy offers sub-nanometer resolution, but often encounters sample charging obscuring the analysis of insulators. Using photoemission electron microscopy with deep-ultraviolet (deep-UV) photocathode, we show sub-surface imaging of MoS$_2$ flakes sandwiched between dielectric overlayers (up to 100 nm-thick) and an underlying SiO$_2$ films. Comparison of photomission yield to modelled optical absorption of dielectric stacks demonstrated that optical standing waves contribute to the sub-surface imaging mechanism. The presence of atomically-thin MoS$_2$ flakes modulates the optical properties of the dielectric stack locally, producing image contrasts of the buried MoS$_2$ with submicron lateral sensitivity. The results presented here underscore the role of optical effects in enhancing the depth sensitivity of photoemission images produced using low-energy photons. The benefit of this approach includes non-destructive imaging of buried interfaces and sub-surface features useful for analysis of microelectronics circuit and of nanomaterial integration into electronic devices.

Study of the Electrical Disorder Sources in Transferred CVD Graphene

Electrical disorder in CVD (chemical vapor deposition) graphene limits its performance in many applications [1, 2]. Recent works on graphene sensing applications have shown that disorder induces uncertainties in the reading of Dirac voltage, which undermines their sensitivity [3]. However, the sources of electrical disorder have not been thoroughly understood yet in literature. This work presents a comprehensive study of the sources of disorder in CVD graphene. Utilizing Raman spectroscopy mapping and atomic force spectroscopy (AFM), we correlated the carrier concentration distribution [4] of transferred CVD graphene to its topographic image. The results show that due to the embedded ripple structure, which originates from the thermal expansion coefficient mismatch against the growth substrate, graphene forms uneven separation to SiO$_2$ substrate according to the ripple array. Consequently, the hole doping received from SiO$_2$ [5] alternates in a periodical manner. Further, we bisected the mapping data of graphene according to its ripple structure into valley (topographically lower) and peak (elevated by ripples) groups, and show that valley region is more disordered. Such additional disorder is from the enhanced charge interaction with the impurities in the substrate [6]. The results suggest that the disorder in graphene depends on the morphology of the ripple array, which is eventually determined by the degree of mismatch between the graphene and the growth substrate [7]. Finally, we performed AFM and Raman spectroscopy mapping on the same sample after rapid thermal annealing (RTA). The results indicate that annealing heals the size unevenness from ripple, and therefore alleviates the non-uniformity in doping distribution across the sample. However, as thermal annealing relocates graphene closer to the substrate [8, 9], graphene suffers more disorder from SiO$_2$. This study suggests that ripple is essentially not a disorder source, whereas it contributes to disorder when there is substrate doping. The authors acknowledge funding from Boston Scientific Corporation.

Unique Stacking Configurations in Bilayer Ribbons Grown on Monolayer Grain Boundaries by Chemical Vapor Deposition

Stacking orientation of atomically-thin 2D layers may serve as an interesting way to tune their optical and electronic properties for optoelectronic applications. However, it is a challenge to engineer it in a desirable way. Here, we demonstrate a synthetic strategy to enable the growth of bilayer crystals exhibiting a wide range of stacking configurations. Detailed second harmonic generation (SHG), low-frequency Raman spectroscopy, and atomic-resolution scanning transmission electron microscopy (STEM) studies of bilayer WS$_2$ ribbons are performed to reveal that the defects on the grain boundaries facilitate the growth of bilayers with a wide range of stacking angles. First-principles calculations proposed possible mechanisms of the orientationally arrangement of bilayers. We also show that the low-frequency Raman serves as a distinct signature for fast differentiation of new stacking configurations. Our finding shows a promising way to direct synthesis of bilayer crystals with weak interlayer coupling and specific mutual monolayer orientations, which is important for their future optoelectronic applications.

2D Electrides and Their Use in Atomically Thin Heterostructures

The properties of 2D materials motivate the exploration of new atomically thin materials. One class of 2D materials, demonstrated experimentally, is 2D electrides, which consist of a layer of atoms and layers of electrons on the surface. The layers of electrons are delocalized into layers of 2D electron gas. As a result, 2D electrides, such as 2D Ca$_3$N$_2$, have exciting properties like high electrical mobility, high carrier concentrations, and ultra-low work functions. To synthesize 2D Ca$_3$N$_2$, we exfoliated the layered bulk crystal Ca$_3$N$_2$ in appropriate organic solvents to shear few-layer sheets. Careful study using X-ray diffraction and transmission electron microscopy coupled with selected area diffraction showed that the sonicated Ca$_3$N$_2$ yielded crystalline 2D sheets. Measurements by ultraviolet photoelectron spectroscopy and UV-Vis-NIR spectroscopy confirmed that the 2D sheets retain the metallic electronic structure of the bulk and could serve as excellent transparent conducting materials. To build on this result conceptually, we performed computations using density functional theory (DFT) that suggest that the 2D electrides, when brought into contact with other 2D materials, donate massive amounts of electron density (up to 0.5 e- from formula unit of acceptor) and form quasi-covalent bonds between materials. This unique behavior constitutes a conceptually new type of heterostructure with properties distinct from either monolayer. Here we report calculations of electrode/graphene, electrode/hBN, electrode/black phosphorus, and electrode/Zr$_2$S$_2$ heterostructures. Exterinsic electron transfer from the 2D electrode to the acceptor creates a strong electrostatic attraction, which results in an interlayer distance (~2.0 Å) much smaller than traditional van der Waals distances in the case of Zr$_2$S$_2$. The high degree of electron transfer into Zr$_2$S$_2$ raises the Fermi level of Zr$_2$S$_2$, which populates its conduction band and converts the wide bandgap semiconductor into a metal. By calculating different orientations of the heterostructures, we show that the electron transfer and the interlayer distance are inherently coupled. We provide calculations of the anisotropic work function and give analysis of the electronic structure as one example of the exciting properties of this new type of heterostructure.

Fabricating Waveguide Patterns for Rapid Optoelectronic Evaluation of TMD Material Integration

The most common form of data communication in present day is via electrons shuttling through metal wires. However, this presents severe losses leading to incoherent communication for long-reach applications. Light propagating through a well-defined path, such as in a waveguide, offers the most promising future in data communication. Optical on-chip and inter-chip connections provide high-bandwidth communication in short-reach applications as well as very little losses for long-reach applications. We are to explore a broad range of 2D metal dichalcogenides and their alloys such as MoS$_2$, MoSe$_2$, WS$_2$, and WSe$_2$, for applications as advanced opto-electronic materials. The combination
of tunable bandgap, interface-determined structure in the absence of a bulk and Fermi-level control by electrical contacts renders them a materials system with great potential for application as emitters and sensors, e.g. for on-chip and inter-chip optical communication. The high stability and facile preparation of MoS2 and related materials suggests great potential in this system, rendering them an ideal target for a research project that seeks novel materials for mastering energy and information on the nanoscale to create new technologies. We use the Molecular Foundry nanofabrication facility to fabricate on-chip waveguides out of a silicon nitride on silicon dioxide substrate including edge-couplers initially and grating-couplers that are tailored to the bandgap of common TMD materials between 1.5 and 1.9 eV. These grating couplers act as seed locations via etching and depositing specific metals, initially molybdenum, via e-beam evaporation due to its directional nature. Preliminary data utilizing waveguides with couplers at unsuitable wavelength (but within the abilities of the lithographic processes available to us) show structurally promising result, but lack functionality. Preliminary seeding growth results show monolayer MoS2 single islands on side walls. More results will be acquired using the optical wave-guide testbed system built in a nitrogen enclosed glove-box environment.

QN03.10.29 Structure and Properties of High-Mobility MoTe2, Phase Aniruma Singh1, Ryan Beams2, Irina Kalish2, Sergiy Krylyuk2 and Albert Davydov2; 1Arizona State University, Tempe, Arizona, United States; 2National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 3Food Drug and Administration, Silver Spring, District of Columbia, United States.

Recent experimental demonstration of temperature- and electric field- driven reversible phase transition of the semiconducting 2H-polymer of MoTe2 to the metallic JT- polymorph has been shown to be an appealing strategy for phase-change devices and ohmic contacts for nanoelectronics. However, several studies have reported a non-intentional loss of Te in microscopic regions of the films leading to the formation of Te-deficient phases such as MoO3[1] and MoO2[2]. In this study, we present the experimentally measured as well as density-functional theory computed Raman spectra of the MoTe2 phase to guide an unambiguous experimental identification of this Te-deficient phase. Using first-principles simulations, we also examine the structure, energetic stability, electronic and vibrational properties of MoTe2 compound and fourteen Mo-intercalated MoTe2 and MoO2 phases. We find that, unlike MoTe2, MoO2Te4 is amenable to Mo-intercalation which increases its charge-carrier mobility. [1] ACS Nano 9.6, 6548-6554 (2015); [2] Advanced Materials 29.18 (2017)

QN03.10.30 Nonvolatile Memories with Graphene Ferroelectric Field-Effect Transistors—Up-Scaling and Practicality Morteza Hassanpour Amiri and Kamal Asadi; Max-Planck Institute for Polymer Research, Mainz, Germany.

Graphene has a great promise for many opto-electronic applications. Chemical vapor deposition (CVD) of graphene is a technologically viable method for graphene production. Conventional photolithography and deposition of metal contacts on top of the transferred graphene layer to fabricate microelectronic devices is potentially invasive for graphene, and yields large spread in device parameters, and can inhibit up-scaling. In this contribution, we use an alternative process technology in which both lithography and contact deposition on top of graphene are prevented. First a pre-patterned substrate is fabricated that contains all the device layouts. Then CVD graphene is transferred on top using a conventional or laser induced forward transfer. The metal–graphene contact shows low contact resistances below 1 kΩ μm. The conformal transfer technique is scaled-up to 6” wafers with statistically similar devices, and can be applied by the transfer of any two-dimensional material. Next, we demonstrate ferroelectric field-effect transistors (GraFeFET) using the conformal transfer technique. As ferroelectric gate we use a ferroelectric polymer, poly(vinylidenefluoride-trifluoroethylene), P(VDF-TrFE). Device processing was optimized to obtain robust, highly reproducible GraFeFETs that operates at both electron and hole accumulation regimes. We present further dual-gated GraFeFETs wherein the on/off ratio can be controlled by a second nonferroelectric gate. Finally, we present a model that captures the device physics of a GraFeFETs by incorporating the polarization of the ferroelectric gate. The model predicts practicality of the graphene ferroelectric field-effect transistors, and gives criteria to improve the on/off ratio and the memory performance.

QN03.10.31 Spatially Resolved Solid-State Reduction of Graphene Oxide Thin Films Maica Morant and Kamal Asadi; Max-Planck Institute for Polymer Research, Mainz, Germany.

The current paradigms at both the industrial and research level produce reduced graphene oxide (rGO), an insulating form of graphene, only in the bulk form. For a wide range of applications, from microelectronics to water peroration, spatially resolved and controlled reduction of GO in (thin-)film is needed to reestablish electrical conductivity. Such demands require a paradigm shift in the reduction process, which should be free from intentionally used auxiliaries such as electrolytes and high temperatures. Reestablishment of the electrical conductivity in GO is (partially) obtained by reduction through high temperature treatment in a reducing atmosphere, or using strongly reducing chemicals or electrolytic processes. The reduction methods, as noted above, are suited only for bulk graphene oxide. Spatially resolved reduction of thin films of graphene oxide is important for wide range of applications such as in microelectronics, where an electrolyte-free, room temperature reduction process is still needed. In this contribution, we present spatially resolved solid-state reduction of graphene oxide thin films. We demonstrate that the reduction mechanism is based on electrolysis of water that is adsorbed on the graphene oxide thin film. The reduced graphene oxide thin-films show sheet resistance of only several kΩμm, with weak temperature dependence. Graphene oxide can be produced on a large scale and processed using low-cost solution casting techniques. Spatially resolved reestablishment of conductivity in GO can be used in electrically controlled water peroration or in micro- and nanoelectronic applications for instance as an anti-fuses.

QN03.10.32 Effects of Conductive Polymer Composite Layering on EMI Shielding During Additive Manufacturing Eugene Zakar, Theodore Anthony and Madan Dubey; U.S. Army Research Laboratory, Adelphi, Maryland, United States.

Spin coating and drop casting are viable methods for rapid and low-cost manufacturing of components for flexible devices and sensors. We investigated the cumulative effects of layering a conductive polymer mixture containing 2wt.% multiwall carbon nanotube (MWCNT) filler in a poly(3,4-ethylenedioxythiophene)poly(styrene sulfonate) (PEDOT:PSS) binder solution for application to electromagnetic interference (EMI) shielding. We determined the effects of adding solvents to the mixture, and heating for faster curing of the composite film. EMI shielding effectiveness (SE), or the measured attenuation, of the composite layers was quantified by a vector analyzer using the coaxial method in the frequency range 12-18 GHz (Ku-band).

The surface of a Mylar substrate 2mm in thickness that we used is hydrophobic in nature and does not easily wet making it difficult for any film adhesion. Rather than use traditional methods of creating hydrophilic surface by acid soaking or plasma exposure we overcame this difficulty using a simpler and more reproducible method by adding a spin coated adhesion layer of PMMA.

Drying time of the composite layer on the flexible Mylar substrate was reduced from 24 hours to 60 minutes by the addition of IPA (1:1) in the solution mixture, and further accelerated to 10 minutes with the aid of hot plate heating. Heating was optimized at 40°C for all the samples were prepared with IPA (1:1) unless stated otherwise.

RESULTS AND OBSERVATIONS: Spin coating the composite mixture yielded extremely thin films 0.05 μm, 0.15 μm, and 0.45 μm using 1x, 3x, and 9x times coating passes respectively. Their low SE of 0.1 dB, 0.25 dB, 0.5 dB were attributed to their very high film resistance of 2.5 MΩ, 25 KΩ, and 4.7 KΩ respectively. The composite stack is semi-transparent at a total thickness of 0.45 μm.

Drop-casting the composite mixture produced 10x times thicker films compared to the spin coating method. A single drop-casting produced a film 4.4 μm with a 4-point resistivity of 280 Ω·sq, and SE=5 dB. Interestingly, when we remove the IPA(1:1) which promotes faster drying of the PEDOT:PSS solution, the resistivity of the mixture reduced to 125 Ω·sq and the SE surged up to 16 dB. This seems an IPA free mixture solution yielded 3x times improvement in SE with the same thickness, due in part to the lower resistivity. A composite stacking of 4.4 μm is opaque to the naked eye.

We further examined the effects of diluting only the PEDOT:PSS component of the mixture. Drop-cast PEDOT:PSS solution has a thickness of approximately 200 nm, 250 Ω·sq resistivity and SE=12 dB. When diluted with H2O (1:1) the resistivity increased to 545 Ω·sq and SE decreased to 7.5 dB. When alternatively diluted with IPA (1:1) the resistivity increased to 415 Ω·sq but the SE decreased only slightly to 11 dB compared to the pure solution. In summary, the dilution of PEDOT:PSS solution with H2O (1:1) has a detrimental effect, in comparison to dilution with IPA (1:1) that has a subtle degradation of SE.

Drop casting 4-layers composite mixture yielded yet a greater thickness of 15 μm, with lower 63Ω/sq resistivity and higher SE=13 dB, compared to 1-layer drop-casting of 4.4 μm with SE=5dB. The SE total of 4-layers is less than the total additive effect of each layer increment. When we added two Mylar substrates with drop-casted 4-layers one top of another, a cumulative composite thickness of 30 μm (15 μm + 15 μm) was achieved that yielded an SE average ~ 17 dB. We also observed an enhanced attenuation peak of 21dB at 17 GHz, likely due to the effect from a 2mm Mylar separation absorber layer [1] formed between the two conductive polymer layers.
Sodium ion batteries are a promising more environmentally sustainable alternative to Li-ion batteries. However, the larger sized sodium ion cannot be hosted by the graphene anode material used in Li-ion batteries, and so significant research is devoted to the development of disordered carbon materials with a more open structure to serve as an alternative. One promising candidate, hard carbon, is composed of nanodomain of stacked rippled graphene.

Na intercalation into the galleries of this material is found experimentally to be energetically favorable; however, its d-spacing, while larger than graphite, is smaller than the anode material used in Li-ion batteries, and so significant research is devoted to the development of disordered carbon materials with a more open structure to serve as an alternative. One promising candidate, hard carbon, is composed of nanodomain of stacked rippled graphene.

The experimental study on the piezoelectric properties of MoS\(_2\); has shown that the cyclic stretching and releasing of MoS\(_2\) exhibits promising piezoelectric characteristics for the odd number of layers. However, the state-of-the-art relies on the mechanical exfoliation technique and its relatively small size (e.g., flakes) limits the practical adoption of MoS\(_2\) for applications requiring large-area device or system integration. In this work, we applied an unique CVD (chemical vapor deposition) technique to grow a large surface area, easy-transfer MoS\(_2\) (2cm \(\times\) 2cm) film on a SiO\(_2\) substrate, which was thoroughly characterized by using a variety of structural and electrical analysis methodologies, including Raman spectroscopy and piezoelectric testing on the flexible substrate. This work will provide a new insight on the practical application domain where the large-area, piezoelectric MoS\(_2\) can be best utilized for energy harvesting purposes.

Non-equilibrium synthesis and processing enables a wide variety of materials systems with tuned properties. Here we report how a prototype setup allows laser illumination to be coupled into a (scanning) transmission electron microscope (TEM) for real-time observations of non-equilibrium synthesis. The pulsed laser deposition of atomically-thin 2D materials can be performed at elevated temperatures from amorphous nanoparticles “building blocks”, and is suspected to occur by the general process known as crystallization by particle attachment (CPA). To investigate how amorphous nanoparticles of transition metal dichalcogenides (TMDs) crystallize into atomically-thin 2D layers, the process is broken into two steps. First, nanoparticles are deposited at room temperature onto TEM grids by pulsed laser deposition, and then are rapidly heated by a laser within a TEM to observe how they crystallize, fuse, and reorient into thin layers. Characterization of these “building blocks” by high-resolution electron microscopy and spectroscopy, as well as first principles modelling, is required to infer valuable information on the times scales and kinetics of the growth processes of these nanomaterials. Especially, the mobility of the nanoparticulate species on the TEM grids is highly dependent on the grid material. In addition to commercial ultrathin SiO\(_2\) grids, graphene and other 2D crystalline layers grown...
by chemical vapor deposition are utilized as platforms for synthesis, which yielded different microstructures and different kinetics. Electron energy loss spectroscopy (EELS) is utilized to understand the electronic properties and composition of synthetic 2D crystals and their heterostructures in the TEM. The observation with EELS at cryogenic temperatures with a mono-chromated TEM allows also to map with high spatial resolution the distribution of excitons. The energy of the excitons is very sensitive to the local structure and can be directly compared to photoluminescence and Raman spectra. In addition, post-growth atomic-resolution ADF-Z-STEM measurements permit the characterization of crystal phases, defects and grain boundaries at the atomic scale. These results are compared with ex situ laser annealing experiments and optical spectroscopic measurements. These nanoscale measurements to understand the growth mechanisms of crystalline 2D films from amorphous precursors should enable more rapid advancement of laser processing at the macroscale.

QN03.10.37
Excellent Metal-Free SERS Platforms Ruey-Chi Wang and Yu-Hsuan Chen; Department of Chemical and Materials Engineering, Kaohsiung, Taiwan.

Highly-sensitive surfaced-enhanced Raman scattering (SERS) platforms were prepared by depositing graphene oxide (GO) layers on ZnO thin films via suction filtration followed by proper heat treatments. FTIR spectra show that oxygen-containing function groups (FGs), were significantly increased after specific heat treatments. SERS measurements show that the FGs benefit enhancement factors (EFs) of SERS effects. In the work, the effects of GO thickness, heating temperature/time, and atmosphere on the FGs and SERS were investigated. Ultraviolet photoelectron spectroscopy (UPS) was employed to characterize electronic structures of the GO/ZnO composite with different heat treatments. The GO/ZnO composite annealing in Ar atmosphere at 100°C for 3h demonstrates a high EF value of exceeding 70000 for Rhodamine 6G detection. Raman mapping shows uniform intensity distribution of enhanced signals from the detection molecules. The SERS platforms show a high retention of more than 75% after aging in dark for six months. The metal-free, high-sensitive, and stable GO/ZnO composites are promising for fabricating low-cost and high-performance SERS platforms for chemical and bio-sensing.

QN03.10.38

Molybdenum disulfide (MoS2) is a kind of transition metal dichalcogenide (TMD) materials which has attracted great attention due to its various interesting properties[1][2]. MoS2 is very promising for electronic and optoelectronic devices because of indirect band gap (~1.2 eV) for few layer and direct band gap (~1.8 eV) for monolayer MoS2[3]. In MoS2 based Schottky devices, Schottky barrier height depends on the thickness of MoS2 because of its tunable electronic properties[4][5]. MoS2 have been deposited by different methods such as exfoliation, CVD, hydrothermal synthesis and other techniques. Here, we have used DC sputtering technique to fabricate metal-semiconductor junction of MoS2 with platinum (Pt) metal contacts. In this work, MoS2 thin film (~10 nm) was deposited on p-Silicon (111) using DC sputtering technique at optimized parameters. Schottky metallization of Pt metal (diameter~1mm) was also done using DC sputtering. Temperature dependent current-voltage (I-V-T) characteristics of Pt/MoS2 Schottky diodes have been investigated in the temperature range 80-300 K in the steps of 20K. Forward I-V characteristics Pt/MoS2 junction are analyzed to calculate different Schottky parameters such as Schottky barrier height, ideality factor, series resistance, Richardson constant and standard deviation. Schottky barrier height increases and ideality factor decreases on increasing the temperature from 80-300K. The I-V-T measurements suggest the presence of barrier inhomogeneities at the metal-semiconductor (Pt/MoS2) junction. Schottky barrier inhomogeneities occur if the interface is not flat or rough, then the Schottky barrier height is not remain constant and vary locally. Current transport through the junction is a temperature activated process. The electrons at low temperature pass over the lower barriers and therefore the transport will be dominated by current flowing through the patches of lower Schottky barriers and results in larger ideality factor. As the temperature increases, more and more electrons overcome the barriers and this causes the ideality factor to be close to unity and apparent temperature independent current.

The Evidence of Phase Transition from 1T Phase to 2H Phase of Vanadium Diselenide Dian Li, Xiong Wang and Xiaodong Cui; University of Hong Kong, Hong Kong, Hong Kong.

Vanadium diselenide (VSe2) usually exists at the 1T crystal-phase in bulk form. While the DFT calculation predicts that both 1T and 2H phase are possible stable structures at 2D limit, though 2H phase VSe2 is not reported as yet. In this work, we report the phase transition from 1T phase to 2H phase by annealing multilayer VSe2 at about 650K accompanying evidence of metal-insulator transition and Raman scattering.

Synthesis of High-Crystalline Bulk MoSe2 Controlling the Gas Flow Kim Jeonghun, Na Liu, Coo Sooho and Sunkook Kim; Sungkyunkwan University, Suwon, Korea (the Republic of).

Two-dimensional transition metal dichalcogenides (TMDs) have attracted researchers for their broad application in semiconductor industry. As their controllable band gap, electronic characteristic and unique optical characteristic are suitable to fabricate electric device such as field-effect transistor. Here we show a synthesis method to control the quality of the bulk MoSe2 using chemical vapor deposition. Argon and hydrogen are the most popular carrier gas and reducing gas, respectively. The ratio of Ar and H2 determines the quality of the MoSe2. Furthermore, the crystallinity increased with increasing gas flow rate. To investigate the quality and uniformity of the bulk MoSe2, Raman spectroscopy, scanning electron microscope, energy dispersive analysis of X-ray, and X-ray photoelectron spectroscopy were performed. MoSe2 thin film transistor was then fabricated with typical bottom gate structure on a SiO2/Si substrate with Al2O3 passivation. The room-temperature carrier mobility for the device was about 21 cm2/Vs. This study demonstrates the novel approach in growth MoSe2 with high crystallinity and its application to electronic devices.

Gate-Controlled Photovoltaic Effect of Black Phosphorus/WSe2 Heterojunction Dohyun Kwa, Min-Hye Jeong, Hyun-Soo Ra, A-Young Lee and Jong-Soo Lee; Department of Energy Science and Engineering, Daegu Gyeongbuk Institute of Science and Technology (DGIST), Daegu, Korea (the Republic of).

Semiconductor two dimensional (2D) materials have shown great potential in optoelectronic devices because of their high carrier mobility and very thin thickness. Recently, many groups have explored the heterojunction structures based on semiconducting 2D materials for photovoltaic applications as ultrathin p-n diodes. For high-performance photovoltaic devices, the electron-hole balance is an important parameter because it has effect on the formation of the built-in field across the device. In this study, we exhibit multi-layer black phosphorus (BP)/WSe2 p-n heterojunction device and demonstrate the photovoltaic effect of the device by electrostatically controlling carrier concentration into BP. The gate-controlled heterojunction device exhibits a high current rectification of 105, external quantum efficiency of 4.4% under the 405-nm laser illumination, and solar efficiency of 4.6% under the AM 1.5 solar spectrum. Our works suggest that making a balance of charge carriers in the 2D heterojunction p-n diode is highly prioritized for the high performance 2D
Atomically thin graphene exhibits fascinating mechanical properties, although its hardness and transverse stiffness are inferior to those of diamond. So far, there has been no practical demonstration of the transformation of multilayer graphene into diamond-like ultrahard structures. Here, we show that during nanoindentation at room temperature, 1-layer graphene on SiC(0001) (1 layer graphene + buffer layer) exhibits a transverse stiffness and hardness comparable to diamond, showing resistance to perforation with a diamond indenter and a reversible drop in electrical conductivity upon indentation. Density functional theory calculations suggest that, upon compression, the 1-layer graphene film transforms into a diamond-like film, producing both elastic deformations and sp$^2$ to sp$^3$ chemical changes. Experiments and calculations show that this reversible phase change is not observed for a single buffer layer on SiC or graphene films thicker than two layers. Indeed, calculations show that whereas in 1-layer graphene layer-stacking configuration controls the conformation of the diamond-like film, in a multilayer film it hinders the phase transformation. Our findings identify supported 1-layer graphene as an interesting candidate for pressure-activated adaptive ultrahard and ultra-thin films and for force-controlled dissipation switches. Our study opens up new ways to investigate graphene-to-diamond phase transitions at room temperature in low-dimensional systems. Finally, this work suggests a new route to produce and pattern single-layer diamond in graphene through stabilization of the diamond-like phase, with applications ranging from nanoelectronics to spintronics.

High-Bias Characterization of Single-Crystalline $\text{WTe}_2$ Nanobelts for Future Nanoscale Interconnects

Hwa Kim$^1$, Jong Hwa Kim$^1$, Jae-Ung Lee$^2$, Jong Uk Kim$^3$, Hyung Duk Yun$^4$, Yeeseon Sim$^5$, Jaewon Wang$^5$, Do Hee Lee$^6$, Shi-Hyun Seok$^7$, Ta Il Kim$^8$, Hyongsik Cheong$^9$, Zonghoo Lee$^{10}$ and Soon-Yong Kwon$^{11}$

As elements of electronics are downsized to the nanoscale, the microstructure is no longer stable under current stress in practical applications. For example, conventional interconnect metals (i.e., poly-crystalline Cu and W) suffer from size effects related to both surface and grain boundary scatterings, thus impeding current injection into the materials contributed by the exponentially increased resistivity.$^{(1)}$ Accordingly, high current-carrying van der Waals (vdW) metals such as quasi-one-dimensional (quasi-1D) transition metal (TM) chalcogenides (i.e., TiS$_2$, TaSe$_2$, and WTe$_2$)$^{(2-5)}$ have drawn new attention as alternatives for downscaled interconnects owing to their dangling-bond-free surface and quasi-1D atomic intermetallic bonds, which allow highly mobile carriers to reduce their diffusive motion. However, a lack of reliable bottom-up approaches to obtain high-quality 1D single crystals on a desired substrate hinders systematic electrical characterizations and further applications of the materials. Moreover, a high-bias analysis of TM chalcogenides depending on size under different ambient environments remains to be studied, which will allow us to understand their electrical breakdown mechanism and energy transfer through different interface dimensions.

In this study, we report an investigation of the low- and high-field electrical properties of single-crystalline $\text{WTe}_2$ nanobelts, mainly focusing on their electrical failure and current-carrying capacity. To synthesize stoichiometric, quasi-1D $\text{WTe}_2$ crystals, a eutectic alloy (e.g., Cu$_2$Te, or Au$_2$Te)$_3$ was introduced to provide a liquid-like Te-rich ambient condition. Because of this approach, a systematic investigation of the electrical properties of the crystals became possible as a function of channel dimensions by avoiding degraded edges by harsh etching$^{(6)}$ and random crystalline orientations,$^{(7)}$ which are unavoidable for the exfoliated flakes. The resultant $\text{WTe}_2$ nanobelts could sustain significantly high breakdown current densities ($J_D$) of up to ~100 MA/cm$^2$ and electrical input power per channel length of ~16.4 W/cm, which are higher than those of conventional interconnect metals and any other TM chalcogenides to date.$^{(8)}$ The energy dissipation and carrier scattering models exploited in this study revealed that the high current-carrying capacity of the quasi-1D products is because of a rather scattering-free transport behavior as well as suppressed electromigration in the encapsulated devices until the channels’ breakdown, as compared to the air-exposed ones. We believe that our strategy sufficiently promises the potential for applications in future downscaled nanoelectronics owing to the unique fundamental electrical characteristics of the quasi-1D layered $\text{WTe}_2$ single crystals compared to other vdW materials.

The low density of 3D structures can allow efficient charge carrier transport in the films and the low film resistivity ensured by these novel processes showcase a strong potential for implementation in electronic devices.

Layered Perovskite Nanofiber Heterojunctions with Tailored Diameter to Enhance Photocatalytic Water Splitting Performance André Bloesser and Roland Marschall.
University of Bayreuth, Bayreuth, Germany.

Controlled heterojunction design was combined with diameter-tailored electrospinning to prepare mesostructured photocatalysts, leading to strongly enhanced photocatalytic water splitting rates. The (111)-layered perovskite Ba$_3$Ta$_2$O$_7$ [1] in heterojunction with Ba$_3$Ta$_3$O$_{10.5}$ [2] was for the first time prepared as nanofibers by means of electrospinning, including variation of the fiber diameter. [3] The result is a tailored mesostructured heterojunction leading to hydrogen evolution reaction rates from water/methanol mixtures of up to 4.4 mmol h$^{-1}$ with a photocatalyst, and remarkable water splitting activity after Rh−Cr$_2$O$_3$ decoration with hydrogen production rates up to one mmol h$^{-1}$. Our studies also confirm the photocurrent doubling effect of sacrificial alcohols exhibiting α-H atoms with this heterojunction, in contrast to tert-butanol.

Designer Synthetic 2D Materials—The Cases of Xenes and Anisotropic MoS$_2$ Alessandro Molle; CNR-BIMM, Agrate Brianza, Italy.

Making adjustable two-dimensional (2D) materials is an emerging route to reach a superior control of functional properties and access new device performances or applications. With this aim in mind, here I will give consideration to two distinct cases. On one hand is the case of the epitaxial Xenes, an emerging class of 2D monoatomic lattice beyond graphene; on the other hand is the anisotropy design in MoS$_2$ nanosheets. By close analogy with graphene, epitaxial Xenes are comprised of monoatomic elements arranged in a honeycomb lattice but unlike graphene, Xenes are epitaxially grown on substrates and exhibit a varying degree of buckling and/or puckering in the lattice structure [1]. Examples in this respect are silicene, germanene, stanene, borophene, epitaxial phosphorene, and recently synthesized antimonene and tellurene. Buckling in Xenes can be taken as a leverage to tune the electronic and quantum properties making it possible for Xenes to appear as semiconductors, semimetals, metals topological and trivial insulators. Not only the wealth of electronic states in the Xenes makes them suitable as nanotechnology platforms, but also topological transitions among these electronic states are predicted to take place as a function of an external solicitation (e.g. vertical electric field, applied stress) thus paving the way to the full exploitation of topology in devices at the 2D level. I will focus on silicene as representative story [2]. Then I will show the route and challenges for Xenes to be integrated in nanoelectronic devices by briefly describing a universal approach to Xene processing and eventually the concept of a topological field effect transistor.

A different case of morphology design at the 2D level is the chemical vapour deposition of MoS$_2$ nanosheets on patterned substrates. The highly conformal character of the MoS$_2$ growth allows for the achievement of an anisotropically modulated MoS$_2$ nanosheet where the phonon and electronic properties are observed to be strongly morphology dependent. The so-induced morphological anisotropy is reflected in the anisotropy of the physical characteristics, such as the phonon spectrum, intrinsic charge fluctuations, and the exciton dynamics. Implications on the band-gap and exciton engineering will be discussed, and the potential for applications envisioned [3].

9:30 AM QN03.11.06
Vapor-Phase Amine Intercalation for the Rational Design of Photonic Nanosheet Sensors Bettina V. Lchtsch 1,2; 1Nanochemistry, Max Planck Institute for Solid State Research, Stuttgart, Germany; 2Chemistry, University of Munich (LMU), Munich, Germany.

The development of vapor sensors with tunable sensitivity and selectivity based on rational molecular design is challenging, however at the same time of great interest due to the manifold applications in our everyday life, e.g. in air quality monitoring or food control. Here, we introduce a design concept for photonic vapor sensors based on stimuli-responsive, swellable 2D nanosheet materials. Antimony and tantalum phosphate (H$_3$Sb$_3$P$_2$O$_{14}$ and HMP$_2$O$_{8}$ (M = Sb, Ta) nanosheet-based Fabry-Pérot interference sensors as manifold applications in our everyday life, e.g. in air quality monitoring or food control. Here, we introduce a design concept for photonic vapor sensors based on stimuli-responsive, swellable 2D nanosheet materials. Antimony and tantalum phosphate (H$_3$Sb$_3$P$_2$O$_{14}$ and HMP$_2$O$_{8}$ (M = Sb, Ta) nanosheet-based Fabry-Pérot interference sensors as touchless displays based on humidity responsive 2D nanosheets.

10:00 AM BREAK
10:30 AM QN03.11.07
Pulsed Laser Deposition Conversion of 2D Transition Metal Dichalcogenides to Form Alloys and Vertical Heterojunctions Yu-Chuan Lin,1 Yiling Yu1 Chenze Liu1,2,3 Alexander A. Puretzky1,3, Mina Yoon1, Christopher M. Rouleau1, Gyula Eres1, Gerd Duscher2,7, Kai Xiao1 and David B. Geohegan1; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2The University of Tennessee, Knoxville, Knoxville, Tennessee, United States.

The nonequilibrium nature of laser-based synthesis and processing provides a promising alternative for the synthesis of van der Waals alloys and heterostructures of 2D transition metal dichalcogenides (TMD). Using chalcogen vapor plumes generated by pulsed excimer laser ablation of solid S, Se, or Te targets in vacuum and low-pressure background gases, the chalcogen composition of existing 2D crystal monolayers or multilayers can be digitally modulated to form new alloys or vertical heterostructures in order to controllably alter and explore their optoelectronic properties. In this talk, starting with existing monolayer and bilayer WS$_2$ or WSe$_2$ grown on various substrates (and suspended) we demonstrate the versatility of this approach to adjust the composition and property-tune mixed WS$_2$WSe$_2$, monolayers, and partially convert bilayers to form vertical heterojunctions. In both cases, depending on the global strain inherent in the initial TMD crystal (resulting from the initial growth at elevated temperatures), the plasma-induced
exchange of S-Se atoms in the TMD layer creates an additional biaxial strain that can subsequently induce unfavorable cracks or wrinkles in the 2D alloys. However, by choosing a suitable thermal expansion coefficient for the substrate for the initial growth of the 2D crystals, we show that the additional biaxial strain-induced deformation induced by chalcogen replacement can be mediated to allow the 2D crystals to avoid wrinkles and cracks, while retaining their lattice structure. Using this pulsed laser deposition conversion approach, we demonstrate that a homogenous bilayer TMD (e.g., a WS₂ bilayer) grown by chemical vapor deposition (CVD) can be converted into vertical heterojunctions, such as bilayer WS₂–WS₂. The conversion of different bilayer stacking configurations is explored. Photoluminescence and Raman spectroscopy, and scanning transmission electron microscopy confirm that the original bottom layer is nearly intact, even when the top layer is fully converted into another chalcogen composition. Second harmonic generation measurements reveal that the degree of conversion of the top layer depends on the crystallographic stacking between the top and bottom layers. For example, while the 2H-stacking configuration of bilayer WS₂ is found to be the most stable under Se plume irradiation, other stacking configurations are found to have lower thresholds for chalcogen replacement, enabling full conversion of the top WS₂ layer to WSe₂ at 350 °C to form a vertical heterostructure. This approach provides a simple and efficient way to fabricate both 2D alloys and vertical heterostructures.

Enabling Flexible 2D Materials Through Laser Transformation Nicholas Glavin; Air Force Research Laboratory, Dayton, Ohio, United States.

Two-dimensional (2D) materials have the potential to enable flexible electronic devices with exceptional properties for future wearable sensors. One major hurdle still to overcome is the limited growth and processing schemes to manipulate these unique materials on flexible substrates. In this talk, we will discuss using lasers and other light sources to locally transform 2D MoS₂, WSe₂ and heterostructures on polymeric substrates for controlled crystal structure, chemistry and functionalization at both a local (<10 μm) and global (>1cm²) scale. To understand the transformation process, kinetics studies using in-situ spectroscopy enabled insight into fundamental crystal formation and conversion of amorphous to crystalline MoS₂. This information enabled direct laser writing of 2D materials on flexible substrates for controlled crystal structure for sensing applications. Additionally, circuits were constructed out of the laser transformation of 2D materials to form various crystal structures and oxide phases with altering electronic properties. Finally, large area, wafer-scale crystallization of stretchable 2D photodetectors with the use of a broadband pulsed lamp source demonstrate the feasibility of large scale transformation as a means to create unique device constructs. The versatile technique of laser manipulation of 2D materials directly on polymer substrates can potentially enable truly revolutionary flexible electronics based on the unique van der Waals structures.

11:15 AM QN03.11.09
Band Gap and Interface Engineering of Atomic Layered Semiconductors Weihao Zheng, Honglai Li, Tiefeng Yang, Biyuan Zheng and Anlian Pan; Hunan University, Changsha, China.

Two-dimensional (2D) layered semiconductors, notably transitional metal dichalcogenides (TMDs), have recently attracted considerable interest, due to their atomically thin geometry, unique electronic and optical properties and potential applications in integrated nanosystems. Band gap and interface engineering within these nanostructures is fundamentally important to design and create semiconductor heterostructures with tailored electronic band structures for diverse functions and applications[1-7]. Although significant effort and progress have been made to realize composition modulation among different chalcogenide nanostructures, precisely spatial band gap modulation within single 2D semiconductor nanostructures has always been a considerable challenge. In this talk, I will report our recent progress on the band gap and interface engineering of 2D atomically thin layered materials. I will show how to realize composition and band gap continuously modulated 2D semiconductors through alloying of two semiconductor compounds with different band gaps[8-9], and how to achieve sharp interfacial composition profiles of 2D semiconductor heterostructures through the real-time composition control[10]. More importantly, the growth control of 2D atomic layered heterostructures: lateral epitaxy vs. vertical stack[11], and some interesting optical and optoelectronic properties and device applications of these novel nanostructures will also be exhibited. In addition, I will reveal the strain-tuning atomic substitution mechanism of 2D semiconductor materials, which is driven by the strain between the substituted and host lattices[8, 10].

Materials Science with Two-Dimensional Atomic Layers Pulickel Ajayan; Department of Materials Science and NanoEngineering, Rice University, Houston, Texas, United States.

There has been tremendous interest in recent years to study two-dimensional (2D) atomic layers which form building blocks of many bulk layered materials. This was started by the spectacular discovery of graphene. This talk will focus on the materials science of the emerging field of 2D atomic layers of various compositions. Several aspects that include synthesis, characterization of defects, doping and manipulation will be explored with the objective of achieving functional structures with atomic layer building blocks. The concept of nanoscale engineering and the goal of creating new artificially stacked van der Waals solids and 3D constructs will be discussed through a number of examples including graphene and other 2D layer compositions. The talk will explore the emerging landscape of 2D materials systems that include hybrid compositions and multi-component 2D alloys. Some of the anticipated applications of these materials will also be discussed.

SESSION QN03.13: Photonic Properties and Devices II
Session Chair: Victor Brar
Thursday Afternoon, April 25, 2019
PCC North, 100 Level, Room 129 A

1:30 PM *QN03.13.01
This talk will present recent highlights from our research on two-dimensional (2D) materials and devices including graphene, boron nitride (h-BN), and transition metal dichalcogenides (TMDs). The results span from fundamental measurements and simulations, to devices, to system-oriented applications which take advantage of unusual 2D material properties. On the fundamental side, we have measured record velocity saturation in graphene [1,2], as well as the thermal properties of graphene nanoribbons [3]. These are important for electronic applications, which can exhibit substantial self-heating during operation [4]. Taking advantage of low cross-plane thermal conductance, we found unexpected applications of graphene as ultra-thin electrode to reduce power consumption in phase-change memory [5]. We have also demonstrated wafer-scale graphene systems for analog dot product computation [6].

We have grown monolayer 2D semiconductors by chemical vapor deposition over cm² scales, including MoS₂, with low device variability [7], WSe₂, MoSe₂ – and multi-layer TMDs MoTe₂ and WTe₂ [8]. Importantly, ZrSe₂ and HfSe₂ have native high-K dielectrics ZrO₂ and HfO₂, which are of key technological relevance [9]. Improving the electrical contact resistance [10], we demonstrated 10 nm transistors using monolayer MoS₂, with the highest current reported to date (∼400 nA/µm), approaching ballistic limits [11]. We also directly measured the saturation velocity and saturation current in monolayer MoS₂, finding it is thermally-limited (i.e. by device self-heating and phonon scattering) to about one-third of that of silicon and about one-tenth of that of graphene [12]. Using Raman thermometry, we uncovered low thermal boundary conductance (∼15 MW/m²K) between MoS₂ and SiO₂, which could limit heat dissipation in 2D electronics [13]. We are presently exploring unconventional applications including thermal transistors [14], which could enable nanoscale control of heat in “thermal circuits” analogous with electrical circuits. These studies reveal fundamental limits and new applications of 2D materials, taking advantage of their unique properties.

2:00 PM *QN03.13.02
Emerging Device Applications of 2D Materials
Luke Sweetlock, Vincent Gambin, Philip Hon and Jesse Tice; NG Next, Northrop Grumman Aerospace Systems, Redondo Beach, California, United States.

Two-dimensional materials exhibit unique and dramatically tunable optical and electronic properties. In this seminar, we will describe the fundamental exploration of some of these extraordinary properties, and how these materials are leveraged to create improved or even fundamentally novel devices that point towards impactful applications. A common theme throughout will be the value of highly interdisciplinary and collaborative discovery.

Highly voltage-tunable optical properties will be described in the context of graphene/gold heterostructure metasurfaces. Smooth modulation is observed in the reflected phase of infrared light of over 200 degrees at an infrared wavelength of 8.7 microns [1]. This fast optoelectronic tuning mechanism could enable photonic phased arrays for beamsteering and other high speed reconfigurable elements.

Thinatomically materials can also exhibit novel functionality which is without direct analog in bulk media. For example, an active material developed by oxidation of 2D boron nitride demonstrates formation of atomic scale conductive filaments under electronic bias, exhibiting memristive switching with femtojoule energy consumption [2].

Many emerging device concepts exploit the strong anisotropy of 2D materials and their properties. Multilayers comprised of 2D semiconducting MoS₂ exhibit strong anisotropy between lateral within-layer conduction and interlayer vertical transport, as well as inhomogeneous vertical carrier distribution. From systematic study of charge transport in these structures, a new mechanism for negative transconductance (NTC) device implementation is observed [3].

We have also demonstrated wafer-scale graphene systems for analog dot product computation [6].

Colloidal β-In₃Se₃: Monolayer Nanosheets and Their High Photoresponsivity
Sandeep Ghosh; The University of Texas at Austin, Austin, Texas, United States.

The advent of graphene in the recent years has led to widespread investigations on two-dimensional (2D) semiconductors of layered metal chalcogenides (LMCs). This is mostly directed towards their ultrathin and flexible electronic applications as many 2D LMCs interact strongly with light, exhibiting high-power-density optoelectronic devices. This is especially true for those 2D LMCs which comprise of post-transition metals (like In₃Se₃ here), when compared to their transition metal counterparts. Although vacuum deposition and micromechanical cleavage are the most popular techniques for producing high quality 2D LMCs, they suffer from limitations like costly high temperature instrumentation and polydispersity sampling (respectively). Colloidal chemistry, in this regard, offers an alternative low temperature synthetic route with unique morphological control. In this presentation, we will describe the colloidal synthesis of single-layer β-In₃Se₃ nanosheets with lateral sizes tunable from ~300 to ~900 nm. Such synthesis of a single layer of this material, which is five-atom thick (Se-In-Se-In-Se), was accomplished by using short aminonitriles (decyandiamide or cydanamide) as shape controlling agents in a two-stage hot injection process. Discerning the phase of our synthesized nanosheets was particularly challenging since the In₃Se₃ system exhibits intricate polymorphism, especially in the few layer range. A combined analysis comprising of HRTEM and XRD with ED was employed for this. The intensity ratio between two diffraction peaks from two-dimensional slabs of the various phases were compared, which were determined by diffraction simulations in the first place. This was further corroborated by comparing and fitting the experimental X-ray diffraction pattern with Debye formula simulated patterns and also with side-view HRTEM imaging and simulation. The as-synthesized β-In₃Se₃ nanosheets were found to be indirect band gap semiconductors (Eg = 1.55 eV). Single nanosheets were then contacted by Ti/AI or Ti/Au electrodes in order to fabricate photodetectors which showed high photoresponsivities (of the order of 10⁷ A/W at few pW laser power) at low laser power and fast response times (order of few milliseconds). These values of photoresponsivity and response times are comparable to the best photodetectors based on single- and few-layer 2D semiconductors that were reported so far, and in particular to those of multilayer β-In₃Se₃, which implies a higher photoresponsivity per layer in the monolayer regime.

3:15 PM *QN03.13.04
Advanced Optoelectronics Based on Active Metasurfaces
Yu Yao, Ali Basiri, Jing Bai, Xiaohui Chen, Chao Wang and Zubair Rafique; School of Electrical, Computer and Energy Engineering, Arizona State University, Tempe, Arizona, United States.

Optical metasurface refers to a kind of nanostructured material with sub-wavelength thickness and on-demand optical properties. By rationally engineering the metasurface structures, one could achieve new capabilities for the manipulation of light, e.g., ultra-thin flat lenses, waveplates and holographic plates. In this talk, I will present the unique capability of metasurfaces to address the fundamental limitations in traditional optical materials and realize ultra-compact optoelectronic devices with various functionalities, which are highly desirable for practical applications.

I will discuss about recent progress on mid-infrared modulation based on metasurface integrated with active tuning element. I will first discuss novel design concepts and device implementation of modulators with large modulation depth and broad bandwidth, followed by a summary of our recent progress on system implementation of spatial light modulation and wavefront control. I will also present how to exploit the great flexibility of metasurfaces to manipulate light and enhance light matter interaction in nanometer-size structures to enhance the performance and enable unique functionalities of photodetectors. I will discuss about various schemes we have implemented to enhance infrared photodetection in graphene-metasurface hybrid structures. Moreover, I will also briefly discuss about a full-stokes polarimetric imager sensor with chip-integrated metasurfaces.

3:45 PM *QN03.13.05
Heterogeneous Exciton Engineering of Two-Dimensional Materials on 3D Wrinkle Architectures
Jin Myung Kim¹, Jaepil So², Michael Cai Wang³,⁴, Hong-Gyu Park⁷ and
Strain engineering has been a promising approach to control exciton dynamics and photoluminescence properties of two-dimensional (2D) semiconductors. In particular, strain concentrated on submicron area of 2D WSe$_2$ or WS$_2$ is known to create quantum emitters by exciton funneling and exciton confinement through bandgap gradient. While the previous approaches have introduced 2D layers suspended on top of nano- or micro-patterns to achieve spatially deterministic strain, predictability and modulability of strain have been limited due to challenges in interface control (e.g., uniformity) and dynamic configurability (e.g., rigid substrate). Here, we present predictable and reconfigurable strain gradient in atomically-thin WSe$_2$ via three-dimensional (3D) elastomeric wrinkle architectures. This approach allows 2D WSe$_2$ to be deformed conformally along the wrinkled substrate comprised of a stiff skin layer (SiO$_2$) on top of a soft polydimethylsiloxane (PDMS) substrate. As a result, the strain exerted on WSe$_2$ was periodically changed to tensile and compressive strains at peaks and valleys of the wrinkles, respectively. By tuning wrinkling parameters (e.g., prestrain, skin layer thickness) and encapsulation methods, we were able to achieve photoluminescence (PL) emission shift of as much as 123 meV, corresponding to approximately 2.3% strain. Furthermore, thanks to the use of elastomeric substrate, the applied strain can be tuned reconfigurably by post stretching/releasing processes, with PL shift dynamically modulated. Time-resolved PL decay measurements revealed heterogeneous exciton recombination where tensile strain leads to longer exciton lifetime compared to unstrained or compressive strained regions. Our results demonstrate a 3D architecture based active platform not only for excitation engineering of 2D semiconductors, but also for other strain-responsive 2D devices which can exploit the merits of spatially and dynamically controllable strain engineering.

4:45 PM QN03.20.07
Mechanically Crumpled All-2D Material Photosensor for Enhanced Photosensitivity Juyeong Lee, Pilgyu Kang, Jihan Mun, Yeageun Lee, Sang-Woo Kang and Sung-Woo Nam
University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; Korea Research Institute of Standards and Science (KRISS), Daejeon, Korea (the Republic of)

Atomically-thin two-dimensional (2D) materials provide a unique and promising platform for optoelectronic applications due to their optical, electronic, and mechanical properties. Monolayer molybdenum disulfide (MoS$_2$) is one of the most widely studied semiconducting 2D materials for photosensors with its direct bandgap. Despite of advantageous features of 2D materials, the low optical absorption of monolayer MoS$_2$, resulting from its single-atom-thickness, limits higher photosensitivity. In this presentation, we report a mechanically self-assembled, crumpled MoS$_2$ photosensor with graphene electrodes. We use graphene as electrodes in our all-2D photosensor because of its mechanical robustness, electrical conductivity and barrier-free contact to MoS$_2$. Our photosensor exhibits (i) enhanced photosensitivity from crumpled MoS$_2$ structure, (ii) high stretchability with mechanical durability, and (iii) anisotropic photocurrent generation from anisotropic topography via exciton funneling effect. We demonstrate enhanced internal photosresponsivity of our crumpled MoS$_2$ photosensor, by comparing with flat MoS$_2$ photosensor. Our photosensor was further stretched up to 150% without introducing major structural damage, and mechanical durability of the sensor was verified with 1000 cycles of stretching-releasing test. Our approach to mechanical self-assembly of atomically-thin materials offers a simple but effective way to enhance photosensitivity and suggests a new way to engineer exciton funneling in 2D material system.
We investigated the fundamental origin of material degradation and developed a surface-engineering approach to render few-layer black phosphorus stable for several months in ambient conditions. The findings revealed that the key cause of degradation is photo-oxidation which is specifically accelerated when the material is exposed to UV light. Building on this knowledge, we used an ionic liquid on the surface that sequesters reactive oxygen species (ROS) that are responsible for surface deterioration.[3] We further created a dry-etch procedure to control the layer-thickness (hence bandgap) and engineer controlled defects in the material.[4] Subsequently, the defect engineered layers were exploited to generate unique photoresponse in BP which was deployed to mimic neural synaptic interfaces using optical stimuli.

In summary, we have conducted a full suite of studies ranging from understanding the fundamentals of degradation to developing protection techniques without interfering with the desirable properties of 2D BP. Subsequently, we report a simple defect engineering strategy and exploit them for various functionalities including the creation of an artificial optical synapse.

8:15 AM QN03.14.02

Ionic Substrate Effects on Graphene
Karen Long1, Adam Friedman2 and Jeremy Robinson3; 1Naval Surface Warfare Center, Dahlgren, Virginia, United States; 2Laboratory for the Physical Sciences, College Park, Maryland, United States; 3U.S. Naval Research Laboratory, Washington, District of Columbia, United States.

While graphene is well known to have exceptional electrical properties, those properties can be greatly affected by its substrate. Electron-phonon scattering has been shown to contribute to the optical absorption and interaction with polar substrate phonon modes in order to control electron transport. Instead of polar substrates, we have investigated graphene and graphene nanoribbons on BaF2. The BaF2 is grown epitaxially on either Si, resulting in (111) BaF2 or GaAs, resulting in (100) BaF2 which is lattice matched. As a result, unlike SiO2, we have an atomically crystalline surface upon which CVD grown graphene sheets are placed and then formed into nanoribbons by ion lithography. BaF2 has a wide Strahlenband around 50um, making it a good candidate for coupling to surface phonon plasmons in the far IR. To study the substrate effects, we use EFMs AFMs which provides a relationship between the electrostatic potential and the voltage applied to the tip. By mapping the phase change vs voltage, we can obtain the work function. EFS measures the force gradient versus the force providing a better resolution of the electrical properties. Since BaF2 grows (111) on Si by forming triangles in three directions, we can use STM to determine edge effects which can be polar. In building, heterostructured materials it is important to understand the valence band offset and the heterostructure interface. We use XPS spectra of the valence band to obtain the valence band offset formed from a BaF2 surface.

8:30 AM QN03.14.03

Scanning Tunneling Microscopy and Spectroscopy of Wet Chemically Synthesized Porous Graphene Nanoribbons
Kaitlyn Parsons1, Adrian Radoseva2, Mohammd Pour1, Tao Sun1, Narayana Aluru1, Alexander Sinitskii2 and Joseph Lyding1; 1Electrical and Computer Engineering, University of Illinois at Urbana-Champaign, Urbana-Champaign, Illinois, United States; 2Materials Science and Engineering, University of Illinois at Urbana-Champaign, Urbana-Champaign, Illinois, United States; 3Chemistry, University of Nebraska–Lincoln, Lincoln, Nebraska, United States; 4Mechanical and Science Engineering, University of Illinois at Urbana-Champaign, Urbana-Champaign, Illinois, United States.

The bottom-up wet chemical synthesis of graphene nanoribbons (GNRs) opens interesting opportunities for tailoring the GNR structure with atomic precision [1]. Atomically precise porous GNRs are a new chemically synthesized variation for which the fabrication procedure yielding multiple pores in a single ribbon and the electronic details of the ribbon have not been reported. In this work, porous GNRs are dry contact transferred in ultrahigh vacuum to clean silicon and III-V semiconducting substrates and examined using UHV scanning tunneling microscopy (STM) and spectroscopy (STS). STM imaging confirms the expected porous structure and indicates a unique electronic feature at the graphene nanopores, and STS measurements indicate a 2.0 eV bandgap. These results are compared to first-principles DFT simulations in which an increased local density of states is also reported. Since BaF2 crystals of various thicknesses shows results consistent with our transport measurements. A GW correction predicts a 3.24 eV bandgap. Illumination of pore effects in GNRs contributes to an increased understanding of the tunability of GNR electronic structure. Porous GNRs have potential applications in molecular filtration, detection and DNA sequencing.

Graphene-Based Photonic Devices for Terahertz Applications
Peter Qiang Liu; State University of New York at Buffalo, Buffalo, New York, United States.

In recent years, graphene has attracted significant amount of research efforts on multiple fronts in the photonics field, mainly thanks to its attractive material properties such as high carrier mobility at room temperature and large tunability of carrier concentration via electrostatic gating. Development of reliable and high-throughput processes of graphene transfer also make integrating graphene with a wide variety of other materials, structures and devices relatively straightforward. Moreover, in the mid-infrared to terahertz (THz) spectral range, graphene can support highly confined surface plasmon modes with relatively long lifetime, and therefore drastically enhance the light-matter interactions in various processes which can be exploited by a wide range of applications. There has been a plethora of proof-of-concept demonstrations and further developments of graphene-based photonic devices for different applications and spectral regions, and research in these fields is growing rapidly. In this talk, I will present some of our recent work on employing graphene as a key functional material in various photonic devices operating in the THz spectral region, including high-speed modulators, beam steerers, photodetectors and molecular sensors. These devices may facilitate the ongoing development of THz technologies and applications such as THz wireless communications, imaging and sensing.

9:30 AM QN03.14.06

Quantum Transport in Few-Layer Graphene and Phosphorene Devices
Jeannic Lau; The Ohio State University, Columbus, Ohio, United States.

Low dimensional materials constitute an exciting and unusually tunable platform for investigation of integer and fractional quantum Hall states. Here I will present our results on transport measurements of high quality graphene and phosphorene devices. In rhombohedral-stacked tetraylayer graphene, we have observed a large intrinsic gap at half filling, up to
80 meV, that arises from electronic interactions[1]. In Bernal-stacked-tetralayer, we have observed multiple Lifshitz transitions as charge density, magnetic field and displacement field are tuned[2]. In few-layer black phosphorus devices with mobility up to 50,000 cm²/Vs, integer QH states are resolved at a few Tesla, and fractional states at filling factor - 4/3 and -0.56±0.1 are observed[3]. These results underscore the strong electron correlation in atomically thin systems.

The properties of 2D materials can be modified by structural defects, so controlling the nature and concentration of such defects provides a means of tailoring material properties for specific applications [1]. This study examines the effect of ion-irradiation on damage production in graphene, with particular emphasis on the effect of ion fluence and nuclear stopping power (S_n) on the concentration and structure of defects; the significance of collective effects associated with molecular ion irradiation; and the role of the substrate in damage production.

Experiments are conducted on supported (G/SiO₂) and suspended (Gs) graphene films, with the former produced by exfoliation of highly oriented pyrolytic graphite (HOPG) and the latter by chemical vapor deposition (CVD). The films are irradiated with 30 keV H⁺, Li⁺, C⁺, Sr⁺ and Ge⁺ ions to fluences (Ω) in the range 10^{10}-10^{16} ions/cm² and analysed using Raman Spectroscopy (RS). The density and structure of defects are determined from Raman analysis using the phenomenological models of Lucchese et al. [2] and Eckmann et. al. [3], respectively. Substrate effects are assessed by comparing damage in G/SiO₂ and Gs irradiated under identical conditions and by comparing damage in G/SiO₂ irradiated with 30keV C⁺ at incident angles of 30°, 45° and 60° relative to the surface normal. G samples are also irradiated with 60 keV C⁺ ions to assess collective effects resulting from multi-ion interactions.

It is shown that defect production scales with the nuclear stopping power of the ions, and that the structure of the defects evolves with increasing ion-fluence from an initial mix of Stone-Wales defects and divacancies, to defects with an increasing fraction of higher-order topological defects. A comparison of the defects created in suspended graphene films by 30 keV C⁺ ions and 60 keV C⁺ ions further showed that the damage created by dimer ions closely matched that produced by monomer ions with twice the fluence, suggesting that there are no significant collective effects associated with the molecular ion irradiation.

The predictions of reference [4] that ion-irradiation damage in supported graphene films is dominated by recoiling ions and sputtered atoms from the substrate is also tested by comparing defect accumulation in supported and suspended films irradiated under identical with 30 keV C⁺ ions. No significant difference in defect density is observed for the two samples, clearly showing that defect production is dominated by direct collisions with C atoms in the graphene layer, a conclusion that is further supported by data from variable incident angle studies.

Interfacial Slip and Deformation in 2D Electromechanical Systems Arend M. van der Zande; Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Due to their unparalleled mechanical strength, and stability down to a monolayer, atomically-thin membranes made from two dimensional (2D) materials like graphene and MoS₂ represent the ultimate limit in size of mechanical atomic membranes. Yet, many of the most interesting properties of 2D materials and new functionality arise from the interfaces between layers and in engineering multilayer heterostructures. The last few years have led to a revolution in nanoelectronics from 2D heterostructures where layer-by-layer stacking of monolayer 2D materials with disparate electronic properties leads to functional nanometer scale electronic devices. An open question is how to integrate the outstanding mechanical properties of 2D materials with the enhanced functionality of heterostructures to enable new technologies like 3D foldable circuitry, nanoscale origami, or resonant NEMS utilizing 2D heterostructures as active electronic and mechanical components. In this presentation, we will examine the mechanics of deformation of 2D atomic membranes, the emergence of interlayer slip in van der Waals interfaces, and their impact on nanoelectromechanical systems.

We measure the morphology of multilayer graphene transferred onto steps in a hBN substrate. We find the graphene conforms with nanoscale curvatures down to 1 nm, which is allowed by the introduction of slip dislocations between the graphene layers. From the curvature, we find that the bending modulus of the slipped graphene is linearly dependent on the number of layers rather than the cubic dependence that would be predicted from continuum mechanics. Next, we examine the evolution of buckle and fold instabilities in uniaxially compressed graphene and MoS₂ by measuring the topography under increased compression. We observe a material dependent transition from delamination and new fold generation to slip and growth of existing folds. Through a simple energy conservation model, we predict this transition and use it to extract the material dependent interfacial friction. Finally, we engineer electromechanical resonators from atomically thin bimorphs of graphene/MoS₂ as well as twisted bilayer graphene. We observe new features in the tuning behavior of the resonators, including kinks and discrete jumps. These features are not predicted by the tensioned membrane model used to describe the behavior of monolayer 2D resonators, and we attribute them to atomic scale stick-slip behavior in the resonators. Taken together, these experiments show that interfacial slip strongly impacts the mechanics of 2D materials and heterostructures and leads to membranes which are orders of magnitude more deformable than conventional 3D materials. As a result, slip is a critical phenomena which must be considered when engineering mechanically active devices from 2D materials and heterostructures.
Electronic Enhancement of Layered Transition Metal Dichalcogenides via One-Step Chemical Functionalization

Jun Hong Park1, Amritesh Rai2, Jeongwoon Hwang1, Chexi Zhang3, Kyeonggae Cho2, Sanjay Banerjee2 and Andrew Kummel3;* Gyeongsang National University, Jinju, Korea (the Republic of); 2The University of Texas at Austin, Austin, Texas, United States; 3The University of Texas at Dallas, Texas, United States; 4University of California, San Diego, San Diego, California, United States.

In the present report, chemical functionalization is demonstrated to enhance the electrical performance of two-dimensional (2D) layered transition metal dichalcogenides (TMDCs) field-effect transistors (FETs) by applying a one-step dipping process utilizing ammonium sulfide [(NH4)2S] solution. The adsorption process at the surface of WSe2 via chemical treatment is elucidated at the molecular level using scanning tunneling microscopy (STM) and spectroscopy (STS). Molecule resolved STM and STS reveal that the molecular adsorption on monolayer (ML) WSe2 surface induces a band structure transition with the reduction of electronic band gap from 2.1 eV to 1.1 eV and the Fermi level shift towards its valence band edge (VBE), consistent with an increase in the density of positive charge carriers. The electronic transformation of WSe2 with this one-step chemical treatment is confirmed by density functional theory (DFT) calculations which reveal that molecular ‘SH’ adsorption on monolayer WSe2 significantly reduces the energy gap between the valence and conduction bands, consistent with a high density of positive charge carriers. These results suggest that one-step chemical functionalization of 2D layered transition metal dichalcogenides (TMDCs) enables the introduction of rigid functional groups at the surface to induce tailorable electronic properties, opening up opportunities for the development of novel electronic and optoelectronic devices.

SESSION QN03.15: Mechanical Properties and Opto-Electromechanical Effects

11:30 AM QN03.14.10
Hierarchical Phonons in a Two-Dimensional Superatomic Semiconductor
Kihong Lee1, Xinjue Zhong1, Bonnie Choi1, Daniele Meggioraro1,2, Filippo De Angelis1,2, Xavier Roy1 and Xiaoyang Zhu1;1 Columbia University, New York, New York, United States; 2Istituto Italiano di Tecnologia, Genova, Italy; 3CNR-ISTM, Perugia, Italy.

Designing materials with structural hierarchy is of fundamental interest in materials science since it uncovers unique physical properties and functions. The field of two-dimensional (2D) materials is highly active and rapidly expanding, but hierarchical material design in 2D materials has been challenging. Here, we report a novel 2D semiconductor with a hierarchical structure composed of covalently linked ReSe2 clusters. The material, a 2D structural analogue of the Chevrel phase, is prepared by mechanical exfoliation of the van der Waals solid ReSe2Cl6. Using scanning tunneling spectroscopy, photoluminescence and ultraviolet photoelectron spectroscopy, and first-principles calculations, we determine the electronic band gap (1.58 eV), optical band gap (1.48 eV), and exciton binding energy (100 meV) of the material. The latter is consistent with the partially 2D nature of the exciton. ReSe2Cl6 is the first member of a new family of 2D semiconductors whose structure is built from superatomic building blocks instead of simply atoms; such structures will expand the conceptual design space for 2D materials research.

To demonstrate its unique properties, we bring our attention to hierarchical phonons of the material. Phonon couplings to electrons, excitons and other phonons play key roles in material properties, such as charge transport, thermal transport, light emission, energy transfer, and superconductivity. In conventional atomic solids, such as Si or GaAs, there are only extended phonons as determined by bonding and crystalline symmetry. Phonons are uniquely important in nanomaterials due to quantum confinement and spatial localization in zero, one, and two dimensions (0D, 1D, 2D). In quantum dots, the 0D confinement and local symmetry/interfaces can lead to strong electron-phonon coupling. In 1D carbon nanotubes and 2D graphene or transition metal dichalcogenides, the reduced dimensions also enhance phonon coupling to electrons or excitons. In these materials, their phonon modes are intimately related to their dimensionalities, as demonstrated from radial breathing modes, interlayer sliding modes, and interlayer breathing modes. Here we expand the phonon space by adding localized 0D phonon modes to delocalized phonon modes in a hierarchical superatomic semiconductor. With coherent phonon spectroscopy, we observe three distinct phonons showing strong electron-phonon coupling and correlated with three different steps of dimensional hierarchy. Additionally, these phonons, including the localized 0D breathing of each superatom, the delocalized twisting of superatoms in each 2D layer, and interlayer breathing modes, can be concurrently generated by above-gap impulsive excitation. The presence of local phonon modes in an extended crystal opens the door to controlling material properties from hierarchical phonon engineering.

11:45 AM QN03.14.11
Capillary Origami with Atomically Thin Sheets
Challhlee Choi1, Joeson Wong2, Souvik Biswas2, SungWoong Nam1 and Harry Atwater3;1 Mechanical and Science Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Applied Physics and Materials Science, California Institute of Technology, Pasadena, California, United States.

Origami is perhaps best known as an art form that transforms flat sheets of paper into intricate three-dimensional (3D) structures. Inspired by this technique, recent works have demonstrated the folding of two-dimensional (2D) materials into micron-scale structures actuated by thermal and chemical perturbations. "Capillary origami," in which the surface tension of a liquid droplet on a flat sheet causes the sheet to fold, is a particularly attractive origami technique because it can be designed for liquid-liquid interfaces, enabling many biological and chemical applications. Here, we extend capillary origami techniques to 2D materials, using droplets in liquid systems to fold micron-scale polyhedral sheets from monolayer molybdenum disulfide (MoS2), a 2D semiconductor. The geometries of the final folded origami are preprogrammed by lithographic design of different starting shapes and the introduction of rigid metal panels to define hinges. These origami structures are further made self-folding by manipulating the miscibility of the droplets on the sheets, growing and shrinking the droplets to dynamically control folding. This work demonstrates a new avenue for actuating 2D materials into pre-designed 3D structures.
First-principles calculations predict that epitaxial growth of Au on 2D transition metal dichalcogenides (TMDCs) should induce selective strain in the top layer of a multilayer stack. The ability to manipulate strain in this way would have implications for the nanomanufacturing of these materials for opto-electronic devices, such as the ability to modulate the band gap within a single monolayer.

4D scanning transmission electron microscopy (4D STEM) is used to investigate the strain states present in the Au-MoS$_2$ system. Where Au is evaporated onto MoS$_2$, we find consistent compressive biaxial strains up to a stunning 9% in MoS$_2$ as well as previously unreported epitaxial relationships, imposing anisotropic strains, between the two species. Further, it appears that the strain is confined to the monolayer in contact with the Au, while other layers in the structure remain unstrained. These findings open up new avenues of inquiry in the investigation of TMDC-metal interactions.

We will present the results of extensive characterization of the various morphologies and strain states found at the Au-MoS$_2$ interface via 4D STEM. This technique involves recording a selected area electron diffraction (SAED) pattern every few nanometers across a two-dimensional sample area, and the resulting data is a 2-D array of 2-D diffraction patterns, comprising a 4-D dataset. Extremely large, information-rich datasets are produced, which requires a large-scale approach to data analysis. In order to meet this need for high-throughput analysis, we develop a novel machine learning approach that identifies, indexes, and characterizes the 10,000s of SAED patterns in these 4D STEM datasets utilizing a neural network (NN). The NN is trained on simulated diffraction patterns to recognize different crystal species and orientations (e.g., MoS$_2$ [001], Au [111], Au [211]). The strain states of the identified crystals are then characterized using conventional analytical methods.

These findings provide empirical motivation for the Au-assisted exfoliation of TMDCs for anticipated applications in nanoelectronics, photonics, and sensing. Moreover, this evidence of ultrahigh strains bears implications for band gap engineering in monolayer TMDCs. This multidisciplinary work directly integrates modern computer science deep learning techniques with microscopy and materials science, bridging a knowledge gap in the field and opening the door to rapid characterization of nanoscale structures.

2.15 PM QN03.15.04 Photodetector in h-BN Encapsulated Bilayer Graphene Field-Effect Transistor Teerayut Uwanno, Teerayut Uwanno, Takashi Taniguchi, Kenji Watanabe and Kosuke Nagashio; 1The University of Tokyo, Tokyo, Japan; 2College of Nanotechnology, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand; 3National Institute for Materials Science, Tsukuba, Japan.

Recent progress on automatic driving technology further requires infrared detectors with faster response and room temperature operation. Although fast response is achieved for quantum type HgCdTe and quantum-dot infrared photodetector (QDIP), the thermal noise inherently prevents the infrared detection by narrow gap semiconductors at room temperature [1]. Here, bilayer graphene (BLG) phototransistor with the electrically tunable band gap is theoretically suggested to have the IR detectivity even at room temperature because the gate action due to the photoexcited carriers amplify the photocurrent and this amplification can overcome the thermal noise [2]. In order to experimentally prove the current amplification by phototransistor action, the understanding of the basic mechanism behind the photoresponse without phototransistor action is critical. In this study, we investigated the photoresponse to the visible light in h-BN encapsulated direct-gap BLG-FETs on SiO$_2$/Si and quartz substrates. For the visible light detection, a Ni top gate electrode with ~20 nm thickness and ~5 μm width was used. In the transport measurement at 10 K for the BLG heterostructure FET on the SiO$_2$ Si substrate, a pronounced photocurrent was observed around the charge neutrality point and the photoresponse at the charge neutrality point increased with increasing the band gap. Moreover, it was found that photoresponse diminished above 100 K. On the other hand, for the device on the quartz substrate, the photoresponse was quite limited even at 10 K. This comparison suggests that the photoresponse in the present device is dominated by bolometric effect, not by photodetection. In previously reported BLG bolometer with SiO$_2$ top gate [3], the responsivity at the displacement field of 0.65 V/mm disappeared at ~40K, while the responsivity of the present device at the same displacement field was retained up to ~80K. This improvement is because the reduction of charged impurities in the heterostructure with h-BN resulted in stronger temperature dependence of channel resistance at the charge neutrality point.

As a summary, the dominant photoresponse without phototransistor action in h-BN encapsulated direct-gap BLG-FETs is bolometric effect and the bolometric response is much improved than that in the BLG encapsulated with oxides. The phototransistor action will become prominent when the top gate length is reduced to the carrier diffusion length in BLG (~250 nm).

2.30 PM QN03.15.05 Fast Graphene Photodetector with Responsivity >10$^4$ A/W Krishna Murali, Nithin Abraham, Sarthak Das, Sangeeth Kallatt, Medha Dandu and Kausik Majumdar; Indian Institute of Science, Bangalore, Bengaluru, India.

Graphene absorbs light of extremely wide wavelength range owing to its gapless bandstructure. This makes graphene a promising material for ultra-broadband photodetection [1]. In addition, due to high mobility, the graphene photodetectors can exhibit high speed operation [2]. However, there are two important roadblocks that prohibit graphene from being a highly sensitive photodetector. First, graphene being extremely thin material, can absorb only ~2.3% of the incident photons in a monolayer. Second, the lifetime of the photo-generated carriers is very short (~ ps). Thus, it is important to separate them in a time scale less than this to obtain a sizable photocurrent. Most of the graphene detectors, for example, metal-graphene junction [2], graphene p-n junction [3] and biased bilayer graphene [4], thus exhibit low responsivity. In this regard graphene detectors based on photogating effect are attractive which exhibit large responsivity [5-7]. However, these structures often rely on light absorption by a different material, like MoS$_2$ [5] and quantum dot [6], thereby the wavelength of operation is limited to the light absorption threshold of the respective absorbing material. These high-gain photogating devices also exhibit slow transient response with remnant photocurrent, and a gate pulse is often required to flush trapped carriers and restore initial state [5, 7] – necessitating additional circuit.

We propose and experimentally demonstrate a new class of photodetector using graphene/WS$_2$/MoS$_2$ van der Waals heterojunction in a floating gate structure. Graphene is used both as light absorbing medium as well as conducting channel in plane. A fraction of the photoelectrons generated in graphene is transferred vertically in an ultra-fast time scale to floating monolayer MoS$_2$ through the WS$_2$ spacer barrier layer. The electrons, after being transferred to MoS$_2$, thermalize in short time scale to the conduction band edge of MoS$_2$. While they can return to graphene by tunneling through WS$_2$ bandgap, a steady state population of electrons is created in a short time scale in MoS$_2$. The transferred photoelectrons in MoS$_2$ in turn electrostatically gate the graphene channel by strong capacitive coupling through the ultra-thin WS$_2$ spacer layer. When light is turned off, the captured electrons in MoS$_2$ swiftly tunnel through WS$_2$ to graphene due to the built-in field, automatically shutting off the gating action. This suppresses remnant photocurrent and no extra gate pulse is required to flush the confined electrons.

The stack is systematically characterized photoluminescence quenching measurement as a function of temperature. The photodetector exhibits a responsivity in excess of 10$^4$ A/W in the NIR regime with a specific detectivity of 1.6x10$^{11}$Jones, which is higher than that of any existing graphene-absorption-based detector by several orders of magnitude. The photodetector also maintains high speed of operation (sub-millisecond transient response) which marks an important step towards building graphene based high speed, ultra-wideband photodetector with high sensitivity across bands.

The tutorial will give an overview of some unresolved theoretical and experimental problems in the field of nanoscale thermal transport. Particular attention will be devoted to the outstanding questions and techniques aimed at understanding non-diffusive transport regimes at the nanoscale where the Fourier law breaks down. The main goal of this tutorial is to present our current understanding of these issues, and give some ideas how to move forward.

In the first part of the tutorial, Prof. Philip B. Allen will discuss when and why the Boltzmann transport theory for phonons fails, and present its possible extensions to the nanoscale. He will also discuss the outstanding issue of defining and measuring the local temperature.

In the second part, Prof. David G. Cahill will provide an overview of what is known and not known in the physics of thermal transport at the nanoscale with an emphasis on experimental studies of materials and their interfaces at temperatures near ambient. In particular, he will discuss the breakdown of the diffusion equation at small spatial and temporal scales.

8:30 AM
Heat Transport – Fundamentals and Theory for Nanoscale  
Philip B. Allen; Stony Brook University, The State University of New York

Crystals have quasiparticle excitations: electrons, holes, phonons, magnons, etc. These particles are “normal modes” of excitation. They have energy Ek, where k “labels” the mode (wave vector k, branch index n, and possibly other indices like spin). They also have velocities, vk=dEk/dk. In equilibrium, the number of particles in mode k is given by the Fermi-Dirac or Bose-Einstein distribution nk. If the system is out of equilibrium, the number of particles in mode k is Nk. These modes all transport heat if the system is out of equilibrium. The heat current is the sum of vkNk. Therefore, the fundamental object of study is the nonequilibrium distribution Nk-nk. The usual method for studying this is the Boltzmann transport equation (BTE). What are the important issues? (1) When and why can the BTE fail? (2) How should the BTE be extended to work for nanoscale heat sources? (3) How is the local temperature defined and measured? None of these questions is fully answered. Partial answers will be discussed. The discussion will focus on heat carried by vibrations in insulators. There are three reasons motivating this choice. (A) Phonons have very diverse mean free paths. Many insulators have lower frequency phonon modes with long mean free paths which can exceed the dimensions of heating elements or measuring probes. These provide interesting challenges to theory and experiment. (B) Phonon quasiparticle modes are easier to deal with in one important sense. At higher temperatures, quantum aspects fade out, and classical ideas, including classical molecular dynamics simulation, become powerful tools. (C) Amorphous and other disordered insulators have vibrational normal modes of diverse character that can be modeled theoretically (for example, in the “propagon/diffuson/locon” picture). Heat conduction in metals is also important, but the dominant electron and hole carriers of heat are less diverse. They are easy to treat in “conventional” crystalline metals, and hard to treat in “exotic” metals.

10:30 AM
Current Understanding and Unsolved Problems in Thermal Transport at the Nanoscale  
David G. Cahill; University of Illinois at Urbana-Champaign

On length scales large compared to the mean-free-paths and equilibration lengths of the excitations that carrier heat, the diffusion equation is an accurate description of the relationship between temperature fields and heat fluxes. On small spatial and temporal scales, this simple description fails due to i) scattering and finite transmission of excitations at boundaries; ii) out-of-equilibrium distributions of heat carriers that are induced by heat flow across material interfaces; and iii) non-equilibrium between phonons, electrons, and magnons. In this tutorial lecture, I will provide an overview of what is known and not known in the physics of thermal transport at the nanoscale with an emphasis on experimental studies of materials and their interfaces at temperatures near ambient.

SYMPOSIUM QN04

Nanoscale Heat Transport—Fundamentals  
April 23 - April 26, 2019

Symposium Organizers  
Olivier Delaire, Duke University
Nanoscale Thermal Metrology Using SEM, TEM and Confocal Microscopy

Chris Dames;1,2 University of California, Berkeley, Berkeley, California, United States;2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

I will review several collaborative efforts at developing new non-contact methods for heating and thermometry at the nanometer scale. Examples include techniques based on SEM (e-beam as a point heater; secondary electron yield as a thermometer), TEM (thermometry using the Debye-Waller effect), and confocal microscopy (luminescence thermometry of individual nanoparticles).

A Multi-Temperature Model for Non-Equilibrium Thermal Transport

Xiaolin Ruan, Purdue University, West Lafayette, Indiana, United States.

Conventionally, the two-temperature model has been widely used for electron-phonon coupled non-equilibrium thermal transport. However, many recent applications have shown that different phonon branches can be in strong thermal non-equilibrium. Therefore, assuming a local equilibrium lattice can lead to misleading or wrong results. Here, we present a multi-temperature model to capture the non-equilibrium among different phonon branches, and demonstrate its advantages over the conventional two-temperature model for bulk materials and across interfaces.

Specular Reflection Creates Lowest Thermal Phonon Conductivity

Martin Maldovan; Georgia Institute of Technology, Atlanta, Georgia, United States.

The thermal conductivity of materials is not a fixed physical property but can be manipulated by controlling the transport properties of thermal phonons. Recently, a large number of experiments have been introduced where thermal conduction is reduced by orders of magnitude via phonon mean free path reduction through diffuse surface scattering. In contrast to established work that use the diffuse surface scattering of phonons as the physical mechanism to reduce the thermal conductivities, in this talk we show that the largest reduction of thin film heat conduction is achieved via specular scattering. Our results thus create a new paradigm for heat conduction manipulation since smooth surfaces – in contrast to rough surfaces – can be more effective on suppressing thin film phonon heat conduction.

Phonon Heat Conduction and Nanoscale Disorder—From Scatterings to Localizations

Sebastian Volz; CNRS–University of Tokyo, Tokyo, Japan.

Effect of structural disorder on phonon thermal conduction remains an open question with a large spectrum of physical effects, as the plane-wave description of atomic vibrations is expected to become irrelevant. In a first stage, atomic scale disorder will be investigated in various systems –silicon [1], SiGe nanowires [2], partial-crystal partial-liquid [3], 2D [4,5] - with atomic scale simulations. Secondly, thermal properties of nanoscale random materials [6,7] will be presented to raise the question of the eventual impact of localization on heat conduction.

Far-Field Submicron Thermoreflectance Imaging

Amirkoushyar Ziabari, Sami Alajlouni and Ali Shakouri; Birck Nanotechnology Center, Purdue University, West Lafayette, Indiana, United States.

Self-heating and localized hotspots can limit the performance of electronic and optoelectronic devices. Contact-related artifacts and diffraction limit the accurate temperature measurements at deep submicron scale. Here we combine thermoreflectance (TR) imaging with a robust image reconstruction technique to achieve accurate temperature maps of nanoscale metal interconnects. Reconstructing accurate temperature profiles from far-field diffraction-limited images is an ill-posed inverse problem. To formulate the inverse problem, we developed a model based imaging process technique based on a Bayesian framework that consists of a maximum-a-posteriori (MAP) cost function with Generalized Gaussian Markov random field priors (GGMRF). The imaging system was approximated by a Gaussian blurring kernel using the information about the pixel dimensions, numerical aperture of the lens used in the system as well as the wavelength of the light. The iterative coordinate descent (ICD) optimization is then used to minimize the corresponding cost function and extract the temperature profiles.

We performed the reconstruction both for numerically designed experiments as well as experimental thermoreflectance thermal images. Additionally, statistical analysis of the resolution limit shows that image reconstruction is a strong function of signal-to-noise ratio. We carried out detailed analysis to investigate the impact of the signal-to-noise ratio.
on extracting the accurate temperature of nanoscale features. Theoretical and experimental results demonstrate accurate thermal mapping of objects down to 100nm. The proposed non-contact technique provides an alternative to techniques such as scanning probe that are often slower and quite sensitive to surface roughness. Additionally, the technique can be applied to other far field imaging experiments to study the performance of nanoscale optoelectronic and plasmonic devices.

Since quasi ballistic phonons dominate submicron thermal transport in many semiconductors at room temperature, there are questions about the definition of temperature and what actually a thermometer measures. Transient hyperspectral imaging as well as resistance thermometry are used to study the apparent temperatures of various metals and nearby semiconductors and to verify our submicron TR imaging results. Indications for superdiffusive and hydrodynamic heat flow are briefly described.

2:00 PM QN04.02.02
Pre-Interface Phonon Scattering Effect in Thermal Transport Across Solid Interfaces Eungkyu Lee, Ruiyang Li and Tengfei Luo; University of Notre Dame, Notre Dame, Indiana, United States.

Understanding phonon transport across solid-solid interfaces can greatly impact thermal engineering in many solid-state applications. Conventionally, phonon scattering is considered impediment to thermal transport. In this study, we present systematic study of the effect of pre-interface phonon in thermal boundary conductance using non-equilibrium molecular dynamics (NEMD) simulations. We first examine the fundamental role of anharmonic phonon scattering in thermal transport across an artificial solid junction, which consists of a monatomic lattice and a diatomic lattice. Using interatomic force parameters expanding up to the third-order, we investigate how inelastic phonon scattering processes in the diatomic lattice layer influence thermal boundary conductance. It is found that the anharmonicity inside the diatomic lattice layer promotes phonon-phonon energy conversion between optical and acoustic phonon modes, which eventually lead to enhanced thermal transport across the solid junction by populating more acoustic phonon modes with higher transmission probability through the pre-interface phonon scattering. Importantly, we find that anharmonic scattering effect in the pre-interfacial region is more important than that right at the interfaces in thermal transport. Next, we explore pre-interface phonon scattering effect in thermal transport across SiC/GaN interfaces by doping isotopes in the GaN, where the SiC/GaN interface is of technological importance in power electronics. We use $^{11}$N or $^{35}$Ga as isotopes in NEMD simulations. By tuning various isotope-doping characteristics (i.e., the isotope concentration, skin depth of the isotope region, and its distance from the interface), we investigate an enhancement of thermal conductance across SiC/GaN interfaces. We find that 10% of $^{11}$N isotope in GaN layer can increase TBC by as much as 23% compared to the isotopically pure cases. In addition, when the isotope-doped region is located away from the SiC/GaN interface, the TBC enhancement still exist, showing pre-interface phonon scattering by isotopes is mainly responsible for the enhanced TBC. Moreover, analysis of spectral temperatures of phonon modes reveal that heat transfer rates by low frequency phonons ($< 20$ THz) across SiC/GaN interfaces increase after isotopes are introduced.

Our studies demonstrate that pre-interface phonon scatterings can help redistribute phonon energy, so that phonon modes with higher transmission probability can be more populated, which leads to TBC enhancements across solid-solid interfaces. Development of new theoretical models should consider this pre-interface phonon scattering effect. Practical materials design can also take advantage of this effect to enhance interfacial thermal transport.

2:15 PM QN04.02.03
Predicting the Phonon Mode-Resolved Specularity Parameter Using the Atomistic S-Matrix Method Zhuo-Yong Ong; Institute of High Performance Computing, Singapore, Singapore.

The phonon specularity parameter represents the probability of the phonon being specularly scattered by a surface and is crucial for understanding phonon-mediated thermal transport in low-dimensional semiconducting or insulating materials such as thin films and nanowires. However, there exists no reliable and accurate method to predict the relationship between the mode-dependent specularity parameter and the atomistic structure of a non-ideal edge or interface. [1] In addition, the dependence of the specularity parameter on wavelength, direction and polarization cannot be determined reliably with current theories.

To treat this problem, we introduce an S-matrix approach [2] that is grounded conceptually in conventional quantum mechanical scattering theory and developed from our earlier extension of the Atomistic Green’s Function (AGF) method, [3] allowing us to compute the scattering amplitude between an incident phonon and a reflected or transmitted phonon. The utility of our approach is illustrated through two example calculations. In the first example, we study the specularity dependence on edge chirality and explain how specularity is reduced for the ideal armchair edge in graphene, shedding light on the findings by Wei, Chen and Dames [4]. In the second example, we investigate grain boundary phonon scattering in graphene and provide direct evidence that the the specularity is significantly different between reflected and transmitted phonons. [5] Our S-matrix method resolves some of the existing difficulties in predicting the mode-dependent specularity parameter and opens the way for analyzing how edges and interfaces can be modified to control phonon scattering with atomistic precision.

High-Throughput Thermal Conductivity Predictions and Spatial-Temporal Imaging Ding Ding$^{1}$ and Kedar Hippalgaonkar$^{2,3}$; $^{1}$Institute of Materials Research and Engineering, Singapore, Singapore; $^{2}$MSE, Nanyang Technological University, Singapore, Singapore; $^{3}$Singapore Institute of Manufacturing Technology, Singapore, Singapore.

With nanostructures in solid state materials reaching the size of the phonon mean free path and lower, quasilocalistic and anisotropic effects play significant roles in their thermal properties. Many new experimental techniques have been developed to probe phonon physics at such lengthscapes, however ascertaining spatially dependent thermal properties typically requires control of parameters in the spatial or frequency domain. Here, I will present our proposal for a one-shot optical pump-probe methodology that can potentially directly image both spatial and temporal temperature profiles. Coupled with a multi-parameter optimization of the heat diffusion equation, this technique can prove powerful in measuring anisotropic and quasilocalistic heat transport directly, serving as a high-throughput tool for screening of thermal properties. Coupled with first principles DFT calculations of the grunsen parameter and debye temperature of a large number of compounds extracted from Materialsproject.org, I will illustrate a vision of how machine learning can be used for prediction of desirable thermal properties.

3:30 PM *QN04.03.01
Research into magnetic devices – emerging memory, logic, and oscillator technologies – is enabled by magnetic imaging techniques that possess simultaneous picosecond temporal resolution and 10 – 100 nm spatial resolution. Conventionally, this combination is available only at facility-based research centers using e.g., pulsed x-ray dichroism techniques. In addition, many of the most exciting magnetic material systems, including ultrathin ferromagnetic or antiferromagnets insulators buried beneath heavy metals are difficult to image with any method. To address these challenges in a accessible way, we have developed a table-top spatiotemporal magnetic microscope based on nanoscale, picosecond thermal pulses. Our method takes advantage of magneto-thermal interactions that couple heat flow to electron or spin transport, including the anomalous Nernst effect [1] and the longitudinal spin Seebeck effect [2]. Using focused light as a picosecond heating source, we demonstrate that these imaging modalities have time resolution on the order of 10 ps and sensitivities to magnetization angle of 0.1 – 0.3°/Hz for ferromagnetic metals and insulators. In combination with phase-sensitive microwave current imaging, phase-sensitive ferromagnetic resonance imaging [3] enables direct imaging of the gigahertz-frequency magnetic driving torque vector, which is valuable for understanding spin-orbit interactions [4]. We also demonstrate magneto-thermal imaging of antiferromagnetic order in FeRh and NiO, offering a simple and accessible method to study spin-orbit torque switching of antiferromagnetic materials [5]. Finally, we will describe how time-resolved magnetic imaging can be extended to greatly exceed the optical diffraction limit, both theoretically [6] and experimentally. We demonstrate scanning a sharp gold tip illuminated by picosecond laser pulses as the basis of a nanoscale spatiotemporal magnetic microscope.

4:00 PM QN04.03.02 Spin-Lattice Dynamics Calculations of Phonon-Magnon Coupling in Bulk Magnetic Materials Joseph Cooke and Jennifer R. Lukes; University of Pennsylvania, Philadelphia, Pennsylvania, United States.

We present calculations of phonon-magnon coupling in bulk iron and nickel using spin-lattice dynamics [1,2], an increasingly popular simulation technique in which atomic spins and positions are computed simultaneously. It has been shown recently that a position-dependent magnetic anisotropy term is required to allow for full two-way coupling of thermal energy between the spin and lattice subsystems [3,4], but the parameters in this term are not known for many materials. Here we describe a procedure to obtain these parameters from experimental data on iron and nickel. We find that simulations including our parameters yield physically meaningful thermalization of spin and lattice systems and produce coupling times on the order of 100 ps, which agrees with the order of magnitude for coupling times reported by others [3,5].

4:15 PM QN04.03.03 Effect of External Magnetic Field on Electron-Phonon Coupling and Transport Properties Jiayue Yang, Wenjie Zhang and Linhua Liu; School of Energy and Power Engineering, Shandong University, Qingdao, China.

With its merit of being controllable, nondestructive and easy-to-apply, magnetic field demonstrates great advantages in engineering electrical and thermal transport for practical applications. Yet, the scientific challenge is to better understand how the quantum behaviors of electrons and phonons that dominate the electrical and thermal transport respectively, are modulated by the external magnetic field. In this work, we apply the all-electron first-principles simulations to calculate the influence of external magnetic field on the intrinsic electron-phonon coupling, and then investigate its effect on the electronic thermal conductivity of representative metals (Al, Ni and Nb), superconducting transition temperature of hydrogen sulfide and magnetoresistance of monolayer WTe₂. For the electronic thermal conductivity study, the crucial issue is that electron-phonon coupling dominantly determines electron’s lifetime and external magnetic field can modulate electronic thermal transport by altering the electron-phonon coupling. We observe opposite change trend of electronic thermal conductivity with varying external magnetic field in Al, Ni and Nb, which is closely related to its electron localization function. Moreover, we find that magnetic field can slightly reduce the superconducting transition temperature of hydrogen sulfide and then modulates the thermoelectric properties of Al, Ni and Nb.

4:30 PM QN04.03.04 Quasiparticle Thermometry in Nonequilibrium Systems Xiaoxin E. Li; University of Texas at Austin, Austin, Texas, United States.

In nonequilibrium phenomena, different quasiparticles such as phonons and magnons may exhibit different temperatures with the caveat that temperature is only strictly defined for an equilibrium system. Spin caloritronics, as an emerging field, investigates the interplay between the transport of spin and heat. In the representative spin Seebeck effect [1], a thermal gradient across a magnetic material generates a spin current. Many theories hypothesize that a temperature difference between the energy carriers of the spin and lattice subsystems, namely the magnons and phonons, is necessary for such thermal nonequilibrium generation of spin current. The experimental evidence for such phonon-magnon nonequilibrium has been critically lacking [2] because of the difficulty to characterize phonon and magnon temperatures independently.

We use Brillouin light scattering (BLS) to investigate thermally driven spin current in a prototypical magnetic insulator yttrium iron garnet (YIG). BLS, as an inelastic light scattering technique, is conceptually the same as Raman scattering. It is optimized to probe low-frequency excitations, e.g., acoustic phonons and magnons. These quasiparticles are the main energy and spin carriers in magnetic insulators. Three different quantities (i.e., central frequency, linewidth, and integrated intensity) associated with the BLS spectra are the main energy and spin carriers in magnetic insulators. Three different quantities (i.e., central frequency, linewidth, and integrated intensity) associated with the BLS spectra all vary with temperature systematically and can be used as a temperature sensor for probing phonons and magnons independently [3]. We show how BLS spectra can be used to probe phonon-magnon non-equilibriums [4], measure pure spin current, and evaluate magnon chemical potential in a magnetic insulator thermally driven out of equilibrium.

References:
Scanning Thermal Microscopy (SThM) allows the thermal characterization of materials with a submicrometric spatial resolution [1]. While obtaining qualitative trends, e.g. by means of maps, is straightforward, determining reliable quantitative thermal data from the experiments is challenging because the probe-sample heat exchange depends strongly on parameters such as the size, geometry and surface states of probe and sample [2-3]. There is a need for a complete and accurate thermal measurement methodology, which is the aim of this work. We focus on heated probes dissipating heat flux into samples initially at ambient temperature. Simultaneous heating and measurement of the SThM probe temperature provide information on the sample effective thermal conductivity.

For three different electrically-resistive and Joule-heated SThM probes, involving different sizes and sensor materials (etched Wollaston-wire microprobe, palladium nanoprobe and doped silicon nanoprobe), an improved methodology for thermal conductivity local-point measurement was developed. Studies in ambient and vacuum conditions were considered. The methodology enables to eliminate the impact of thermal drifts occurring in such experiments, to deal with the variation in the laser irradiation on the cantilever and probe, and to detect any change at the tip apex due to a deformation or a contamination. As a consequence, results are reproducible with a temperature resolution of the order of few millikelvins.

Specimens of well-known thermal conductivity spanning between 0.1 and 150 W.m⁻¹.K⁻¹ and surfaces controlled in terms of roughness and nanomechanical properties were used as reference materials in order to obtain a calibration curve for each probe. In the three cases, their applications allow us to clearly confirm that thermal-conductivity measurements with SThM are limited to low thermal conductivity materials (k < few W.m⁻¹.K⁻¹). This is due to the designs of the cantilever of the three probes and may not easily be improved. As expected, reducing the probe size and placing it in vacuum improves the spatial resolution, but it also induces unfortunately an increase of sensitivity to the tip-sample contact physical parameters (e.g. roughness, thermal boundary resistance, surface state), which is detrimental to the accuracy.

The impact of roughness on the thermal conductance at the contact was studied in detail. Samples consisting of several sets of silicon surfaces with out-of-plane Sq roughness parameters of ~0.5, 0.4, 4, and 12 nm were prepared by anodic oxidation [5]. Our results show that roughness induces a thermal conductance decrease at the contact up to 35% compared to a flat silicon sample, depending on the probe and environment. Precise knowledge of the surface state is therefore key to accurate measurements.

The calibration and methodology were applied to characterize thin films of oxides and materials involved in electronics. The experimental results are backed by finite-element simulations (FEM) including effective thermal conductivities when the size requires it, local heat sinks representing thermal constrictions of typical sizes smaller than the energy carrier mean free paths (when FEM is not able to capture the correct physics), and thermal boundary conductances in the Acoustic or Diffuse Mismatch Models (AMM-DMM). Advantages and drawbacks of SThM are discussed in light of the results.

The research leading to these results has received funding from the EU FP7 Programme under GA n°604668. and French ANR Programme under project TIPTOP.
while angstrom-scale responses can be tracked in reciprocal space. In UEM, as in other ultrafast electron and X-ray experiments, the Debye-Waller (DW) effect is often invoked when explaining photoinduced scattering intensity changes and when determining transient temperatures by relating the changes to atomic thermal vibrations. While this enables direct probing of the intrinsic lattice response to thermal effects with high spatial and temporal resolutions, reliance on transient intensity changes of diffracted beams poses significant challenges. This is because factors other than mean-square atomic displacements can produce signal changes similar to those generated by thermal effects [3-5]. Therefore, in order to accurately and precisely determine nanoscale transient temperatures using ultrafast scattering methods, deleterious effects that obfuscate intensity changes arising from atomic thermal vibrations must be identified, quantified, and deconvolved.

To address this, we have systematically studied and quantified a number of potential effects that can arise during in situ fs photoexcitation that may impact DW-type responses and the resulting interpretations [6]. Using small-grained polycrystalline aluminum films as a well-characterized test system, we explicitly illustrate the impact of specimen tilting and translation via rigorous statistical analysis of Debye-Scherrer-ring intensities obtained from numerous individual specimens and measurements. Despite having more than 10⁶ individual grains within the selected areas, we find that tilting by as little as a fraction of a degree, or translating a 22.5-μm diameter illuminated region by only 20 nm, yields statistically-significant changes in the diffracted-beam intensity. This result is at first surprising, as one may have expected a uniform distribution of random zone-axis orientations under such conditions, thus circumventing any negative effects due to specimen tilting and translation. We explicitly show this is not the case, and we explore and quantify several sources of error and artifacts, such as slight texturing of the polycrystalline films due to surface-energy minimization. Possible approaches to mitigating inaccuracies in the DW-calculated temperatures are also addressed, including effective methods of data normalization and consideration of ideal specimen geometries for such studies.

Correlating Coherent Structural Dynamics to Photoexcited Charge-Carrier Behaviors Using Femtosecond Electron Imaging

Daniel Del¹; Daniel R. Cremons¹,² and David J. Flannigan¹
¹University of Minnesota Twin Cities, CEMS, Minneapolis, Minnesota, United States; ²NASA Goddard Space Flight Center, Greenbelt, Maryland, United States.

Intense femtosecond (fs) photoexcitation of semiconducting materials can lead to the generation of high densities of charge carriers, shifting the Fermi-Dirac distribution into a highly non-equilibrium state. The relaxation pathways available to this new state are numerous, and the associated mechanisms can be intermingled and highly non-linear [1]. One particular pathway is via the excitation of highly-coherent, low-frequency acoustic phonons that propagate outward from the photoexcited zone [2]. For initially high carrier concentrations, this behavior is attributed either to a time-varying deformation potential or a time-varying thermoelastic effect, depending upon the band structure and the nature of photoexcitation. Importantly, these two regimes can be differentiated temporally, depending upon the carrier densities generated; at relatively high concentrations, Auger recombination begins to further augment the time-varying thermoelastic effect. Indeed, a material as simple as undoped germanium (Ge) displays several intriguing transient behaviors within the context just described. For example, the excited carrier-density lifetimes can be quite long and can significantly overlap with the electron-phonon coupling times, thus heavily interweaving the various relaxation pathways [3,4]. Further, intense fs photoexcitation can lead to the generation of hypersonic electron-hole plasma waves, the nature of which may evolve into coherent acoustic-type oscillatory behaviors [5]. This suggests such behaviors may manifest as coherent, transient lattice-strain effects, the properties of which are directly linked to the hypersonic plasma waves [6].

Here, we describe our efforts to link the photoexcited charge-carrier dynamics in single-crystal Ge to the lattice degrees of freedom using fs electron imaging in an ultrafast electron microscope [7,8]. By leveraging the extreme sensitivity of local diffraction contrast to changes in reciprocal-lattice orientation, we are able to directly image the generation and the evolution of highly-coherent acoustic phonons initially propagating at hypersonic velocities in the plane of the crystal [9]. While each phonon wavefront propagates with a constant velocity, the entire wave train displays a time-varying phase-velocity dispersion, relaxing from initial velocities greater than 35 nm/s to the Ge longitudinal speed of sound (5 nm/ps) within one nanosecond. Analysis of the dispersion curves expected for symmetric dilatational and asymmetric flexural modes indicates the dynamics match most closely to a single, low-order symmetric mode. Interestingly, this symmetric mode appears to give rise only to increased scattering for each wavefront, indicating the reciprocal-lattice shapes (approximated here as rods) are only brought further onto the Ewald sphere rather than being equally distributed during the oscillation. Further, by using a plasma lensing technique [10], we find that the onset of the first phonon wavefronts are delayed by tens of picoseconds or more, relative to the moment of fs photoexcitation. Combined, these anomalous behaviors provide tantalizing hints of charge-carrier-dominant dynamics, rather than lattice deformations caused by coherent phonons, as producing the observed ultrafast contrast behaviors. Those possibilities are explored here.

Thermal Transport in Holey Silicon Membranes Investigated with Optically-Induced Transient Thermal Gratings

Ryan A. Duncan¹; Giuseppe Romano¹; Marianna Sledzinska²; Alokei Maznev³; Jean-Philippe Peraud¹; Olle Hellman¹; Kelvin Nelson¹; ¹Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; ²Catalan Institute of Nanoscience and Nanotechnology, Barcelona, Spain; ³Lawrence Berkeley National Laboratory, Berkeley, California, United States; ⁴California Institute of Technology, Pasadena, California, United States; ⁵Linköping University, Linköping, Sweden; ⁶Boston College, Chestnut Hill, Massachusetts, United States.

In semiconductor nanostructures with feature sizes on the order of 100 nm, thermal transport is expected to be well-described by the phonon Boltzmann transport equation (BTE) with diffuse boundary scattering. However, over the past several years there have been reports of anomalously low effective thermal conductivity values in one- and two-dimensional semiconductor nanostructures. In this study, we investigate thermal transport in nanostructured holey silicon membranes using the non-contact optical transient thermal grating (TTG) technique. We compare the experimental results with two ab-initio BTE numerical techniques. We obtain excellent agreement between theory and experiment, indicating that semi-classical Boltzmann transport theory for phonons is adequate for describing room-temperature thermal transport in semiconductor nanostructures with feature sizes on the order of 100 nm.

QN04.04.06
Theory of Anisotropic Thermal Interface Resistance in Nanocomposite Materials

Iorwerth O. Thomas and Gyaneshwar P. Srivastava; University of Exeter, Exeter, United Kingdom.

We present a theory of anisotropic thermal interface (Kapitza) resistance for rough interfaces in nanocomposite materials. This is based on an extension [1] of a modified effective medium theory [2,3] that includes anisotropically resistive interface regions in a model of the lattice thermal conductivity of anisotropic nano insertions in anisotropically conductive hosts. The thermal conductivities of the host and nanodot insertions have been evaluated using a semi ab-initio theory [4] based on the solution of the linearised phonon Boltzmann transport equation within a generalized [5] Callaway effective relaxation time scheme [6]. Phonon boundary scattering and the Kapitza resistance at the insertion-host interface have been treated by taking into account both specular and diffuse contributions [7,6]. The theory has been applied to a transition metal dichalcogenide (TMD)
nanocomposite consisting of 2H WS2 inserts in a 2H MoS2 host. In general, it is found that the effect of specular scattering due to interface roughness is more pronounced for inserts smaller than 100 nm. Analysis of the results allows us to identify key physical parameters that should prove effective in controlling (i.e. obtaining minimum) lattice thermal conductivity of TMD nanocomposites.

**Impact of Irradiation Induced Nanoscale Defects on Thermal Conductivity of Cerium Dioxide**

Vinay S. Chauhan, Lingfeng He, Jianmei Pakarinen, David Hurley, Marat Khafizov, Mechanical and Aerospace Engineering, The Ohio State University, Columbus, Ohio, United States; Idaho National Laboratory, Idaho Falls, Idaho, United States; Belgian Nuclear Research Center (SCK-CEN), Boeretang, Belgium.

Thermal conductivity is a critical physical property of ceramic nuclear fuels such as uranium dioxide. While cerium dioxide is considered as a solid electrolyte in solid oxide fuel cells (SOFC), in this study it is used as surrogate material to study the properties of nuclear fuel. In nuclear fuel, these oxides are exposed to extreme environments such as high temperature and bombardment with heavy particles. The damage introduced by such conditions in the form of defects generated inside the material can be detrimental to the structural stability of the material and ability to transport heat efficiently. Also, thermal conductivity degradation impacts fuel performance negatively. As a result, thermal conductivity of ceria has been widely investigated as one of the critical properties. This study is aimed at understanding the interplay between these nanoscale defects and the thermal conductivity of ceria.

Polycrystalline ceria samples were irradiated at 600 deg C to the same dose but at different rates using protons accelerated to 2 MeV. These irradiation conditions were chosen to promote the generation of nanoscale defects and to investigate their impact on thermal conductivity of ceria. SRIM simulations were done to identify the peak and plateau damage region inside the sample. The calculations estimated the plateau damage to be ~0.14 dpa. The quantitative analysis of radiation induced dislocation loops including size and density was performed using transmission electron microscope (TEM) for which the samples were prepared using focused ion beam (FIB) system.

X-ray diffraction was used to confirm the stability of the crystal structure and also revealed detectable lattice expansion caused by accumulation of nanoscale defects. In addition to this, thermal conductivity was measured using modulated thermoreflectance methods and showed a notable reduction in irradiated samples. In order to isolate the impact of different defects on thermal conductivity, measurements were done for ambient temperature range of 100 to 300 K. The changes in thermal conductivity were analyzed quantitatively using the classical thermal transport model based on Klemens-Callaway formalism that considers reduction of thermal conductivity by irradiation induced nanoscale defects.

**Multiscale Thermal and Electrical Modeling of CMOS Devices and Circuits**

Robin L. Daugherty and Dragica Vasileska, Arizona State University, Tempe, Arizona, United States.

This simulation work explores the thermal effects on electrical characteristics of CMOS devices and circuits using a multiscale dual-carrier approach. Simulating for electron and hole transport simultaneously allows for complimentary logic gates to be simulated at the device level, while current and voltage continuity are maintained at the circuit level. Further, the electrical model couples with a multiscale thermal solver, which solves for electron-phonon and hole-phonon interactions at the device level and phonon-phonon thermal transport in the packaging level. This methodology allows for the study of package level thermal transport without sacrificing the nuances of device self-heating, ultimately providing a more comprehensive understanding of how these interactions affect power consumption in CMOS systems.

The electrical model is comprised of an ensemble Monte Carlo simulator coupled with a Poisson solver. This framework provides accurate electrical characteristics in quasi-static regimes by iteratively solving for the potential profile and the electric fields then simulating the effect of the electric field on charge carriers. The Monte Carlo simulator solves the Boltzmann Transport by balancing each particle’s movement in real and momentum space with the collision integral through probabilistic scattering mechanisms. This framework provides current and voltage characteristics for each device; current and voltage continuity are maintained by solving at the circuit level.

Similarly, the methodology for simulating thermal characteristics includes two scales. At the device scale, the energy balance equation determines the transfer of energy from charge carriers to phonons. High-energy electrons or holes relinquish energy to optical and acoustic phonons through scattering and optical phonons decay into acoustic phonons. At the package level, a Fourier law solver simulates the subsequent conduction of heat in the form of lattice vibrations.

This framework proved effective in previous simulations for the electro-thermal characteristics in NMOS devices. This work demonstrates the effectiveness of the dual-carrier electrical solver in simulating CMOS circuits. Future work requires the coupling the dual-carrier electrical solver with the previously proven thermal solver to provide comprehensive electro-thermal simulations of CMOS systems.

**Graphene Composites for Thermal and Electromagnetic Shielding Applications—Performance Below and Above Percolation Thresholds**

Fariborz Kargar, Zahra Barani, Jacob S. Lewis, Ruben Salgado, Sahar Naghibi, Ece Aytan and Alexander A. Balandin; Phonon Optimized Engineered Materials (POEM) Center, Department of Electrical and Computer Engineering, Materials Science and Engineering Program, Bourns College of Engineering, University of California, Riverside, Riverside, California, United States.

Excellent heat conduction properties of graphene and the progress in the large-scale few-layer graphene exfoliation make the prospects of graphene composite applications particularly promising [1-2]. We investigated thermal properties of the epoxy-based composites with a high loading fraction – up to 45 vol. % – of the randomly oriented electrically conductive graphene fillers and electrically insulating boron nitride fillers [3]. It was found that both types of the composites revealed a distinctive thermal percolation threshold at the loading fraction above 20 vol.%. The graphene loading required for achieving the thermal percolation was substantially higher than the loading for the electrical percolation. Graphene fillers outperformed boron nitride fillers in the thermal conductivity enhancement. It was established that thermal transport in composites with the high filler loading is dominated by heat conduction via the network of percolating fillers. Unexpectedly, we determined that the thermal transport properties of the high loading composites were influenced strongly by the cross-plane thermal conductivity of the quasi-two-dimensional fillers. It was also found that composites with the certain types of few-layer graphene fillers reveal an efficient total electromagnetic interference shielding in the important X-band frequency range, while simultaneously providing the high thermal conductivity [4]. The efficiency of the dual functional application depends on the filler characteristics: thickness, lateral dimensions, aspect ratio and concentration. Graphene loading fractions above the electrical and thermal percolation thresholds allow for strong enhancement of both the electromagnetic interference shielding and heat conduction properties. Interestingly, graphene composites can block the electromagnetic energy even below the electrical percolation threshold, remaining electrically insulating. The dual functionality of the graphene composites can substantially improve the electromagnetic shielding and thermal management of the airborne systems while simultaneously reducing their weight and cost.

loading of graphene and boron nitride fillers,” ACS Applied Materials and Interfaces, (2018) DOI:10.1021/acsami.8b16616.

QN04.04.10 Fine-Tuning the Acoustic Phonon Spectrum in Bulk Crystals via Incorporation of the Size-Dissimilar Substitutional Dopant Atoms—Brillouin—Mandelstam Spectroscopy Study Fariborz Kargar1, Elias H. Penilla2, Chun-Yu T. Huang1, Ece Aytan1, Javier E. Garay2 and Alexander A. Balandin1; 1Phonon Optimized Engineered Materials (POEM) Center, Department of Electrical and Computer Engineering, Materials Science and Engineering Program, Bourns College of Engineering, University of California, Riverside, Riverside, California, United States; 2Advanced Materials Processing and Synthesis (AMPS) Laboratory, Department of Mechanical and Aerospace Engineering, University of California, San Diego, San Diego, California, United States.

Acoustic phonons make a dominant contribution to thermal transport in insulators and semiconductors, scatter electrons and holes, and participate in the non-radiative carrier recombination processes. Acoustic phonons are important in certain types of the Auger recombination processes where they are needed to satisfy the momentum conservation. A possibility of engineering the acoustic phonon spectrum provides a tuning capability for changing thermal conductivity and electron – phonon interactions [1]. Until recently, the tuning of the phonon spectrum has been associated with the nanostructured materials, where the phonon dispersion undergoes modification due to the periodic or stationary boundary conditions. In this talk, we describe a drastically different approach for changing the acoustic phonon spectrum of the materials, which does not rely on nanostructuring [1]. We change the phonon spectrum in bulk crystalline materials via introduction of a small concentration of dopant atoms that have a substantially different size and mass from those of the host atoms. We report results of Brillouin – Mandelstam spectroscopy (BMS) of transparent Al2O3 crystals with Nd, Cr and other atoms used as substitutional dopants. The ionic radius and atomic mass of Nd atoms are distinctively different from those of the host Al atoms. Our results show that even a small concentration of Nd atoms incorporated into the Al2O3 samples produces a profound change in the acoustic phonon spectrum. The frequency and velocity of the transverse acoustic phonons decrease by ~4 GHz and ~600 m/s, respectively, at the Nd density of only ~0.1 %. In contrast to Nd dopants, both the ionic radius and atomic mass of Cr atoms are closer to those of the host Al atoms. The BMS results show that the phonon group velocity does not significantly change when the substitutional dopants are similar in size and mass to the host atoms. Our findings confirm that even a small concentration of dopants with strongly dissimilar size and mass can result in a profound change in the bulk phonon spectrum. The difference in atomic size can result in the crystal lattice distortion, i.e. increased inter-atomic plane distance associated with the incorporation of larger atoms. The obtained results, demonstrating a possibility of fine-tuning the phonon spectrum in bulk materials, have important implications for a range of electronic and optoelectronic devices. QN04.04.11 Electron-Phonon Coupling in Metal Contacts—Two-Temperature Molecular Dynamics Simulations Henry Aller, Jonathan A. Malen and Alan McGaughey; Mechanical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

The interface between a metal and a semiconductor that have dissimilar phonon frequency spectra typically exhibits a low thermal boundary conductance, as found for many Au/semiconductor interfaces. A thin metal layer (i.e., a contact or adhesion layer) placed between the gold (i.e., the capping layer) and the semiconductor can increase the thermal boundary conductance, an effect that has been attributed to the contact serving as a vibrational bridge. The impact of a change in the electron-phonon coupling due to the presence of the contact on the thermal boundary conductance, however, is not fully understood. To assess the roles played by vibrational bridging and electron-phonon coupling, we apply a two-temperature non-equilibrium molecular dynamics simulation approach. By specifying the heat flow through a structure, we can predict the temperature profiles in the electronic and phononic subsystems and the resulting thermal boundary conductance(s). Four types of structure built from metals (M) and semiconductors (SC) are considered: M/M, M/SC, M/SC/SC, and SC/SC/SC. Increasing the contact layer thickness for the M/MS/SC systems results in a monotonic increase in thermal boundary conductance, matching trends from previous experimental studies. The phonon density of states in the contact layer identifies the existence of non-bulk phonon modes for small thicknesses. Increasing thickness results in contact layer phonons gradually shifting to bulk frequencies, which explains the occurrence of the plateau in thermal boundary conductance for large thicknesses. A comparison between the M/M/SC, M/SC/SC, and SC/SC/SC systems provides insight to how the electron-phonon coupling in each metal layer impacts thermal boundary conductance.

QN04.04.12 Extending the Lattice Boltzmann Phonon Transport Approach Towards the Ballistic Regime Natalia Bedoya-Martinez, Verena Fritz and René Hammer; Materials Center of Leoben, Leoben, Austria.

The thermal conductivity is a system property rather than a material property alone, i.e. the mechanisms that govern the thermal conductivity strongly depend on the system (e.g. length scale, phonon confinement, ballistic interface and boundary effects). A specific model, then, capable to account for the different mechanisms should be used. Among the different models to study thermal transport, the most standard one is based on the Fourier’s law, which can be implemented either in the framework of classical or ab-initio molecular dynamics (MD) simulations. MD builds on classical Newton’s equation of motion and, therefore, does not account for nuclear quantum effects that are present below the Debye temperature [1]. Furthermore, ab-initio and MD simulations may feature strong size effects due to the limited size of the computational domain. Fourier’s law based models, thus, do not properly account for the ballistic, wave like, and quantum phenomena of heat transport.

At a length scale, L, of the order of the phonons mean free path, λ, a statistical description of the phonon transport using the Boltzmann transport equation is required (e.g. 50% of thermal conductivity in bulk silicon at RT comes from phonons having mean free paths > 500 nm [2]). This, however, is very demanding from a computational point of view. Even new developments (e.g. energy based and deviational formalism [3]) in stochastic Monte Carlo methods, are still too expensive to simulate 3D device problems on standard workstations. Deterministic methods for solving the phonon Boltzmann transport equation, on the other hand, suffer from ray effect and / or false scattering [4]. These effects strongly limit their accuracy in the high Knudsen number regime (i.e. λ<< L).

Here, we present a set of improvements on the lattice Boltzmann method (LBM), in order to extend its applicability far into the ballistic regime. First of all, we get rid of the numerical boundaries by allowing adaptive time steps. This allows us to go beyond the grey approximation (i.e. average phonon properties), and to introduce several phonon species with different group velocities on one grid. Secondly, we go beyond the next neighbour hopping for the LBM stencil. This allows to increase the number of discretized directions (e.g. to reduce the ray effect) without introducing false scattering. The new numerical algorithms are applied to standard 2D transient and stationary phonon heat transport cases, with different group velocities on one grid. Secondly, we go beyond the next neighbour hopping for the LBM stencil. This allows to increase the number of discretized directions (e.g. to reduce the ray effect) without introducing false scattering. The new numerical algorithms are applied to standard 2D transient and stationary phonon heat transport cases, and are benchmarked against analytical and numerical solutions given by the discrete ordinate method and MC simulations.

QN04.04.13 Thermal Conductivity of CuSn Matthias A. Daemuel1, Arad Azzii2, Sitaram Pant2, Faramarz Hadian2, Eric J. Cotts3 and Scott N. Schiffres4; 1Mechanical Engineering, Binghamton University, Bing, New York, United States; 2Department of Physics, Binghamton University, The State University of New York, Binghamton, New York, United States.

In order to realize vertical integration for next generation electronics packaging, purely intermetallic bonding is a promising contender to replace solder. The thermal properties of these industrially important intermetalities are relatively unstudied and poorly understood. Due to their high melting temperatures intermetallics bonds provide stability through
several refinements enabling vertical packaging. However, in vertical packaging the interconnects must carry a significant portion of the heat away from the chip. In an effort to better understand the thermal capability of fully intermetallic bonding Frequency Domain Frequency Domain Thermoreflectance mapping was used to determine thermal conductivity of the arc-melted CuSn with respect to crystallographic orientation. This will be complemented by electron backscatter diffraction mapping of the crystal orientation.

QN04.04.14
Uncovering Phonon Transport Mechanisms Underneath Nanoscale Heat Sources Hossein Honarvar1, 2, Joshua Knobloch1, Travis D. Frazer1, Jorge Nicolas Hernandez Charpak1, Begona Abad Mayor1, Mahmoud I. Hussein2, Henry Kapteyn1 and Margaret Murnane1; JILA/Physics, University of Colorado Boulder, Boulder, Colorado, United States; 1Aerospace, University of Colorado Boulder, Boulder, Colorado, United States.

Nanostructured and quantum materials are enabling revolutionary advances in nanoscience and nanotechnology. These engineered materials promise to go beyond what is offered by natural materials. Advances in materials growth now make it possible to synthesize 3D nanostructured materials with nanometer resolution creating nanosystems with tunable electronic, electronic, photonic, magnetic, and thermal properties for a variety of applications including nanoelectronics, thermoelectrics, photovoltaics, and sensors. However, understanding of the fundamental mechanism behind many of these applications is still incomplete, making the development of powerful theoretical and experimental tools a priority for many material research communities.

Understanding thermal transport in nanostructured systems has long been a challenge. In the last few years, experimental techniques have pushed the measurement limits on systems with characteristic dimensions and geometries down to tens of nanometers, often times finding new surprising physical behaviors [1]. However, it is still challenging to apply appropriate models that connect novel data to meaningful thermal properties and fundamental mechanisms. Most researchers rely on using effective or phenomenological diffusive models or the linearized Boltzmann transport equation that are not able to capture all of the observed nanoscale effects and nonlinear interactions [1-3]. This is because it is very difficult to perform atomistic simulations over experimentally-relevant length scales, due to prohibitive computational requirements. As a result, there is a large gap in understanding of how the nanoscale phonon physics unfold for different size and geometries to modify the transport properties. Moreover, possible coherent effects are often not adequately included in current models.

The focus of this work is understanding thermal transport in nanostructured materials by bridging the gap between theory and experiment. In particular, previous work done in our research group uncovered a new thermal transport regime named “collectively-diffusive” by tracking the heating and cooling of periodic arrays of nanoscale heat sources on bulk crystalline silicon and sulphide substrates [1]. This regime emerges from the interaction between the nanoscale geometries and energy carriers in materials. In particular, when nanoscale heat sources are placed closer, they cool down faster than when farther apart—the opposite of heat dissipation dynamics of the macroscale. The observed increase in heat dissipation efficiency has large consequences in thermal management in microelectronic devices, and is currently not captured by models available to both researchers in academia and industry. In this work, we present the results of steady-state molecular dynamics (MD) simulations that can model the experimentally-explored geometries, and how these results provide a global understanding of non-diffusive phonon dynamics that appear to dominate energy transport in the deep nanoscale regime. Our MD results of nanoscale heat sources indicate that we are able to successfully capture the novel collectively-diffusive thermal dynamics observed recently.

QN04.04.15
Thermal Conductivity of Perovskite-Structured Superlattices from First-Principles Calculations Qi Zhang1, Xue Xiong2, Eugene Rasaga2, Simon Phillip2 and Aleksandr V. Chernyatsky1; 1Physics, Missouri University of Science and Technology, Rolla, Missouri, United States; 2Material Science and Engineering, University of Florida, Gainesville, Florida, United States.

Low thermal conductivity materials are important for a variety of applications, including thermal barrier coatings and thermoelectric devices. Superlattices are particularly interesting due to the possibility of lowering thermal conductivity. Numbers of explanations have been proffered for the low thermal conductivity of superlattice structures. A full explanation, however, has yet to be developed. Here, we are presenting the thermal transport properties of natural perovskite-structured superlattices, the Ruddlesden-Popper (RP) series of phases of the Sr-Ti-O system, formed by the interleaving of SrTiO3 perovskite layers with SrO rocksalt layers. We have computed their thermal conductivity from first principles via the Boltzmann-transport equations (BTE) approach encoded in the PhonTS software package. In short, the thermal conductivity is determined by computing the heat current using the nonequilibrium phonon density distribution function, which in turn is found as a solution of the linearized BTE for phonons. The required input for the BTE are the second and third spatial derivatives of the total energy with respect to atomic positions which we have obtained from the DFT calculations performed using the Vienna Ab initio Simulation Package (VASP) computational package. A clear minimum in the thermal conductivity as a function of a number of STO layers is observed. Results are compared with the recent experimental data.

QN04.04.16
Controlling Thermal and Electrical Properties of Composites Using Percolating Network of Nanowires with Fusible Tips Konrad Rykaczewski and Robert Wang; Arizona State University, Tempe, Arizona, United States.

Development of polymer composites with high thermal conductivity is necessary for thermal management of microelectronics. Percolation of metallic filler particles and reduction of the thermal contact resistance between individual particles (e.g. via thermal or electromagnetic fusing) can significantly improve thermal conductivity of composites. However, composite materials with connected metallic particles can also conduct electricity, creating a risk of short-circuiting in chip-board and the inter-chip gaps. In this presentation we theoretically show that this can be resolved with the application of fusible metallic coatings to the tips of nanowires with thermally conductive, but electrically insulating cores [1]. Specifically, we use Monte Carlo simulation-validated analytical models that relate the ratio of the coated and total nanowire lengths to the fraction of fused, and thus conductive, bonds within percolating networks of these structures to show that thermally conductive, but electrically insulating composites can be achieved using these novel nanowire structures. We discuss silver-like coatings, which only form conductive bonds when contacting the silver-like coating of another nanowire as well as liquid metal-like coatings, which form conductive bonds regardless of whether they contact a coated or uncoated segment of another nanowire. We show that use of the liquid metal-like coatings will yield twice as many thermally conductive bonds as silver-like coatings while maintaining a negligible risk of electrical short-circuiting.

Magnon and Phonon Dispersion, Lifetime and Thermal Conductivity of Iron from Spin-Lattice Dynamics Simulations Zeyu Liu1, Xufei Wu1, 2; 1Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, Indiana, United States; 2Center for Sustainable Energy (ND Energy), University of Notre Dame, Notre Dame, Indiana, United States.

In recent years, the fundamental physics of spin-lattice (e.g., magnon-phonon) interaction has attracted significant experimental and theoretical interests given its potential paradigm-shifting impacts in areas like spin-thermoelectrics, spin-caloritronics, and spintronics. Modelling studies of the transport of magnons and phonons in magnetic crystals are very rare. In this paper, we use spin-lattice dynamics (SLD) simulations to model ferromagnetic crystalline iron, where the spin and lattice systems are coupled through the atomic position-dependent exchange function, and thus the interaction between magnons and phonons is naturally considered. We then present a method combining SLD simulations with spectral energy analysis to calculate the magnon and phonon harmonic (e.g., dispersion, specific heat, and group velocity) and anharmonic (e.g., scattering rate) properties, based on which their thermal conductivity values are calculated. This work represents an example of using SLD simulations to understand the transport properties involving both magnon and phonon dynamics.

QN04.04.18
Normal Modes for Thermal Transport Anup Rai and Jacob Eappen; North Carolina State University, Raleigh, North Carolina, United States.

Normal modes of vibrations can be extracted from atomistic simulations by projecting the real space trajectories onto the reciprocal space. Normal modes coordinates are not
unique and their primary function is to transform the coupled Hamiltonian to a set of independent harmonic oscillators. Several descriptors of normal modes exist but not all of them are appropriate for analyzing thermal transport. In most normal mode analyses (NMA), complex normal mode coordinates are employed, which combine the modal contributions of waves moving in opposite directions. The wave-vector \( q \) that is represented in the complex normal modes does not uniquely represent a wave traveling in the \( +q \) or \( -q \) direction, instead it denotes an average of both directions. Thus the popular complex normal modes have a theoretical inability to resolve a real heat current along a specific direction-dependent wave-vector \( q \).

In this work, we employ a set of real asymmetric normal mode coordinates, which can distinguish lattice waves moving in opposite directions – a virtue that immediately endows the ability to discriminate a heat current in a certain direction. These normal mode coordinates have a real amplitude \( A(q_p) \) that is not equal to \( A(-q_p) \). We then derive an expression for heat current that is real, and which can be expressed as a difference between the squares of the amplitudes in \( +q \) and \( -q \) directions. Finally, we drive a correction term for phonon lifetime that arises from the correlation between modes moving along opposite directions.

QN04.04.19

Recent experiments have evidenced that effective Fourier models are unable to predict heat transfer at the nanoscale [1,2]. This has a big impact on electronic engineering that relies on this law to study the thermal behavior of their devices.

One of the last proposals to better describe thermal transport at the nanoscale has been phonon hydrodynamics. In this line, the Guyer-Krumhansl equation has been proposed as the required generalization of the Fourier law to describe heat transport at this scale [3]. This equation is combined with the Kinetic Collective Model (KCM) to obtain the included parameters from ab initio calculations [4,5]. One of the main advantages of this approach is that its simplicity allows to obtain solutions for arbitrary geometries using Finite Element Methods. Therefore, this combination offers a full predictive framework to describe thermal conductivity in semiconductors in general geometries with characteristic sizes up to the order of the hybrid thermal characteristic length.

Validation of the model has been done with experimental data for different systems such as semiconductor porous membranes with different periodic alignments, thin membranes with different constrictions or 2D materials. In parallel, the tool offers also the interpretation of the results in terms of new phenomena like vorticity and viscosity, giving an insight on the reason for the reduction of the effective thermal conductivity at reduced scales.

Effect of Intrinsic and Extrinsic Defects on Phonon Heat Transfer in Nanostructured Metals Peter V. Sushko, Richard Williams, Christopher Barrett and Marvin Warner; Pacific Northwest National Laboratory, Richland, Washington, United States.

Ongoing efforts in low temperature experimental research, including the work on quantum materials and high energy physics experiments, underscores the need to achieve and maintain ultra-low temperatures. Of particular interest are metal-non-metal systems, in which the dominant mechanism of heat transfer switches at the interface, and nanomaterials, in which structural and chemical deviations from idealities may lead to significant deviations from the Fourier law.

We investigate how phonon component of the heat flux across nanoscale metals is affected by point defects, dislocations and model two-dimensional defects. Gaseous models for the heat source and heat sink are adopted and the computations are conducted using classical molecular dynamics approach. Analysis of the heat transfer coefficients, as derived via Green-Kubo relation, suggests that surface nanopatterning and chemical defects have larger an effect on the heat propagation than intrinsic defects.

Thermal Transport Across Rough Interfaces — A Finite-Difference Time-Domain Study Laleh Avazpour, Sina Soleimankahnoj, Suraj Suri and Irena Knezic; University of Wisconsin-Madison, Madison, Wisconsin, United States.

Heat transport across interfaces in nanostructures is an important open problem that arises into play in the design and operation of electronic and thermoelectric devices. In particular, lattice mismatch across the interface and the interface profile strongly influence thermal transport. In this work, we study elastic-wave scattering at the junction between two different materials. We solve the elastic-wave equations with the finite-difference time domain (FDTD) technique. We investigate the effects of mode conversion and energy trapping at the interface and how they are affected by interface roughness and lattice mismatch. The results provide a unique outlook on the interfacial heat transport and its effect on the operation of nanodevices.

QN04.04.22
Thermal Conductivity of Small-Angle Misoriented Bilayer Graphene Chenvang Li, Bishwajit Debnath and Roger Lake; Electrical and Computer Engineering, University of California, Riverside, Riverside, California, United States.

The properties of misoriented bilayer graphene have recently received renewed interest after the discovery of superconductivity at very small rotation angles. Compared to the electronic properties, the effect of misorientation on the phonon and thermal properties has received less attention. For the larger misorientation angles, the in-plane thermal conductivity depends not on the angle, but on the commensurate lattice constant, and the thermal conductivity decreases approximately linearly as the commensurate lattice constant increases [1]. This trend is qualitatively consistent with the hypothesis that the zone folding gives rise to an increase in Umklapp scattering that reduces the low-energy phonon lifetimes and thus the thermal conductivity. However, our recent calculations show that as the misorientation angle falls below 13.2°, this trend reverses itself, and the thermal conductivity starts increasing back towards the value of the unrotated structure. For angles below 13.2°, the thermal conductivity initially increases rapidly as the angle decreases from 13.2° to 7.3°, even though the commensurate lattice constant is monotonically increasing. As the angle continues to decrease down to 1.9°, which is the smallest angle simulated, the thermal conductivity gradually returns to its unrotated value.

For small angles with minimal commensurate unit cells, the commensurate lattice constants monotonically increase as the angles decrease, so that it is not clear what determines the functional dependence of the thermal conductivity in the small angle regime. Is it the misorientation angle or the commensurate lattice constant? To answer this question, we investigated two very different angles, 3.9° and 20.3°. Both of these angles which have exactly the same commensurate lattice constant of 3.6 nm. The thermal conductivities of the two structures are identical indicating that the functional dependence of the thermal conductivity in the low angle regime continues to be on the lattice constant rather than on the misorientation angle.

As the lattice constant increases, the reciprocal lattice constant decreases, so that Umklapp scattering should become more accessible to the low-energy, small-wavevector phonons that determine the thermal conductivity. All else being equal, the increased scattering should decrease the thermal conductivity. While this picture is consistent with the trends in the large angle regime, in the small angle regime (<13°), this is the opposite of the trend that we observe. However, as the misorientation angle returns to zero degrees, the thermal conductivity must return to that of the AB aligned structure, and this is what we observe. In this talk, we will describe the thermal transport in the low angle regime, and we will present our analysis of the thermal transport that includes the average phonon velocities and density of modes, and we will also present a spectral decomposition of the lattice thermal conductivity determined from the force-velocity cross correlation function.

The investigation uses both nonequilibrium molecular dynamics (NEMD) and ab-initio density functional theory (DFT) combined with the phonon Boltzmann transport equation. For the NEMD direct calculations of the thermal conductivity, the width of the simulated bilayer graphene structures is approximately 10 nm. To ensure that the results do not

Spatial Mapping of Thermal Boundary Conductance at Interfaces of Metal and 2D Materials David B. Brown1, Wenqing Shen2, Diego Vaca3, Xufan Li4, Kai Xiao4, David B. Geohegan5 and Satish Kumar4, Georgia Institute of Technology, Atlanta, Georgia, United States; 6Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Improving the thermal transport across interfaces is a necessary consideration for micro- and nano-electronic devices and necessitates accurate measurement of the thermal boundary conductance (TBC) and understanding of transport mechanisms. Two-dimensional transition metal dichalcogenides (TMDs) have been studied extensively for their electrical properties, including the metal-TMD electrical contact resistance, but the thermal properties of these interfaces are significantly less explored irrespective of their high importance in their electronic devices. We isolate individual islands of MoSe2 grown by chemical vapor deposition using photolithography and correlate the 2D variation of TBC with optical micrograph images of the MoSe2 islands. We measure the 2D spatial variation of the TBC at metal-MoSe2-SiO2 interfaces using a modified time-domain thermoreflectance (TDTR) technique which requires much less time than full TDTR scans. The thermoreflectance signal at a single probe delay time is compared with a correlation curve which enables us to change the signal in real-time with respect to the TBC at metal-MoSe2-SiO2 interface as opposed to recording the decay of the thermoreflectance signal over delay times of several nanoseconds. The results show higher TBC across Ti-MoSe2-SiO2 interface compared to Al-MoSe2-SiO2. An image analysis method is developed to differentiate the TBC for different MoSe2 layers, which reveals the TBC in single-layer regions is higher than bilayer. We perform traditional TDTR measurements over a range of delay times and verify TBC is higher at Ti-MoSe2-SiO2 interface compared to Al-MoSe2-SiO2 highlighting the importance of the choice of material to heat dissipation at electrical contacts in TMD devices.

QN04.04.24
The Influence of Interfacial Structure and Strain Energy on Phonon Transport Riley C. Hans and G. J. Snyder; Northwestern University, Chicago, Illinois, United States.

Phonon transport across interfaces is an inherently complex topic of great scientific and technological importance to fields ranging from microelectronics to energy materials. Here, I will present several experimental and theoretical results which aim to establish a fundamental understanding of heat transfer across interfaces, specifically grain boundaries (GBs). First, I will demonstrate how phonon diffraction and dimensionality crossover effects arise when the nanoscale structure of interfaces and GBs is considered. An expression for the relaxation time of phonon interacting with GB strain fields (τ(GB)) is presented and is shown to effectively describe the temperature dependence of the lattice thermal conductivity (κL) of polycrystals at low temperatures (<100 K). At these temperatures the total phonon relaxation time is dominated by interactions with GBs, and the temperature dependence of κL reveals important information about the nature of the phonon-GB interaction. Next, an experimental study is presented where the thermal boundary resistance is measured on individual Si-Si twist GBs at different twist angle. The thermal boundary resistance at GBs again seems to be dominated by the interfacial strain field. Finally, it is shown how the thermal boundary resistance can be controlled by modifying the GB complexion with 2D materials. Specifically, several layers of graphene can be introduced into the GBs of skutterudite materials which dramatically increases the materials thermal boundary, while negligibly effecting electronic transport. This results in a significant improvement in zT and a 24% improvement in device efficiency which was measured experimentally.

QN04.04.25
Study of Phonon Transport in GaN Thin Films Using Boltzmann Transport Equations Nitish Kumar, Ajit K. Vallabhaneni and Satish Kumar, Georgia Tech, Atlanta, Georgia, United States; 2Qualcomm, San Diego, California, United States.

GaN is a promising wide bandgap material for radio frequency and power electronics applications due to higher breakdown voltage and efficiency. However, the high-power dissipation could result in the formation of hot-spots and high temperature in localized regions which could significantly affect the performance and reliability of these high-power devices. Therefore, it’s necessary to understand the thermal transport mechanism in GaN based electronics to develop efficient thermal solutions. In this study, we develop a phonon transport model based on the first-principles Density Functional Theory (DFT) along with the non-gray Boltzmann Transport Equations (BTE) to predict the steady-state and transient spatial temperature distribution in a GaN thin film with localized power dissipation. First-principles DFT calculations are conducted to calculate the phonon properties of the GaN, such as phonon life time, mean free path and group velocity. The full non-gray BTE is solved across the entire domain to calculate the temperature distribution near the hot spot in the thin film where ballistic effects dominate and the results are compared with the Fourier model. We observed that the BTE model is needed to obtain accurate temperature distribution as the Fourier model would significantly under predict the hot spot temperature. However, solving BTE in the entire domain might be time-consuming and expensive. Therefore, we developed acceleration techniques to reduce computation time of solving the BTEs without significant loss of accuracy in temperature estimation. BTEs for phonon modes with Knudsen number less than the cut-off are simplified into Fourier like equations to improve computation time. These equations are selected based on a cut-off Knudsen number, which can be adjusted to get desired accuracy. The effect of diffusive-ballistic effects on hot spot temperature rise in time has been investigated. The results from this work will help us understand the mechanism of phonon transport in the GaN thin film and provide insights for the future design of GaN based electronic devices.

QN04.04.26

Nanoscale phonon properties have recently received attention because new material properties can be designed by tailoring vibrational behaviour. This has triggered significant efforts towards a better nanoscale control and manipulation of thermal processes in materials. In this context, the reduction of the physical size of materials also resulted in the need of improved spectroscopic techniques and methods to characterize phonon and thermal properties of materials with higher spatial resolution. Recently, aberration-corrected electron microscopes were equipped with monochromators, thus opening the doors for phonon spectroscopy studies in nanomaterials using an electron probe of the size of a hydrogen atom. For instance, this advancement allowed us to obtain spatially-resolved maps of phonon scattering in a single nanoparticle (≤100 nm) with nanometer resolution [1]. Also, due the nature of the inelastically scattered phonons by phonons, the scattering amplitude exhibit a dependence on temperature and the spatial distribution of the scattering has several types of localization. In this work, exploiting the characteristic of the phonon scattering, we present a non-invasive method to measure the local temperature of a single nanostructure using an electron probe. We determined the local temperature of nanostructures with high precision (down to 1K) and sub-nanometer spatial resolution (down to 2Å) [2].

We obtained energy-loss/energy gain spectra from nanostructures (nanostructures and nanoparticles) and using a Nion STEM microscope equipped with a monochromator to study the phonon response in the infrared range using a 1.5 Å probe with an energy spread of 9 meV. Our instrument allows the detection of acoustic bulk phonon excitations down to 20 meV [1]. The amplitudes of the energy-loss and energy-gain probabilities are linked by the Boltzmann factor, as established by the Principle of Detailed Balancing (PDB). We measured the nanostructure temperature by plotting the logarithm of the ratio of the scattering amplitude on the gain and loss sides of zero energy. The obtained curves are linear with a 2 standard deviations and agreed very well with the accepted values for room temperature conditions. Similar results were obtained for measurements at high temperatures (up to 1000 K). We found also that the temperature of the phonon scattering is highly correlated with the temperature of the nanostructure. This result is also consistent with the previously measured temperature gradient in nanostructures with isolated particles [1], suggesting that temperature gradients from the inside towards the surface should be detectable. We also investigated the localization degree of our measurements and we found that highly-localized scattering, associated with the excitation of short-wavelength acoustic phonons, can be used to perform measurements with atomic resolution, because bulk scattering can vary drastically within neighboring atom columns [3]. Meanwhile, surface phonon polaritons can yield accurate averages over a region of interest (several nanometers).
We show that the temperature of a nanofluid can be measured experimentally using phonon scattering, and we verify that PDB holds for nanomaterials at thermal equilibrium. We also think this method holds much promise for studies aimed at understanding nanoscale thermal response (heat transfer, nanoscale energy transport) in nanostructures. We acknowledge support of U.S. Department of Energy, Office of Science, Basic Energy Sciences under Award #DE-SC0005132.

QN04.04.27 Prediction of Thermal Conductance at Liquid-Gas Interfaces Using Molecular Dynamics Simulations James Gonzalez, Josue Ortega and Zhi Liang; Mechanical Engineering, California State University, Fresno, Fresno, California, United States.

Using molecular dynamics (MD) simulations and theoretical calculations, we study heat transfer across liquid-gas interfaces within a planar heat pipe. To determine the thermal conductance (Kapitza conductance), G<sub>K</sub>, at the interface, two heat transfer mechanisms, namely, conduction and evaporation/condensation are considered. In the case of interfacial heat conduction, gas molecules, particularly non-condensable gas molecules, exchange heat with liquid surfaces through gas-liquid collisions, and the theoretical expression for G<sub>K</sub> is derived from the kinetic theory of gases. For interfacial heat transfer by evaporation or condensation, the theoretical expression for G<sub>K</sub> is derived from the Schrage relationships. To assess the accuracies of the theoretical expressions for G<sub>K</sub>, we compare these theoretical predictions to the G<sub>K</sub> obtained directly from MD simulations. For all cases studied, the theoretical predictions agree with the MD simulation results very well. If the density of non-condensable gas in the heat pipe is much higher than that of the working fluid in the gas phase, we find that the interfacial heat conduction could contribute significantly to the total heat flux across the liquid-gas interfaces. The effect of G<sub>K</sub> at liquid-gas interfaces on the overall heat transfer efficiency in a planar heat pipe is discussed.

QN04.04.28 Lone-Pair Electrons Do Not Necessarily Lead to Low Lattice Thermal Conductivity—An Exception of Two-Dimensional Penta-CN<sub>2</sub> Huimin Wang¹,², Nanjing University, Nanjing City, China; ¹University of South Carolina, Columbia City, North Carolina, United States.

It has long been documented in literature that, the lone-pair electrons are generally thought to lead to low lattice thermal conductivity (κ<sub>L</sub>) of bulk materials by inducing strong phonon anharmonicity. In this paper, we show an exceptional case of two-dimensional (2D) penta-CN<sub>2</sub>. Based on the comparative study of four 2D systems, namely planar C<sub>2</sub>N and penta-CN<sub>2</sub> possessing lone-pair electrons and their respective lone-pair electrons free counterpart graphene and penta-graphene, we find that the lone-pair electrons do not necessarily lead to low κ<sub>L</sub> of low-dimensional materials. Opposite tendency of lone-pair electrons affected κ<sub>L</sub> are observed. The κ<sub>L</sub> of planar C<sub>2</sub>N (103.02 Wm<sup>-1</sup>K<sup>-1</sup>) is substantially lower than graphene (3094 Wm<sup>-1</sup>K<sup>-1</sup>) due to the well understood strong anharmonicity induced by the lone-pair electrons. However, penta-CN<sub>2</sub> with lone-pair electrons exhibits more than doubled κ<sub>L</sub> (660.71 Wm<sup>-1</sup>K<sup>-1</sup>) than penta-graphene (252.95 Wm<sup>-1</sup>K<sup>-1</sup>), which is unexpected and contradictory to the traditional theory of lone-pair electrons leading to low κ<sub>L</sub>. By analyzing the bond characteristics, electronic structure and the spatial distribution of lone-pair electrons, the underlying mechanism is attributed to the two competing effects of lone-pair electrons on the phonon anharmonicity. The wide spatial extension of the non-symmetrically distributed lone-pair electrons significantly decreases the bond angle by introducing strong repulsion to the bonding electrons. This leads to the homogenization of bond lengths in penta-CN<sub>2</sub> and compensates the strong lattice anharmonicity due to the far retraction of lone-pair electrons from the N nucleus towards the missing link of the tetrahedron composed of C, N atoms and the collective lone-pair electrons. Consequently, the atomic vibration around the equilibrium position tends to be more harmonious and thus the phonon anharmonicity is weakened, leading to much higher κ<sub>L</sub> of penta-CN<sub>2</sub> than that of penta-graphene. This study offers insight into the unprecedented positive effect of lone-pair electrons on κ<sub>L</sub> from the microscopic picture of electronic structure, which deepens our understanding on phonon anharmonicity and could also facilitate material design with targeted thermal conductivity.

QN04.04.29 Thermal Properties of Phase Change Memories at Device Length Scale Kiumars Aryang¹,², John Gaskins¹, David Olson¹ and Patrick Hopkins¹,²; ¹Mechanical and Aerospace Engineering, University of Virginia, Charlottesville, Virginia, United States; ²Department of Materials Science and Engineering (courtesy), University of Virginia, Charlottesville, Virginia, United States.

Chalcogenide materials such as Ge<sub>2</sub>Se<sub>3</sub>Te<sub>2</sub> (GST), which upon thermal excitation undergo structural transition between amorphous and crystalline phases with applied thermal load, have emerged as a potential material candidate for new memory technologies due to prospective gains in speed, device lifetime, and capacity. In these devices, thermal transport plays a pivotal role as it dictates the efficiency of the read/write process as well as overall power consumption. Here, we measure thermal properties relevant to device operation at material length scale similar to those used in actual devices, such as thermal conductivity, thermal boundary resistance (TBR), and sound speed of both amorphous and crystalline GST using time-domain thermoreflectance. Based on the acoustic echoes obtained from picosecond acoustic results we measure the sound speed of amorphous and crystalline GST to be approximately 2900 m/s. Moreover, we report the TBR with different spacer compositions (W, SiO<sub>2</sub>, and SiN) in contact with GST. The SiN/GST interface shows the highest TBR compared to both W and SiO<sub>2</sub> interlayers. In the case of all spacer compositions, the crystalline GST interface shows a higher interface resistance compared to its amorphous counterpart. Additionally, very thin layers of tungsten (≤ 4 nm) possess a higher TBR when compared to layers thicker than four nanometers, which we attribute to ballistic transport of phonons.

QN04.04.30 Phonon Coupling in Layered Nanomaterials—A Novel Mechanism to Modulate Thermal Conductivity Abhinav Malhotra, Kartik S. Kothari and Martin Maldovan; Georgia Institute of Technology, Atlanta, Georgia, United States.

Thermal conductivity engineering in semiconductors has been primarily focused on using diffusive scattering of phonons at interfaces to reduce thermal transport. In this talk, we show that a novel mechanism - phonon coupling in layered nanomaterials - can be used to both enhance and reduce thermal transport. By considering Silicon and Germanium based structures (bi-layers and tri-layers), we show that the thermal conductivity of the Silicon layer can be reduced below its free-standing value, without directly manipulating its surface properties. We present a methodology to impact the phonon coupling and quantify the role of structural parameters including layer dimensions and interfacial properties. We also show that the same underlying mechanism of phonon coupling leads to thermal conductivity enhancement of the Germanium layer above its free-standing value. The results of this work expand the rational material design paradigm by creating capabilities beyond the diffusive scattering mechanism and adds to the fundamental understanding of phonon transport at nanoscale.

QN04.04.31 Control of Thermal Conductance Through Overlapping Graphene Sheet Junction Phononics Charles A. Sievers¹, Miguel Munoz Rojo², Eric Pop³ and Davide Donadio¹; ¹University of California Davis, Davis, California, United States; ²Stanford University, Stanford, California, United States.

Low dimensional materials, such as graphene and carbon nanotubes, have the highest thermal conductivity, which makes them a promising substrate for heat dissipation in nanoscale electronics. Interfaces play a crucial role in determining the thermal dissipation performances in microelectronic systems and thermal resistance. While it is now well established that graphene has an extremely high in-plane thermal conductivity, the thermal energy flow at multi-layer graphene junctions, and at the interfaces between graphene layers and bulk substrates remains mostly unresolved. Here we consider a two-to-one layer graphene junction, either suspended or supported on silica, for which experimental measurements reported very low thermal conductance. In quantitative agreement with experiments, molecular dynamics and lattice dynamics calculations show that the thermal conductance is one order of magnitude smaller than that of a suspended single graphene sheet, and it stems from the weak interaction between the layers in the bilayer part of the junction. Thermal conductance is further reduced by 30% upon addition of silica substrate due to interference of graphene flexural modes with the substrate. These modes are the major heat transport mechanism that are unaltered by changes in junction surface area. These results show promising ways in which we can modulate thermal dissipation through layered 2D material junctions.

QN04.04.32 Mass Accommodation at a High-Velocity Water Liquid-Vapor Interface Jihui Nie¹, Anirban Chandra¹, Zhi Liang² and Pawel Keblinski³; ¹Rensselaer Polytechnic Institute, Troy, New York, United States; ²California State University, Fresno, California, United States.
We use molecular dynamics to determine the mass accommodation coefficient (MAC) of water vapor molecules colliding with a rapidly moving liquid-vapor interface. This interface mimics those present in collapsing vapor bubbles and characterized by large interfacial velocities. We find that at room temperature, the MAC is generally close to unity, and even with interfaces moving at 10 km/s, it has a large value of 0.8. Using a simplified atomistic fluid model, we explore the consequences of vapor molecule interfacial collision rules on pressure, temperature, and density of a vapor subjected to an incoming high-velocity liquid-vapor interface.

Thermal Transport in Semicrystalline Polyethylene by Molecular Dynamics Simulation Jixiong He, Tingyu Lu and Jun Liu; North Carolina State University, Raleigh, North Carolina, United States.

Recent research has highlighted the potential to achieve high-thermal-conductivity polymers by aligning their molecular chains. Combining with other merits, such as low-cost, corrosion resistant, and lightweight, such polymers are attractive for heat transfer applications. Due to their quasi-one-dimensional structural nature, the understanding on the thermal transport in those ultra-drawn semicrystalline polymer fibers or films is still lacking. We build the ideal repeating units of semicrystalline polyethylene and studied their dependence of thermal conductivity on different crystallinity and interlamellar topology using the molecular dynamics simulations. We found that the conventional models, such as the Choy-Young’s model, the series model, and Takayanagi’s model, cannot accurately predict the thermal conductivity of the quasi-one-dimensional semicrystalline polyethylene. A modified Takayanagi’s model was proposed to explain the dependence of thermal conductivity on the bridge number at intermediate and high crystallinity. We also analyzed the heat transfer pathways and demonstrated the substantial role of interlamellar bridges in the thermal transport in the semicrystalline polyethylene. Our work could contribute to the understanding of structure-property relationship in semicrystalline polymers and shed some light to the development of plastic heat sinks and the thermal management in flexible electronics.

**QN04.04.34**
Thermal Conductivity of ALD Grown PbTe/PbSe Superlattice Thin Films Mallory E. DeCoste1,2, Xin Chen1, Kai Zhang3, Helmut Baumgart4 and Patrick Hopkins1; 1University of Virginia, Charlottesville, Virginia, United States; 2Johns Hopkins University Applied Physics Lab, Laurel, Maryland, United States; 3Old Dominion University, Newport News, Virginia, United States.

We report on the thermal properties of lead chalcogenide-based superlattice thin films grown on planar silicon wafers by atomic layer deposition (ALD). The concept of controlling thermal energy carriers in thin film superlattices of PbTe/PbSe by varying the total thickness and period thickness is experimentally investigated in this work. We demonstrate the use of time domain thermoreflectance (TDTR) to measure the cross-plane thermal conductivity of these systems in order to understand the role of size effects and boundary scattering on the thermal conductivity of the PbTe/PbSe superlattices. The thin films of varying compositions resulted in thermal conductivities that are not strongly dependent on the period thickness, and are weakly dependent on the samples total thickness. This suggests that incoherent transport dominates in the thickness regime studied. Additionally, our results show that increased phonon boundary scattering introduced by the periodicity of the superlattice structure is effective for reducing the thermal conductivity.

**QN04.04.35**
Diffusive to Ballistic Heat Flow Transition in GaP Nanowires Daniel Vakulov1, Subash Gireesan1-3, Ruben Chavez2, Milano Y. Swinkels2, Tom Vogelars3, Pol Torres2, Ilaria Zardo2, Marcel van de Ven1; 1Universitat Politècnica de Catalunya, Barcelona, Spain; 2Department of Applied Physics, TU Eindhoven, Eindhoven, Netherlands; 3Department of Physics, Universitat Basel, Basel, Switzerland; 4Department de Fisica, Universitat Autònoma de Barcelona, Barcelona, Spain; 5Center for Computational Energy Research, Eindhoven, Netherlands; 6Kavli Institute of Nanoscience, Delft, Netherlands.

Realizing ballistic transport at room temperature is challenging due to the decrease of phonon mean free paths with increasing temperature. Only a few studies have reported this non-diffusive behavior1.2. Ballistic transport was observed in SiGe nanowires up to lengths of 8.3 μm at room temperature1. This behavior was attributed to the localization of short-wavelength phonons due to alloy scattering, and long-wavelength phonons with a long mean free path dominating the transport. Longer wires showed diffusive transport1. Here, we report room-temperature ballistic transport in thin ultrapure GaP nanowires and an abrupt, temperature-insensitive transition to diffusive behavior on increasing the diameter. Nanowires with diameter ranging from 25-140 nm were grown using the vapor-liquid-solid technique with gold droplets as a catalyst. TEM images revealed that these wire have an atomically flat side facets, with a thin (2 nm) amorphous gallium oxide layer on top. Thermal conductivities of the individual wires were measured using a suspended device membrane1 with Pt meanders on top, which can be used as a heater and a thermometer. For thick wires (diameter ≥ 50nm), the thermal conductance increases linearly with length, indicating diffusive behavior. For thin wires (diameter ≤ 25 nm), the thermal conductance is independent of length, indicating a transition to ballistic phonon transport. The ballistic transport at room temperature continues to the longest nanowires of 14 μm that we could study. The thermal conductance is surprisingly insensitive to a temperature above 50 K. This shows that boundary scattering dominates other scattering mechanisms. The experimental results are interpreted using a model based on Landauer’s formalism for phonon transport3. This model was used to describe heat flow in thin silicon nanowires4 and in holey silicon5. It takes into account boundary scattering and neglects all other scattering mechanisms. Due to the presence of the thin amorphous oxide layer on the surface, the strength of the boundary scattering is determined by the k-vector perpendicular to the axis of the nanowire. The modes with a small perpendicular k-vector scatter weakly and have a high dependence mean free path l(o), while the other modes scatter strongly, having a mean free path of the order of the diameter of the wire d. The model results agree well with heat transport measurements on 25 and 50 nm diameter wires, correctly predicting the magnitude of the thermal conductance and its length dependence. We explain the diffusive to ballistic transition by the localization of phonons in the 25 nm wire that reflects diffusively from the amorphous oxide layer, accompanied by a strong increase in the mean free path of phonons that reflect mostly specularly. Our work demonstrates the possibility of increased heat extraction in nanostructures and opens new avenues for phonon-based devices.

Surface Plasmon Effects on Interfacial Heat Transport Processes in Gold Nanorods Andrew P. Kelliher1, John A. Tomko2, Brian B. Lynch2, Joseph Tracy3 and Patrick Hopkins1; 1University of Virginia, Charlottesville, Virginia, United States; 2North Carolina State University, Raleigh, North Carolina, United States.

Metal nanoparticles are efficient generators of heat via the photothermal effect, in which the surface plasmon resonance is excited by incident light. Surface scattering of excited electrons contributes to the generation of hot electron-hole pairs, which then thermalize and couple with the lattice to generate phonons. Anisotropic nanostructures often exhibit additional surface plasmon modes which can be tuned by altering their geometries. Gold nanorods, studied here, exhibit plasmon resonance in the near-infrared, making them suitable for applications in medical technologies, such as drug delivery or photothermal cancer therapy. This additional plasmon resonance can be tuned further during the synthesis process to allow of soft robotics components using shape memory polymers. Furthermore, silica overcoatings having various morphologies have been developed to improve thermal stability of these nanorods up to 873 K while reducing toxicity. When using gold nanorods for photothermal applications, the primary descriptors of thermal transport are electron-phonon coupling in the gold nanorods and at their interfaces, and the phonon-phonon thermal boundary conductance across the nanorod/matrix interface. Using complementary ultrafast pump-probe laser techniques, we explore the effect of the surface plasmon on these two thermal descriptors of gold nanorods in a polymer matrix. By using variable pump wavelengths, we are able to selectively excite the surface plasmon modes. We elucidate the effect of the plasmon excitation on electron-electron coupling and electron-phonon coupling, while showing that it has little effect on phonon-phonon thermal boundary conductance at times after the electrons have equilibrated with the phonons. Additionally, in order to assess the effects of overcoatings on thermal boundary conductance, we compare results for three types of overcoated nanorods: those with full silica shells, those with silica/iron oxide composite shells, and those with silica/iron oxide composite shells.
Comprehensive Modeling of Electron and Thermal Transport in Thermionic Energy Conversion Systems
Devon Jensen, Mohammad Ghahami and Keunhan Park;
University of Utah, Salt Lake City, Utah, United States.

Over recent years, thermionic energy conversion (TEC) has received keen revived attention for direct heat-to-electric power generation [1–3]. However, large electrode work functions and the accumulation of negative space charge between electrodes are major issues that have restricted the use of TEC to high-temperature heat sources exceeding 1500K. As one of the potential approaches to mitigate these issues, previous works have proposed to have a sub-micron vacuum gap between the electrodes [4-6]. However, their theoretical models are not comprehensive in accurately modeling the size effect on the electron and thermal transport processes across sub-micron gap distances.

The present work provides a comprehensive look at electron and thermal transport in a TEC system as the gap separation is scaled from tenths of a millimeter down to tens of nanometers. To this end, the energy barrier profile between the electrodes, \(W(x)\), is calculated within the electrostatic framework by considering space and image charge effects. The thermionic current density and heat transfer rate are then calculated by applying the determined maximum value of the energy barrier, \(W_0\), to the rigorous charge transport model. In addition, quantum tunneling of electrons is also considered for nanoscale gap distances. Near-field radiative heat transfer is an important thermal transport mechanism to be considered when the inter-electrode gap distance becomes comparable to or smaller than the thermal wavelength [7]. The summation of the electron (thermionic and electron tunneling) and radiative heat fluxes between the electrodes allows for an energy balance calculation to provide a more realistic anode temperature for device operation and thermionic energy conversion efficiency.

Moreover, we theoretically demonstrate that the nanoscale gap distance shifts a portion of the field-induced charge acceleration regime from a negative to positive operational voltage range, resulting in the enhancement of thermionic power generation by tailoring the surface roughness of the cathode electrode. The obtained results will ultimately provide insight into the design and thermodynamic performance analysis of nano-gap TEC systems based on a fundamental understanding of nanoscale charge and thermal transport physics.

QN04.04.38 Lithium Intercalation-Induced Thermal Conductivity Change of Amorphous WO\(_3\) Films
Ryuta Kobayashi,1 Tong Shen,2 Ayano Nakamura,3 Shunro Harada1,3, Miho Tagawa1,2 and Toru Ujihara1,3,4; 1Department of Materials Process Engineering, Nagoya University, Nagoya, Japan; 2Department of Materials Science and Engineering, Nagoya University, Nagoya, Japan; 3Center for Integrated Research of Future Electronics, Institute of Materials and Systems for Sustainability, Nagoya University, Nagoya, Japan; 4GaN Advanced Device Open Innovation Laboratory, National Institute of Advanced Industrial Science and Technology, Nagoya University, Nagoya, Japan.

Thermal switch, which can turn on/off the heat flow, plays an important role in thermal management. Ion intercalation materials have attracted interests because of their ability to change the thermal conductivities with electrochemical reactions. In our previous study, we have reported a drastic and reversible change in the thermal conductivity of amorphous WO\(_3\) film with H intercalation (0.2 W/mK \(\rightarrow\) 3.1 W/mK). This phenomenon is exactly the function of a thermal switch. In this study, we try to demonstrate another thermal conductivity change of amorphous WO\(_3\) by Li intercalation and investigate the mechanism of the thermal conductivity change from a viewpoint of local cluster network model. Amorphous WO\(_3\) film was prepared on ITO coated glass substrate at room temperature by RF magnetron sputtering in Ar-O\(_2\) atmosphere. Li intercalation into the WO\(_3\) film was performed with 1.0 M LiClO\(_4\) in propylene carbonate. The structure change of the film was determined by X-ray diffraction and Raman spectroscopy. The thermal conductivity of the film was measured by ac calorimetric method.

With increasing intercalated Li concentration, the thermal conductivity decreases, then remarkably increased at around x \(=\) 0.20, and subsequently decreases again. This tendency is similar to amorphous WO\(_3\)-H system. Peak positions of Raman spectra in amorphous WO\(_3\) almost to the same as those of crystalline WO\(_3\) except for the existence of peak of W=O double bonds in the spectra of amorphous WO\(_3\). It seems that cluster of atoms forms network. As the Li content increases, the Raman spectrum becomes more broad, indicating that the structure become disordered. Thus, heat transfer is inhibited by the disorder of the structure. On the other hand, a drastic increase in thermal conductivity may result from local structural phase change. In crystalline WO\(_3\) film, as the Li content increases, the crystal structure of Li\(_2\)WO\(_3\) transforms from monoclinic to tetragonal and further to cubic structure. The thermal conductivity of the cubic structure is larger than those of the other phases. Raman spectrum of amorphous WO\(_3\), at the Li content around the grain boundary. The exhaustive explanation of thermal transport properties in superionic Ag\(_2\)Te in our study will support the future design of superionic conductors based thermoelectrics and more broad energy systems composed of ordered-disordered materials.

QN04.04.39 Molecular Dynamics Study of Thermal Transport in Ordered-Disordered Superionic Ag\(_2\)Te and Its Traditionally Contradictory Enhancement by Nanotwin Boundary
Biao Wu1, Yuangang Zhou2 and Ming Hu1; 1RWTH Aachen University, Aachen, Germany; 2University of California Los Angeles, Los Angeles, California, United States; 1University of South Carolina, Columbia, South Carolina, United States.

Superionic Ag\(_2\)Te, like other superionic conductors, has its unique characteristic of the coexistence of ordered anion lattice and disordered liquid-like motion of cations and has a great potential in thermoelectric applications. Yet physical mechanisms of thermal transport in such ordered-disordered systems have not been well understood, and the traditional lattice vibration concept, i.e., phonons are regarded as heat carriers, fails to explain the governing mechanism in such structures. In our study, we calculate the thermal conductivities and their contributing factors of superionic Ag\(_2\)Te based on the heat flux linear response theory using equilibrium molecular dynamics simulations and explore thermal transport mechanisms by focusing on the effects of the boundary and the nanotwin effect. By decomposing the overall thermal conductivity into two contributing components we found that the convective thermal conductivity is dominant in superionic Ag\(_2\)Te, which results from the free movement of Ag ions. As a consequence, the total thermal conductivity increases abnormally with temperature due to the enhanced cations' mobility at elevated temperatures. Meanwhile, the nanotwin boundary, which has been utilized as a phonon scatter, has been found in our study to unexpectedly improve thermal transport in superionic Ag\(_2\)Te due to the strengthened movement of Ag ions around the grain boundary. The exhaustive explanation of thermal transport properties in superionic Ag\(_2\)Te in our study will support the future design of superionic conductors based thermoelectrics and more broad energy systems composed of ordered-disordered materials.

QN04.04.40 Giant Reduction of Thermal Transport in Polyvinylidene Fluoride Under Tensile Strains
Tengfei Ma, Lei Cao and Yan Wang; Department of Mechanical Engineering, University of Nevada, Reno, Reno, Nevada, United States.

Polyvinylidene fluoride (PVDF), a non-reactive thermoplastic polymer, exhibits overwhelming prospect on pyroelectric and electrocaloric applications. Generally speaking, PVDF is usually polymerized as α-phase but its β-phase isomeride received higher attention due to the significant pyroelectric properties. In this work, we conducted first-principle calculations to investigate thermal transport properties of β-phase PVDF. The thermal conductivities of single-chain and bulk crystalline PVDF were calculated under different tensile strain. The obtained thermal conductivity of bulk PVDF is several orders of magnitude larger than experimental data due to the perfectly aligned chains in our simulation. We found that giant reduction of thermal conductivity in single PVDF chain can be induced by applied strain. The phonon dispersion relations show that this phenomenon might be caused by the reduced group velocity in stretched PVDF chains. The result is contrary to previous observations on amorphous polymers in which thermal conductivities rise with increased strain due to better alignment of chains in stretched amorphous polymers. Therefore, we can conclude that thermal transport in stretched PVDF is mainly coupled by two mechanisms: one is the reduced contribution to the thermal conductivity by each chain and the other is the enhanced contribution by the aligning of chains.

QN04.04.41 AFM Cantilever Based Near Field Radiation Heat Transfer Measurement
Ramteja Kondakindi, Jui-Yung Chang and Liping Wang; Arizona State University, Tempe, Arizona, United States.
It is predicted that when two surfaces are placed in close proximity such that the distance between them is less than the thermal wavelength, radiative heat flux could be significantly enhanced for being the blackbody limit due to near-field radiation or photon tunnelling through nanometer scale vacuum gaps. Recently experimental demonstrations of super-Planckian near-field thermal radiation have been reported between plate-plate or tip-surface configurations. This study aims to develop a home-built thermal metrology for measuring near-field radiative heat transfer between a sphere and a planar surface with well controlled gap distances down to a few nanometers. A bi-material atomic force microscope (AFM) cantilever is used as a thermal sensor, whose temperatures will be measured simultaneously by two means: difference signal due to bending and sum signal with thermorelectance obtained from a position sensitive diode (PSD). Careful calibrations for both bi-material cantilever bending and thermorelectance will be carried out first to establish the relation between the tip temperature and the PSD difference signal from bending, or the sum signal from thermorelectance. The temperature of AFM cantilever will be varied by the laser power, while a power meter will be used to measure the incident, reflected and scattered laser beams to determine absorbed laser power. When the planar sample maintained at room temperature is brought closer with a piezo stage at sub-nm resolution, it is expected that the AFM cantilever will be cooled due to enhanced near-field radiative heat transfer. The thermal conductance from the near-field thermal radiation at different gap distances will be calculated from measured cantilever temperature, absorbed laser power, and sample temperature. Silica microsphere will be attached to the AFM cantilever to promote the near-field radiative heat transfer. Reference samples like quartz and silicon wafers will be measured first to compare with reported experimental results and theoretical calculations for validation. Near-field measurement results with SiC wafer, 2D materials like graphene, or nanostructured metamaterials will be reported. The outcomes of this research aim to enhance the fundamental understandings of radiative heat transfer in the near-field which could lead to advances in microelectronics, optical data storage and thermal systems including energy conversion devices.

QN04.04.42
Evaporation Rates for Molecular Fluids—Molecular Dynamics and Schrage Relationships
Anirban Chandra1, Zhi Liang2 and Pawel Keblinski3; 1Rensselaer Polytechnic Institute, Troy, New York, United States; 2California State University, Fresno, Fresno, California, United States.

Using molecular dynamics (MD) simulations we study the steady state evaporation and condensation processes of molecular polar fluids in a one-dimensional heat-pipe geometry. The non-equilibrium mass flow is driven by controlling the temperatures of the source/sink. The resulting mass fluxes as a function of driving force are evaluated for systems with pure working fluids (e.g., water) and in the presence of non-condensing gases (e.g., water + air). Our results indicate that the molecular velocity distributions in the vapor phase are indeed Maxwellian distributions shifted by the velocity of the macroscopic vapor flow, as assumed in Schrage’s theoretical analysis. Furthermore, we evaluate the mass accommodation coefficient as a function of temperature using equilibrium simulations. Consequently, we determine that the Schrage equations describe the evaporation-condensation rates of molecular fluids with moderate accuracy.

SESSION QN04.05: Hydrodynamics and Disorder

Emergence of Hydrodynamic Phenomena in Collective and Kinetic Regimes
E. Xavier Alvarez1, Javier Bafaluy1, Juan Camacho1, Xavier Cartoixà2, Pol Torres1, Albert Beardo Rico1 and Lluc Sendra1; 1Physics, Universitat Autonoma de Barcelona, Bellaterra, Spain; 2Electrical Engineering, Universitat Autonoma de Barcelona, Bellaterra, Spain.

Two main characteristics make nanoscale thermal transport in semiconductors a complex phenomena full of nuances. The first is the importance of momentum conservation in the phonon-phonon collisions (Normal scattering)1-3. This kind of scattering is not able to destroy momentum and consequently in their presence the phonon distribution cannot relax to its equilibrium form. The second is the large scale range that span the phonon mean free path spectrum4. Because of this the connectivity between two regions in a sample (non-locality) depends on the kind of phonons connecting these regions. The consequence is that heat transport at the nanoscale is still an incompletely described topic.

Phonon hydrodynamics has emerged in the last years as a candidate to cover this gap. The appearance of this regime has been associated to the dominance of non-collisions. Its presence has been proven in 2D materials or at low temperatures5-6, when N-collisions are dominant and in consequence collective effects can be observed easily. But recent works have shown that hydrodynamic effects can still have an important impact when resistive collisions are dominant7-9. In this case its presence has to be noticed through indirect evidences. Hydrodynamics has been used, for example, to understand the lack of validity of the Mathiessen rule in silicon or the dependence of the Thermal Boundary Resistance between two materials on the size of the contact.

Kinetic Collective Model (KCM) has been developed to describe heat transport using two key concepts. On one side, the splitting in collective regime (when normal scattering is dominant) and kinetic regime (when it is not important). On the other side, the inclusion of nonlocal and memory effects that introduce hydrodynamic behavior in the description. From the combination of both concepts it can be shown that hydrodynamic phenomena can emerge in both, collective and kinetic regimes, with different particularities in each case.

The equations obtained from the model are simple enough to be solved using finite element computational tools. We will show the results from a recent developed module implemented in COMSOL. Using KCM equations in combination with ab initio calculated parameters we will describe hydrodynamic effects in 2D materials like graphene and in conventional semiconductors like silicon an use the results to interpret some of the most relevant experimental observations of the last years.

8:30 AM QN04.05.02
Role of Normal Scattering for Thermal Resistance in Phonon Hydrodynamics
Xun Li and Sanghee Lee; University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

Hydrodynamic phonon transport occurs when normal scattering (N-scattering) is much stronger than umklapp scattering. Due to its momentum-conserving nature, N-scattering does not directly cause thermal resistance. In particular, when a sample is extremely large and thus diffuse boundary scattering can be ignored, N-scattering alone cannot cause any thermal resistance. For a sample with finite size, however, N-scattering combined with diffuse boundary scattering affects thermal resistance. We discuss two different mechanisms of thermal resistance associated with N-scattering in finite-sized samples when phonon transport is in the strong hydrodynamic regime. The discussion is based on the Monte Carlo solution of the Peierls-Boltzmann transport equation in both real and reciprocal spaces using an ab initio three-phonon scattering matrix. First, when a sample has a finite width but an infinite length along the heat flow direction, the thermal resistance occurs due to the momentum transfer along the lateral direction (i.e., perpendicular to heat flow direction), called phonon viscous damping effect. The stronger N-scattering, the slower the momentum transfer, resulting in lower thermal resistance. Second, when a sample is infinitely wide but has finite length along the heat flow direction, phonons emitted from heat reservoirs change their distributions from static to displaced Bose-Einstein distributions upon N-scattering. During this transition between non-collective and collective phonon flows, N-scattering causes thermal resistance. The thermal resistance of this case depends on the shape of phonon dispersion provided that the sample length is larger than the mean free path of N-scattering. For graphitic materials, the transition between collective and non-collective phonon flows reduces heat flux by 50% from the ballistic case at room temperature.
Hydrodynamic Transport and Thermal Energy Dissipation

In an overwhelmingly large group of conducting materials thermal and electrical transport are directly related via the Wiedemann-Franz law, which states that the product of the thermal conductivity and the electrical resistivity divided by the temperature is a constant, yielding the Sommerfeld value. In stark contrast to these ordinary conductors, heat and charge flow can de-couple in strongly correlated materials yielding thermal energy dissipation and transport behavior that can be described by the theory of hydrodynamics. In this talk, we will present recent thermal and magneto-electric transport experiments on heat and charge flow in the Weyl semimetal tungsten di-phosphide [1]. We observe a strong violation of the Wiedemann-Franz law that coincides with a transition from a conventional metallic state at high temperatures to a hydrodynamic electron fluid below 20 K. The hydrodynamic regime is characterized by a viscosity-induced dependence of electrical resistivity on the sample width and magnetic field. Based on the accompanying decoupling of momentum conserving and relaxing scattering processes we illustrate that both thermal and electrical transport are bound by the quantum indeterminacy applied to energy dissipation, independent of the underlying transport regime.

In-Plane Heat and Charge Transport in sub-100 nm Thin Films—Surprises from Nanotubes to Magnetic Alloys

Theoretical understanding of phonon dynamics in nanostructures with a significant degree of surface disorder is far from complete. Here, we show how concepts from chaos theory, such as the level-spacing distribution and the geometric mean free path, can shed light on the universal features in phonon dynamics and thermal transport across structures of different dimensions and roughness. Within this context, we simulate lattice dynamics using Monte Carlo in the semiclassical limit and the finite-difference time-domain (FDTD) solution to the elastic wave equation for the elastic-solid limit.

Prominent Localization of Phonons and Strong Deviation to Matthiessen's Scattering Rule Introduced by Dislocation Engineering Heat Transport in Nanoparticle-in-Alloy Composites—The Role of Mie Scattering

Dislocations have prominent scattering to phonons. Tuning dislocation patterns is an effective method to control the thermal conductivity in thermoelectric materials. However, clear impact of dislocation on phonon scattering is still missing, although substantial efforts have been devoted to this issue. By performing non-equilibrium molecular dynamics (NEMD) simulation, the thermal transportation of a rock salt structure PbTe crystal and a body-centered cubic (bcc) iron crystal containing quantitative dislocations have been studied. For the first time, temperature distribution in proximity to the dislocation, spectral heat flux and frequency dependent phonon mean free paths (MFPs) are explicitly obtained. The results not only show that quantitative dislocations suppress the lattice thermal conductivity but also reveal detailed phonon-dislocation scattering processes, which is due to the localization of phonon modes in sample with dislocations. Moreover, we provide a way to scale the scattering rate between the phonons and dislocations which may offer a guidance for engineering to regulate the lattice thermal conductivity by introducing or removing dislocations.

In this talk, we will present recent thermal and magneto-electric transport experiments on heat and charge flow in the Weyl semimetal tungsten di-phosphide [1]. We observe a strong violation of the Wiedemann-Franz law that coincides with a transition from a conventional metallic state at high temperatures to a hydrodynamic electron fluid below 20 K. The hydrodynamic regime is characterized by a viscosity-induced dependence of electrical resistivity on the sample width and magnetic field. Based on the accompanying decoupling of momentum conserving and relaxing scattering processes we illustrate that both thermal and electrical transport are bound by the quantum indeterminacy applied to energy dissipation, independent of the underlying transport regime.

In-Plane Heat and Charge Transport in sub-100 nm Thin Films—Surprises from Nanotubes to Magnetic Alloys

Barry Zink; University of Denver, Denver, Colorado, United States.

Recent advances in thermoelectric materials through nanoscale engineering bring both tremendous promise and serious fundamental measurement challenges. For materials ranging from graphene to carbon nanotube hybrids to nanomagnetic systems or films, samples with one or more dimensions on the sub-100 nm scale are always difficult to thermally characterize. Our approach to these measurements uses micro- and nanomachined thermal isolation platforms that allow exceptional control over thermal gradients and unambiguous alignment of this gradient in the plane of a thin film or nanoscale sample. Micromachined electrical leads enable thermal conductivity, electrical conductivity, and Seebeck effect measurements all on the exact same sample. This allows particularly powerful probe of both the Wiedemann-Franz law and the thermoelectric figure-of-merit, ZT.

In this talk, I will first focus on our recent work on increasing ZT in sub-100 nm thin films by reducing thermal conductivity, which we have demonstrated in two very different systems. In the first, disordered films formed from carefully-selected semiconducting single-wall carbon nanotubes (CNT) show dramatic reduction in thermal conductivity when doped with organic acids.[1] This reduction is likely driven by increased phonon scattering caused by the proximity of the CNT and the dopant molecule, and raises ZT for both n- and p-type films to some of the largest values yet observed in organic systems.[2] More surprising is a strong non-monotonic temperature dependence of thermal conductivity seen in certain preparations of CNT films that drives a sharp increase in ZT over a narrow temperature range.[3] It is not yet clear if this effect is driven by changes in phonon populations or scattering, and further study could lead to a new route to reducing thermal conductivity in CNT thermoelectric systems. The second system showing a surprising reduction in thermal conductivity and increase in ZT are evaporated films of gold. Across a wide range of film thickness we see very strong violations of the Wiedemann-Franz law in gold films, with a measured Lorenz number reduced to less than half the free-electron values near room temperature.[4] Finally I will discuss magnetic alloy films where careful examination of the Wiedemann-Franz law indicates a large additional thermal conductivity. Ongoing work will clarify if this is driven by primarily by phonons or magnons in these systems, and point toward new ways to manipulate spin degrees of freedom in ferromagnets with heat. Work at DU is supported by the NSF (DMR-1709646) and DOE-CINT (DE-AC04-94AL85000).

Unexpected High Inelastic Phonon Transport Across Solid-Solid Interface—Modal Nonequilibrium Molecular Dynamics Simulations and Landauer Analysis Tianli Feng, Yang Zhang, Jingli Shi and Xiulin Ruan; Purdue University, West Lafayette, Tennessee, United States.

As a crucial part in thermal management, interfacial thermal transport is still not well understood. In this paper, we employ the newly developed modal nonequilibrium molecular dynamics to study the Si/Ge interfacial thermal transport and clarify several long-standing issues. We find that the few atomic layers at the interface are dominated by interfacial modes, which act as a bridge that connects the bulk Si and Ge modes. Such bridging effect boosts the inelastic transport to contribute more than 50% to the total thermal conductance even at room temperature. The apparent inelastic transport can even allow effective four-phonon processes across the interface when the mass difference between the two materials is large. Surprisingly, optical phonon modes can contribute equal or more thermal conductance than the acoustic modes due to the bridging effect. From the modal temperature analysis, we find that the phonon modes are in strong modal nonequilibrium near the interface, which impedes the thermal transport. The widely used Landauer approach that does not consider the phonon nonequilibrium can lead to inaccurate results. We have modified the Landauer approach to include the inelastic transmission and modal thermal nonequilibrium. The approach is used to analyze our modal NEMD results, and the mode-dependent phonon transmission function that includes inelastic scattering has been derived. Our results unveil the fundamental thermal transport physics across interfaces and will shed light on the future engineering in thermal management. It provides a method of calculating modal phonon transmission functions that includes inelastic scattering from molecular dynamics.

11:15 AM QN04.06.03
Interfacial Scattering in Boltzmann Transport Simulations of Phonons Giuseppe Romano1, Aria Hosseini1, Jackson Harter1, Todd Palmer1 and Alex Greaney1; 1University of California, Riverside, Riverside, California, United States; 2Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3School of Nuclear Science and Engineering, Oregon State University, Corvallis, Oregon, United States.

Packages that efficiently simulate the Boltzmann transport of phonons have become an established research tool for predicting thermal transport in micro and nanoscale dielectric devices. However, the widespread application of these tools, particularly in industry, is currently hindered by the numerical difficulty of modeling the thermal processes at boundaries and interfaces where the thermal state of the two materials is large. Surprisingly, optical phonon modes can contribute equal or more thermal conductance than the acoustic modes due to the bridging effect. From the modal temperature analysis, we find that the phonon modes are in strong modal nonequilibrium near the interface, which impedes the thermal transport. The widely used Landauer approach that does not consider the phonon nonequilibrium can lead to inaccurate results. We have modified the Landauer approach to include the inelastic transmission and modal thermal nonequilibrium. The approach is used to analyze our modal NEMD results, and the mode-dependent phonon transmission function that includes inelastic scattering has been derived. Our results unveil the fundamental thermal transport physics across interfaces and will shed light on the future engineering in thermal management. It provides a method of calculating modal phonon transmission functions that includes inelastic scattering from molecular dynamics.

Ultrafast Electron-Phonon and Plasmon Scattering Effects in Metals, Non-Metals and Interfaces Probed with Tunable Wavelength Sub-Picosecond Pulses Patrick Hopkins; University of Virginia, Charlottesville, Virginia, United States.

We report on a series of experimental measurements designed to understand the role of hot excited electrons and plasmons and resulting electron-phonon coupling on nonequilibrium electron thermal transport in metals, non-metals and metal/non-metal interfaces. We implement a pump-probe thermoreflectance using sub-picosecond laser pulses with wavelength tunability through the visible and into the IR. We use this tunable photon energy to demonstrate that electron-phonon coupling in metals (e.g., Au, Al, Pt) and non-metals (e.g., silicon and GaAs) can be strongly energy dependent, and when probing near interband transitions, scattering rates can be strongly dictated by electron number densities. We then consider the role of electron-phonon coupling at interfaces between gold and an insulating non-metal substrate with an adhesion layer between the gold and the substrate. We show that under conditions of electron-phonon nonequilibrium and ballistic electron transport, the thermal conductance due to electron-phonon coupling can lead to enhancements in the overall thermal boundary conductance across metal/non-metal interfaces. Next, we consider the heat transport processes across metal/doped semiconductor interfaces, where the energy barrier at the metal/non-metal interface is low enough to promote electron injection across this boundary. We show that electron injection across this boundary can be used as a means to control the electronic thermal transport and electron-phonon scattering rates in semiconductors within the electronic Kapitza length near the metal/doped semiconductor interface. Finally, we study the role that plasmon excitation can have on these electron interfacial properties by considering metal/doped CdO interface in which the CdO supports near-IR plasmon modes.

Chiral Phonons in Two-Dimensional Materials Life Zhang; Nanjing Normal University, Nanjing, China.

The theoretical finding on chiral phonons at Brillouin-zone corners (valleys) of two-dimensional honeycomb lattices has attracted wide attention in the study of phonon chirality very recently [1]. In this talk, firstly I will report and the experimental verification of chiral phonons in monolayer tungsten diselenide [2], where the chiral phonons are identified by the intervalley transfer of holes through hole-phonon interactions during the indirect infrared absorption, and their chirality are confirmed by the infrared circular dichroism arising from pseudoangular momentum conservation. Then I report our recent findings on chiral phonons in center-stacked bilayer triangle lattices where the phonon chirality remain robust with changing sublattice mass ratio and interlayer coupling [3], graphene/hexagonal boron nitride heterostructure where broken inversion symmetry and the interlayer interaction of G/h-BN not only open the phononic gaps but also lift the degeneracy of left-handed and right-handed chiral phonons at valleys [4], and in 2+3 × 3+3 honeycomb superlattices where the nondegenerate chiral phonons at valleys are folded phonon Brillouin-zone center thus being more measurable by helicity-resolved Raman scattering [5]. Collectively, our results on the chiral phonons in these two-dimensional materials could stimulate more experimental and theoretical studies on chiral phonons and promote the future applications on the phonon-chirality-based phononics.

Symmetry-Driven Phonon Chirality and Transport in 1D Materials Lucas Lindsay, Tribhuvan Pandey, Carlos Polanco, Valentino Cooper and David Parker; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Symmetry and dimensionality are essential factors defining lattice dynamics and thermal conductivity in materials. Here, we will present physical insights developed from predictive first principles Peierls-Boltzmann transport in 1D chains and compare them with 2D and bulk materials. In particular, we will discuss how symmetry gives rise to phonon chirality in 1D chains from which phonon-phonon scattering rules are derived. These symmetry-based selection rules limit thermal resistance, while chain coupling breaks these in weakly bonded bulk systems, giving lower κ and larger κ anisotropy.
2:15 PM QN04.07.03
Topological Origins of the Inverse Dependence of the Thermal Conductivity on Temperature of Crystalline and Non-Crystalline Solid States Above Approximately 50 K
Caroline S. Gorham and David E. Laughlin; Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

Thermal transport properties of the solid state are intimately tied to the structure that forms from the undercooled atomic liquid. Above approximately 50 K, the thermal conductivity of glasses ubiquitously decreases with decreasing temperatures while the thermal conductivity of crystalline materials rises sharply with decreasing temperatures; the origin of this inverse behavior has remained a matter of inquiry over the past century. This work elucidates the topological origins of the thermal transport properties of the solid state, by adopting a quaternion number to characterize the orientational order that develops by atomic clustering at temperatures below the melting temperature.

Solidification of undercooled liquids towards crystalline ground states may be viewed as a higher-dimensional realization of Bose-Einstein condensation of superfluids, that are characterized by a complex orientational order parameter, such as helium superfluids and superconductors. Just as complex ordered systems are considered to exist in restricted dimensions in two- and one-dimensions, quaternion ordered systems in four- and three-dimensions may be considered to exist in restricted dimensions. In restricted dimensions, misorientational fluctuations in the form of spontaneously generated topological defects prevent conventional long-range order at finite temperatures. Third homotopy group topological point defects in quaternion ordered systems play the role of vortices in complex ordered systems.

In restricted dimensions, one may observe either a phase-coherent or a phase-incoherent low-temperature state by changing the non-thermal tuning parameter that characterizes the ordered system. For example, in two- and one-dimensional charged complex ordered systems (i.e., Josephson junction arrays), superinsulating ground states may be realized with infinite electrical resistance that is a mirror image of superconductivity. Similarly, solidification in four- and three-dimensions (i.e., quaternion ordered systems) can result in either crystalline and non-crystalline low-temperature states. Resulting thermal transport properties of orientationally-ordered (crystalline) and orientationally-disordered (non-crystalline) solid states are inverse to one another above approximately 50 K, in analogue to the electrical transport properties of Josephson junction arrays across the superconductor-to-superinsulator transition.

Exploring the Upper Limits of Thermal Conductivity in Molecular Crystals
Austin J. Minnich; California Institute of Technology, Pasadena, California, United States.

Molecular crystals that conduct heat are of interest both fundamentally and for applications. Long-standing questions regarding the thermal transport properties of these materials include how crystals with complex unit cells can still possess high uniaxial thermal conductivity despite their large scattering phase space, and what is the distribution of phonon mean free paths in actual molecular crystals that possess many defects. Here, we address these questions using advances in numerical and experimental tools. First, we use ab-initio calculations to show that high thermal conductivity along the chain axis arises from phonon focusing despite intense phonon scattering in the complex crystal. Second, we report the observation of ballistic phonons on micron length scales in semi-crystalline polyethylene using transient grating spectroscopy, allowing us to determine the mean free path distribution. These works elucidate the microscopic details of heat transport in molecular crystals.

Phonon Lifetimes in the Molecular Crystal α-RDX
Gaurav Kumar, Francis VanGessel and Peter W. Chung; Mechanical Engineering, University of Maryland, College Park, Maryland, United States.

Molecular crystals form an important class of materials. They appear in vital medical and defense applications ranging from pharmaceuticals to energetics. Thermal and vibrational properties are particularly critical to know due to their influence over, for instance, tabling strength and initiation sensitivity. The accurate prediction of certain phonon properties like the thermal conductivity and energy transfer rate requires knowledge of anharmonic vibrational properties, in particular the phonon lifetimes. In this study we extend techniques previously used for atomic crystals to predict phonon lifetimes for all branches of the molecular crystal α-RDX. We use two different techniques to predict phonon lifetimes - anharmonic lattice dynamics (ALD) [1] [2] and frequency domain normal mode decomposition (NMD) [3]. We for the first time present the temperature and frequency dependence of phonon lifetimes due to normal and Umklapp processes in α-RDX, and identify phonon modes with high scattering rates which result in high energy transfer rates. Our results indicate that phonon lifetimes in α-RDX do not have a monotonic relationship with frequency. In fact, some high frequency phonons are found to exhibit longer lifetimes than low frequency phonons. This is in contrast with trends observed in atomic crystals [3] [4] [5] and predictions based on Callaway’s model [6] where higher frequency phonons generally have a smaller lifetime and therefore participate more in diffusive transport mechanisms. The longer lifetimes of optical modes enable these modes to carry a significant proportion of phonon thermal energy. In fact, in contrast to the marginal role optical phonons play in thermal transport in atomic crystals, optical phonons in the molecular crystal α-RDX contribute 63-78% of the total thermal conductivity.

Chain Rotation Significantly Reduces Thermal Conductivity of Single-Chain Polymers
Hao Ma and Zhirong Tian; Cornell University, Ithaca, New York, United States.

Kevlar (polyparaphenylene terephthalamide) and PBDT (poly(2,29-disulfonyl-1,49-benzidine terephthalamide))-derivatives have very similar chemical structures with aromatic rings. In this study, thermal conductivities of their single chains were calculated using molecular dynamics simulations. Chain rotation was found to be the key to reducing thermal conductivity. By introducing a new chain rotation factor (CRF), we can easily quantify the chain rotation level of single-chain polymers. We demonstrated that thermal conductivity decreases as the CRF increases. We performed further calculations on phonon properties and unveiled that the small thermal conductivity led by large chain rotation can be attributed to reduced phonon group velocities and shortened phonon mean free paths. Insights obtained in this study can be used for tuning the thermal conductivity of various polymers and facilitating their various applications including thermal energy conversion and management.

Recent Applications of Brillouin Light Scattering Spectroscopy to the Study of Thermomechanical Properties of Nanostructured Soft Materials
Zuyuan

Acknowledgements: This work was supported by the U. S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division.
Nanostructured materials hold promises for a wide range of applications. For example, they could be used as drug delivery carriers, novel coating ingredients, and interfacial fillers. The realization of these applications, however, relies on a good understanding of the thermomechanical properties (e.g., glass transition temperature, elasticity) of the nanomaterials, which could deviate from those of their bulk counterparts due to effects like an increased surface-to-volume ratio and spatial confinement. As a non-contact, non-destructive technique, Brillouin light scattering (BLS) spectroscopy provides unique characterizations of the thermomechanical properties of nanostructured materials via the resolution of hypersonic phonons. In this contribution, three recent applications of BLS will be presented. First, BLS is employed to study core-shell polymer based colloids. The observed nanoparticle vibrational modes provide a direct probe of the particle surface mobility, revealing the critical role of the shell architecture on the glass transition temperature and elasticity of the nanoparticles. Second, BLS is applied to “disentangle” the role of chain conformation (e.g., grafting density, degree of polymerization) on the mechanical properties of thin films of polymer tethered particle (particle-brush) materials with different grafting density and chain length. The bulk modulus, determined based on the BLS-detected sound velocities and the Bragg peak intensity, shows a maximum in intermediate to low grafting density systems, where the hard (silica) cores are partially exposed due to the conformational fluctuations of the grafted (polyethylene) polymer chains. Third, BLS is utilized to understand the effect of confined polymer layers on the effective mechanical properties of hybrid materials composed of alternating polystyrene and hectorite nanolayers. The clear resolution of the direction-dependent quasi-longitudinal, quasi-transverse, and pure-transverse phonon modes from BLS leads to the determination of the full elastic tensor of the materials by assuming them to be transversely isotropic; materials with thinner PVP layers (i.e., stronger confinement) exhibit higher Young’s modulus in the directions parallel and perpendicular to the layers. These studies demonstrate BLS as an effective tool for studying the thermomechanical properties of nanostructured materials. The results improve our understanding of the structure-property relation in the three material systems, and contribute to realizing their applications through guided engineering.

Development of ultrafast electron and X-ray scattering methods has enabled direct routes to probing atomic-scale structural dynamics in myriad chemical and materials systems [1,2]. This in turn has led to new physical insights into molecular and crystal-lattice responses associated with chemical-bond dynamics, phase transformations, electron-lattice correlations, and nanoscale structural motion. Importantly, the detailed nature of materials responses are likely influenced by ever-present lattice discontinuities and nanoscale morphological features. Thus, direct probing of the local structural dynamics would provide a richer, more detailed picture of the overall evolution of ultrafast energy deposition and transport. Here, I will discuss how fs electron imaging with an ultrafast electron microscope (UEM) [3] can be used to directly visualize specific coherent, low-frequency acoustic-phonon dynamics in a variety of materials, with particular emphasis placed on resolving the influence of lattice discontinuities. After a brief overview of the instrumentation and the general experimental approach, I will describe how the concepts of static, real-space imaging with conventional electron microscopes can be used to visualize local coherent lattice oscillations in crystalline materials. Once described, these concepts will aid in understanding a number of photoinduced phonon behaviors we have observed in transition metal dichalcogenides (TMDs) and thin crystals of archetypal semiconductors [4-7]. For example, in TMDs (WSe$_2$, MoS$_2$, and TaS$_2$) we have found that fs photoexcitation leads to the generation of coherent phonon wavetrains preferentially at vacuum-crystal interfaces and extended crystal step edges. This arises via an initial impulsive expansion along the c-axis of van der Waals stacking direction occurring within the first few picoseconds after ultrafast excitation. This impulsive interlayer expansion induces the launch of coherent interlayer phonon wavetrains due to the picosecond development of a phase mismatch between the neighboring layers owing to varying total transit times of the speed-of-sound c-axis phonons between the outer layers. As with the stacking direction, the coherent interlayer modes propagate at the speed of sound (e.g., 5 mm/ps) and initially along a single wavevector oriented perpendicular to the defect nucleation sites prior to the first scattering events. Similarly, in strongly-photoexcited thin crystals of undoped Ge, we directly image a variety of spatially and temporally heterogeneous effects; including the launch of highly-coherent phonon wavetrains propagating with high phase velocities (observable up to 35 mm/ps with the UEM modalities employed), the significantly-delayed (i.e., 10s of picoseconds more) generation of phonon wavetrains relative to the precise moment of fs photoexcitation, and time-varying phase-velocity dispersions displaying single-exponential relaxation to the Ge bulk speed of sound (5 mm/ps) within one nanosecond following fs photoexcitation. This survey of recent results will serve to illustrate the rich and detailed information obtainable with fs electron imaging, with particular emphasis placed on the low-frequency modes highlighted here.

Temperature-Dependent Thermal Diffuse Scattering Measurements Using Scanning Transmission Electron Microscopy
Geoffrey Wehmeyer,$^{1, 2}$ Karen C. Busillo$^{1}$, Andrew Minor$^{1, 4, 5}$ and Chris Dames$^{1, 4}$
$^{1}$Mechanical Engineering, University of California, Berkeley, Berkeley, California, United States; $^{2}$Mechanical Engineering, Rice University, Houston, Texas, United States; $^{3}$National Center for Electron Microscopy, Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States; $^{4}$Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; $^{5}$Materials Science Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Scanning transmission electron microscopy (STEM) thermometry techniques open new possibilities for mapping temperature (T) with high spatial resolution. Existing STEM thermometry methods based on measuring thermally-induced strains must content with small thermal expansion coefficients (~10 parts per million (ppm)/K) for some materials, as well as potentially non-local relationships between strain and temperature. In contrast, the well-known mechanism of thermal diffuse scattering (TDS) offers promise for inherently local T measurements, and Debye-Waller theory predicts that many materials should display large temperature coefficients (~1000 ppm/K) at room temperature and above. This T-dependent TDS has not been leveraged for STEM thermometry, however, because the Debye-Waller effect on the Bragg peak intensity is overwhelmly by the effects of thermal tilts and thermal drift. Here, we demonstrate quantitative TDS measurements using STEM by measuring the diffuse background intensity (rather than the Bragg peak intensity) in energy-filtered scanning electron nanodiffraction patterns. Applying virtual apertures to these diffraction patterns during post-processing allows us to quantify the T-dependent TDS in the diffuse background. Within one nanosecond following fs photoexcitation, this diffuse signal, we measure a position-averaged temperature coefficient of 2400 ± 400 ppm/K for a single-crystal gold film averaged between T=100 K and T=300 K, and compare our results with the predictions of Debye-Waller theory. The measurements display typical temperature uncertainties of 8 K and temperature sensitivities of 51 K Hz$^{-1}$. This TDS-based STEM thermometry demonstration provides a step towards the goal of non-contact nanoscale temperature mapping of thin nanostructures or microelectronics.

In this contribution, three recent applications of BLS will be presented. First, BLS is employed to study core-shell polymer based colloids. The observed nanoparticle vibrational modes provide a direct probe of the particle surface mobility, revealing the critical role of the shell architecture on the glass transition temperature and elasticity of the nanoparticles. Second, BLS is applied to “disentangle” the role of chain conformation (e.g., grafting density, degree of polymerization) on the mechanical properties of thin films of polymer tethered particle (particle-brush) materials with different grafting density and chain length. The bulk modulus, determined based on the BLS-detected sound velocities and the Bragg peak intensity, shows a maximum in intermediate to low grafting density systems, where the hard (silica) cores are partially exposed due to the conformational fluctuations of the grafted (polyethylene) polymer chains. Third, BLS is utilized to understand the effect of confined polymer layers on the effective mechanical properties of hybrid materials composed of alternating polystyrene and hectorite nanolayers. The clear resolution of the direction-dependent quasi-longitudinal, quasi-transverse, and pure-transverse phonon modes from BLS leads to the determination of the full elastic tensor of the materials by assuming them to be transversely isotropic; materials with thinner PVP layers (i.e., stronger confinement) exhibit higher Young’s modulus in the directions parallel and perpendicular to the layers. These studies demonstrate BLS as an effective tool for studying the thermomechanical properties of nanostructured materials. The results improve our understanding of the structure-property relation in the three material systems, and contribute to realizing their applications through guided engineering.
Nanoscale phononic metamaterials make it possible to engineer the thermal, magnetic, and electronic properties of materials, which is essential for nanoelectronics, thermoelectric and data storage devices, or nanoparticle-mediated thermal therapies [1]. Specifically, nanoscale metalattices are a powerful bottom-up approach to tune the propagation of high frequency phonons - highly ordered nanoscale opal templates allow for precise control over nanoscale structure in which different materials can be infiltrated. Moreover, these metamaterials can be organized into hierarchical structures on length scales from nanometers to micrometers which enable unique properties that cannot be accessed using bulk/layered materials [2,3]. In the case of nanoscale thermal transport, metalattices are a powerful approach to further advance our understanding, which is critical since macroscopic diffusive models completely break down at dimensions that are comparable to the mean free path of the heat carriers [4,5]. However, characterizing energy flow in these metalattices is extremely challenging. Most current techniques rely on visible light, which is limited in wavelength to probing heat flow away from nanostructures >100s of nanometers. We can overcome this limitation by utilizing coherent extreme ultraviolet (EUV) light generated by tabletop high harmonic generation (HHG) [6]. The short pulse duration (~10fs) and wavelength (~30nm) of tabletop HHG sources are an excellent match for probing the intrinsic length- and time-scales relevant to nanoscopic dynamics. In this unique EUV nanotomography technique, we use an ultrafast 800nm femtosecond laser to impulsively heat periodic arrays of nickel nanolines deposited on top of a silicon metalattice. We then probe the cooling of the nanolines, and the resulting thermal transport properties of the metalattice, by monitoring the thermally-induced surface deformation using coherent EUV light. In this work, we show how the thermal transport in silicon metalattices is modified due to the metalattice structure. First, we observe a slow thermal decay of the nanolines through the metalattice, suggesting very low thermal conductivity of the metalattice. Further analysis indicates that, not only do these metalattices have lower thermal conductivity than expected from macroscopic predictions, but that the heat flow is a function of the geometry of the heat sources. In addition, these findings are supported by equilibrium Green–Kubo atomistic simulations which show that silicon metalattices are capable of significantly reducing the thermal conductivity below the prediction of continuum models. This suggests that nanostructured metalattices may be able to impede heat flow even more than had been initially thought. The ability to impede the flow of phonons, while allowing electrical current to flow, can dramatically impact applications such as optimized thermoelectric materials, as well as providing routes for enhanced functionality of other nanodevices.

The vibrational thermal conductivity of solid materials is determined by anharmonic effects, i.e., by features of the potential-energy surface (PES) that are not captured by a harmonic second-order Taylor expansion. However, only the leading contribution to anharmonicity (the third-order term in the Taylor expansion of the PES) is accounted for in typical, perturbative first-principles calculations of thermal conductivities [1]. Higher-order terms are neglected in these models, in spite of the fact that such strong anharmonic effects are known to play a decisive role in many technologically relevant materials, e.g., perovskites [2].

In this work, we discuss the ab initio Green-Kubo method [3], which we have developed for the computation of thermal conductivities in strongly anharmonic materials, and present applications of this method for material-science questions. In this formalism, the full PES is explored via equilibrium ab initio molecular dynamics (AIMD), so to account for all anharmonic effects. The thermal conductivity is evaluated via the Green-Kubo equations [4] using a unique first-principles definition of the heat flux [3]. By this means, incoherent and strongly anharmonic effects are directly treated within the real-space AIMD. Coherent, almost harmonic processes are mapped into a reciprocal-space representation [5], so to overcome finite time and size effects. This robust, asymptotically exact extrapolation scheme allows to obtain accurate bulk thermal conductivities – both for strongly anharmonic materials and for very harmonic materials. This is demonstrated for various representative examples with increasing degree of complexity and anharmonicity (e.g. Si, GaO2, ZrO2, and perovskites). These investigations reveal that a correct treatment of higher-order anharmonicity plays a minor role in good thermal conductors, but is essential to achieve quantitative predictions and qualitative insights in highly anharmonic systems [6]. Eventually, we critically discuss strategies to apply the
developed formalism in a computationally efficient fashion in high-throughput frameworks, e.g., to search for strongly anharmonic materials with ultra-low thermal conductivities.

Selective Breakdown of Phonon Quasiparticles Across Superionic Transition in CuCrSe and AgCrSe
Olivier Delaire\(^1\), Jennifer Niedziela\(^1\), Dipanshu Bansal\(^1\), Andrew May\(^2\), Jinxuan Ding\(^3\), Tyson Lanigan-Atkins\(^4\), Georg Ehlers\(^5\), Doug Abernathy\(^6\) and Ayman Said\(^7\); \(^1\) Duke University, Durham, North Carolina, United States; \(^2\) Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; \(^3\) Argonne National Laboratory, Argonne, Illinois, United States. Superionic crystals exhibit ionic mobilities comparable to liquids while maintaining a periodic crystalline lattice. The atomic dynamics leading to large ionic mobility have long been debated. A central question is whether phonon quasiparticles—which conduct heat in regular solids—survive in the superionic state, where a large fraction of the system exhibits liquid-like behavior. Here we present the results of energy- and momentum-resolved scattering studies combined with first-principles calculations and show that in the superionic phase of CuCrSe and AgCrSe, long-wavelength acoustic phonons capable of heat conduction remain largely intact, whereas specific phonon quasiparticles dominated by the Cu or Ag ions break down as a result of anharmonicity and disorder. The weak bonding and large anharmonicity of the Cu / Ag sublattice are present already in the normal ordered state, resulting in low thermal conductivity even in the normal phase, at temperatures below the superionic transition. Further, we find a strong repulsion between Cu / Ag neighbors, affecting the diffusion mechanism. These results show how anharmonic phonon dynamics are at the origin of low thermal conductivity and superionicity in this class of materials. Our studies of atomic dynamics and diffusion will help rationalize the emergence of ultralow thermal conductivity for thermoelectrics and facilitate the design of high-performance solid-state electrolytes for next-generation batteries.

New Thermal Transport Regime for Partial-Strain-Crystalline Partial-Liquid Materials
Ming Hu; University of South Carolina, Columbia, South Carolina, United States. Materials in partial-crystalline partial-liquid (PCPL) state are now widely used as thermoelectrics [Cu₃Se; PRL 118, 145901 (2017), PNAS 111, 15031 (2014), Nature Mater. 11, 422 (2012)] and battery electrodes [LiS; Nano Energy 18, 89 (2015)], due to their low thermal conductivity and high ionic conductivity, respectively. However, the well-developed computational methods for pure crystalline materials such as anharmonic lattice dynamics coupled with Boltzmann transport equation cannot be straightforwardly used to study such systems. By performing first-principles and molecular dynamics simulations, for the first time we give a robust and detailed explanation of the thermal transport mechanism in PCPL material LiS. At the temperature range in which the system can be regarded as a solid, the large hopping of Li is found to be responsible for phonon thermal conductivity’s deviation from the traditional 1/T relationship. At the high temperature range, the contribution of convection and liquid-phonon interaction increase significantly due to the fluidization of Li ions. Furthermore, there is an interplay between the enhanced phonon scattering and the increased force hopping between neighboring atoms as temperature arises, which results in a dip in the evolution of the virial term around 1200K. When the temperature is higher than 1200 K, the virial thermal conductivity increases with temperature due to the contribution of vibrations with extremely short mean free path (i.e., diffusons). This point is validated by the evolution of the accumulative thermal conductivity with mean free path at 1300 K, more than 40% of the heat carried by the S sublattice is contributed by the carriers with mean free path smaller than a few angstroms, which is the typical hopping distance. Our study provides a clear physical map of the heat transport in phase change materials and describes the key mechanisms to guide the design of the future thermoelectrical materials and battery electrodes.

Influence of Ferroelectric Phase Transition on Thermal Properties of GeTe
Diordic Dangic\(^1\), Olle Hellman\(^1\), Eamonn Murray\(^2\), Stephen Fahy\(^3\) and Ivana Savić\(^4\); \(^1\) Tyndall National Institute, Cork, Ireland; \(^2\) California Institute of Technology, Pasadena, California, United States; \(^3\) University College Cork, Cork, Ireland; \(^4\) Imperial College London, London, United Kingdom. GeTe is a well-known thermoelectric material with low lattice thermal conductivity which undergoes a ferroelectric phase transition around 700 K. Using standard first principles calculations, we have shown how the lattice thermal conductivity of PbGeTe alloys could be further suppressed by driving them closer to the phase transition with varying chemical composition \([1,2]\). Here we investigate how this phase transition affects the thermal expansion and the lattice thermal conductivity of GeTe using recently developed first principles methods that account for higher-than-third order anharmonicity \([2,3]\). We find that GeTe exhibits negative thermal expansion near the phase transition \([2]\). This is caused by strong acoustic-soft optical mode coupling \([2]\), which is also responsible for the low lattice thermal conductivity of PbGeTe alloys \([1]\). Surprisingly, our calculations in the framework of temperature dependent effective potentials \([3]\) show an anomalous increase of the lattice thermal conductivity of GeTe at the phase transition. We elucidate the connection between the unexpected conductivity increase and strong anharmonicity.

11:45 AM QN04.10.05
Temperature and Strain Dependent Thermal Conductivity in Ferroelectric Nb:SnTiO Thin Films
Alexandros Sarantopoulos\(^1\), Dipanjana Saha\(^2\), Weeliat Ong\(^3\), Jonathan A. Malen\(^4\) and Francisco Rivadulla\(^5\); \(^1\) Carnegie Mellon University, Pittsburgh, Pennsylvania, United States; \(^2\) Physics, Universidad Santiago de Compostela, Santiago de Compostela, Spain.

SrTiO\(_3\), a well-studied incipient ferroelectric material, has been shown to become ferroelectric in certain conditions of strain and temperature, but the effect on its thermal conductivity is unknown. We present measurements of thermal conductivity in Nb doped SrTiO\(_3\) thin films from 80 K to 300 K. Thermal measurements are conducted using Frequency Domain Thermoreflectance on films deposited via Pulsed Laser Deposition on LSAT, STO, and DyScO\(_3\) substrates, which impose 0.95 % compressive strain, no strain, and 1.15% tensile strain, respectively. We measure a large difference in thermal conductivity between the three substrate imposed strains, where compressive strain results in a 3-fold enhancement to thermal conductivity relative to tensile strain at room temperature. We also observe a greater than 60% reduction in thermal conductivity of the tensioned film as we reduce temperature and it becomes fully ferroelectric. Piezoresponsive Force Microscopy measurements are conducted to investigate the role of ferroelectric domain boundaries as a mechanism for the reduction in thermal conductivity in the ferroelectric phase, where ferroelectric domain boundaries serve as scattering sites for phonon transport. These results are critical to memristor and microwave applications that demand ferroelectric materials, because thermal effects play a major role in performance.

SESSION QN04.11: New Simulation Methods
Session Chairs: Keivan Esfarian and Masahiro Nomura
Thursday Afternoon, April 25, 2019
PCC North, 100 Level, Room 124 A
Over the last decade, a new method has been developed that allows for the detailed study of phonon transport in crystalline solids using first principles methods, such as density functional theory. This approach is powerful, because not only does it exhibit excellent agreement with experiments consistently, it is also capable of predicting the properties of new materials and also explaining anomalous behaviors in some materials. This approach, which is usually based on an expression derived using Fermi’s Golden Rule, however, rather implicitly relies on application of what is often termed the phonon gas model (PGM). The PGM is valid and accurate for pure crystalline solids, which do in fact make up a wide range of the materials of interest for applications. However, there is a growing body of evidence that shows that when one deviates far from an idealized perfect crystal e.g., by introducing randomly distributed defects, alloying elements, interstitials or an interface, the PGM often fails. This is because the shape/character of phonons changes when symmetry is broken and as a result, alloys, amorphous materials and interfaces remain a difficult challenge to describe with the accuracy and predictive capability of first principles.

It is in this respect that molecular dynamics (MD) can play an important role, as it in theory has the ability to fill this gap, since it can be rather ubiquitously applied to any class of solid or molecule with full inclusion of anharmonicity, provided that an accurate empirical potential exists to describe the interatomic interactions. Over the last decade several new methods have been developed that allow for direct calculation of the contributions to thermal conductivity and thermal interface conductance, but the key issue that has been challenging to overcome is still the development of accurate empirical potentials to describe the interatomic interactions. This talk will review recent progress that has been made on this issue, and will outline a potential procedure for how one can utilize first principles calculations to inform empirical potentials that are both fast and accurate (i.e., less than 5% error in forces) consistently for virtually any material where phonons are present. The key is to exploit the fact that phonons are only well defined when all of the atoms vibrate about an equilibrium site i.e., there is no diffusion of atoms or chemical reactions occurring during the MD simulation. Treating this as an implicit constraint, it is possible to use a functional form that accurately reproduces the interactions described by first principles calculations, yet is much faster than machine learned potentials. This talk will provide an overview of this approach and will show initial results for example materials – illustrating for the first time an empirical potential that exhibits less than 5% error in forces, less than 5% errors in dispersion and thermal conductivity, yet can also be used to run stable MD simulations with speed faster than commonly employed potentials such as the Tersoff potential.

2:00 PM QN04.11.02
First Principles Calculations of Thermal Transports in Solids and Liquids Marcello Puligheddu1 and Giulia Galli2, 3; Institute for Molecular Engineering, The University of Chicago, Chicago, Illinois, United States; 1Chemistry, The University of Chicago, Chicago, Illinois, United States; 2Material Science Division, Argonne National Laboratory, Argonne, Illinois, United States.

The prediction of the thermal properties of solids and liquids is central to numerous problems in condensed matter physics and materials science, including the study of thermal management of optoelectronic and energy conversion devices. We present two related methods to compute the thermal conductivity of solids and liquids based on ab initio molecular dynamics (MD) at non-equilibrium conditions. Both methods only require calculations of first principles trajectories and atomic forces. We discuss ab initio MD results and computational requirements for solid MgO and liquid water. We compare with experiments and results obtained with classical potentials and, in the case of solids, with results of equilibrium MD simulations and the Boltzmann transport equation [3].

2:15 PM QN04.11.03

Understanding and controlling heat flow on the nanoscale, and through interfaces, is important for applications related to electronics, heat management and thermoelectrics. From a theoretical perspective, the traditional heat flow in Fourier’s law are widely-believed to fail when treating thermal transport on short time- and length-scales. There exists, however, a variety of beyond-Fourier approaches that accurately and rigorously describe nanoscale heat transport, including (among others) the atomistic Green’s function (AGF) method, molecular dynamics (MD), and the Boltzmann transport equation (BTE). Each method has its advantages, from how MD naturally captures anharmonic processes to how the AGF method can provide detailed mode-resolved transmission coefficients, and thus each has proven useful to study and identify important processes and physics.

Over the past few years, we have been working to develop and apply an alternative approach to phonon transport inspired from the lessons of electron transport, referred to as the McKelvey-Shockley (McK-S) flux method. In this talk, I will briefly introduce the McK-S flux method and focus on recent findings from the application of this method to nanoscale and interfacial phonon transport. In particular, the role of ballistic, non-equilibrium, and inelastic scattering effects, which are captured with McK-S, will be discussed. Moreover, I will show how this framework easily handles first-principles phonon dispersions and scattering rates. Owing to its relatively simple form, which promotes physical insights and efficient solutions, and its ability to seamlessly span from the nanoscale to the macroscale, we believe the McK-S method helps complement the existing suite of techniques.

2:30 PM QN04.11.04
Ab Initio Thermal Transport—From Phonon’s Lifetime to Thermal Conductivity Aleksandr V. Chernatynskiy; Missouri University of Science and Technology, Rolla, Missouri, United States.

Ab initio calculations of the thermal conductivity have become routine due to the availability of the several community codes that employ Boltzmann Transport Equation for phonons. An attractive feature of this method is that it gives access not only to the overall thermal conductivity but also to the specifics of the scattering processes for every phonon in the system. Thus, an incredible level of details is emerging which permits to test analytical theories, predict and explain thermal transport properties in a variety of situations or model systems with the additional phonon scattering mechanisms. In this presentation we will review the particulars of the methodology involved, will illustrate its power on the examples of technologically important materials and discuss the applicability of this technique at the limits of high temperature and pressure. To this end, we will consider thermal transport in natural superlattices, Ruddlesden-Popper phases of the SrTiO3 system, phonon lifetimes of the individual phonons in GaAs, and thermal transport in MgO, one of the main constituents of the Earth’s mantle. Results of the simulations will be compared to experiment, where available.

Directional Heat Flux in Phononic Crystals Masahiro Nomura and Roman Anufriev; The University of Tokyo, Tokyo, Japan.

We experimentally demonstrate formation of directional fluxes of ballistic phonons in one- and two-dimensional silicon phononic nanostructures, in which periodic arrays of nano-
holes or corrugations formed directionality of the thermal phonons. This effect makes guiding and even focusing of heat fluxes possible in silicon nanostructures.

First, using micro time-domain thermoreflectance experiments and Monte Carlo simulations, we studied heat conduction in silicon thin films with aligned and staggered periodic arrays of holes. We found that a significant difference in thermal conductivity appears when the characteristic size of the structures becomes smaller than 100 nm and when the temperatures was decreased [1]. This difference was attributed to directional ballistic phonon fluxes that are formed by the aligned lattice of holes.

Next, we performed in nanowires and experiments with phononic compositions in the corrugated nanowires, though the directionality is weaker [2]. Our analysis shows that the directionality depends on the width of the narrow passages and becomes stronger as the passage narrows [1]. Thus, such periodic phononic structures can be used to guide and emit ballistic phonons in solids. To demonstrate this, we coupled the emission from a two-dimensional phononic crystal into one-dimensional nanowires, in which the ballistic path of the phonons was continued in the direction parallel to the wire. Thus, we measured corresponding nanowire length and temperature dependencies [1].

Finally, we used this concept to create thermal lens nanostructures, which can focus thermal energy in the focal point. Our theoretical and experimental results suggest that the created hotspot is smaller than 200 nm in diameter, and thus can be used in biomedicine, thermoelectrics and wherever selective heating is required [1]. The efficiency of this approach is limited only by the scale and quality of the structures. Thus, as the advancements in nanofabrication technology enable further scaling down, complete control over directionality of ballistic heat fluxes in nanostructures becomes real in the near future.

4:00 PM QN04.12.02

Suppression of Propagon Heat Transport in Amorphous Silicon Nitride Phononic Crystals Naoki Tambo1, Chun Zhou2, Elizabeth M. Ashley2, Yuxuan Liao2, Kouhei Takahashi1, Naito Yasuuki1, Junichiro Shiom1 and Paul F. Nealey3; 1Technology Innovation Division, Panasonic Corporation, Seika-cho, Japan; 2Institute for Molecular Engineering, The University of Chicago, Chicago, Illinois, United States; 3Department of Mechanical Engineering, The University of Tokyo, Bunkyo, Japan.

Recent progress in phonon engineering has revealed the effectiveness of nanotechnology on controlling the thermal transport properties of crystalline materials. However, the impact of nanostructuring on amorphous materials has not been examined thoroughly so far. This is surprising given that amorphous materials play a significant role as crystalline materials in various electronic devices. Understanding the thermal transport mechanism of amorphous materials and elucidating the impact of nanostructuring would be highly essential for the management of future electronic devices.

Here, we have studied the impact of ultrafine nanostructuring on the thermal transport properties of amorphous SiN membranes. Samples examined here are SiN, phononic crystals (PnCs) with two-dimensional array of through-holes created at various pitch sizes ranging from 38-1600 nm. Electron beam lithography was used to fabricate SiN PnCs at pitch sizes above 60 nm. On the other hand, directed self-assembly lithography was used to fabricate ultrafine 38 nm-pitch PnCs. Room temperature thermal conductivity \(k\) of the SiN, PnCs were measured by a time-domain thermal reflectance method. We found that \(k\) of SiN strongly depends on the minimum feature size and the surface-to-volume (S/V) ratio of the PnC structure. PnCs at typical pitch sizes of 100-1600 nm whose minimum feature size exceeds 30 nm exhibited \(k > 2.0 \text{ W/mK}\), which was comparable to that of the unpatterned membranes (\(k = 2.5 \text{ W/mK}\)). On the other hand, a significant reduction in \(k\) was observed when the minimum feature size of the PnCs decreased below 30 nm. In these ultrafine PnCs, we found that the reduction in \(k\) is associated with increase in the S/V ratio. This is consistent with the feature reported in crystalline PnCs where diffuse boundary scattering of phonons is enhanced for those that exhibit higher S/V ratios. Recent studies have implied that heat transport in amorphous materials is governed by two types of vibrational modes, i.e., (i) low-frequency propagating modes that increase with relatively long mean free path (MFP) and (ii) high-frequency diffusive mode that decrease with extremely short MFP. The S/V ratio dependence of \(k\) observed here indicates that reduction in \(k\) of the present PnCs is related to enhanced boundary scattering of these propagating modes. Interestingly, we also found that increase in S/V ratio over 0.1 nm\(^{-1}\) does not lead to reduction in \(k\) of SiN, below 1.1 W/mK. This implies that contribution of propagon to heat transport has been suppressed thoroughly by our ultrafine PnC structure, leaving only the diffusions to contribute to heat transport. The present study on amorphous SiN, PnCs demonstrate the effectiveness of multi-scale phonon engineering on material heat transport properties, where we control the high-frequency vibrational modes by the amorphous disorder while that of the low-frequency vibrational modes is controlled by intentional nanostructuring.

4:15 PM QN04.12.03

Thermal Conduction in Titanium Oxide with an Ordered Arrangement of Planar Faults in Nanoscale Shunta Harada1,2, Naoki Kosaka1, Takashi Yagi1, Katsusi Tanaka1, Haruyuki Inui1, Mihoko Tagawa1 and Toru Ujihara1,2; 1Nagoya University, Nagoya, Japan; 2JST PRESTO, Kawaguchi, Japan; 3National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan; 4Kobe University, Kobe, Japan; 5Kyoto University, Kyoto, Japan.

Homologous series of the Magnel phase titanium oxides (Ti\(_{2}\)O\(_{n-1}\)) are reduced phases of rutile-type TiO\(_{2}\) and are so-called crystallographic shear structures, in which dense planar faults are periodically introduced in the mother rutile structure with their spacing depending on the oxygen deficiency. Due to the low thermal conductivity owing to dense planar defects and tunability of their structures, the Magnel phases received great attention to the application of thermoelectric materials. Recently, suppression and control of thermal conduction by a phononic crystal with periodic nanostructure fabricated by lithography, in which the interference of low-frequency phonons occurs, was demonstrated. Similar to the phononic crystal, it is considered that the periodic atomic scaled structure in the Magnel phase suppresses the thermal conduction of high-frequency phonons, which would lead to the heat manipulation at room temperature. In the present study we investigated the structural perfection of an ordered arrangement of planar defects as well as the thermal conduction in the Magnel phase titanium oxide.

The crystal of the Magnel phase titanium oxide were prepared by the reduction annealing of rutile-type TiO\(_{2}\) in vacuo. We observed the (132)\(_{\text{hkl}}\) planar faults were periodically introduced with an interval of 2.9 nm in the prepared crystal. The perfection of the periodic arrangement of the planar faults are very high and the periodicity disorder was evaluated to be as small as 0.036 nm by scanning transmission electron microscopy observation in atomic scale. Furthermore, the structure perfection of the planar faults was also high, and the effect of the planar faults were evaluated to be 0.035 nm. From the specularity parameter calculation using these evaluated values, the periodic arrangement of the planar faults is expected to behave as specular interface for phonons up to 16 THz. Time-dominant thermoreflectance (TDTR) measurements revealed that thermal conductivity is decreased by the introduction of the periodic arrangements of the planar faults. Compared to the rutile-type TiO\(_{2}\), the temperature dependence of the thermal conductivity for the Magnel phase titanium oxide was small. The analysis of the temperature dependences of thermal conductivity by the Debye-Callaway model indicates that the increase of Umklapp scattering is caused by the introduction of the periodic planar faults. The Considering the structural perfection of the periodic arrangement of the planar faults, the fold of the Brillouin zone would result in the increase in the Umklapp scattering.

4:30 PM QN04.12.04

Thermal Transport in Amorphous Phononic Crystals Yuxuan Liao1, Naoki Tambo2, Kouhei Takahashi2 and Junichiro Shiom1; 1The University of Tokyo, Tokyo, Japan; 2Technology Innovation Division, Panasonic Corporation, Kyoto, Japan.

Heat in crystalline phononic crystals (c-PnCs) are carried by lattice vibrations (phonons). It is well known that thermal conductivity \(k\) of c-PnCs can be reduced when the length scales of phononic structures are smaller than phonon mean free paths (the size effect), therefore, c-PnCs have been seen as an effective way to tune \(k\) of crystalline materials [1]. Here, we theoretically show that amorphous phononic crystals (a-PnCs) also play an important role for tuning \(k\) for amorphous materials. Indeed, a large proportion of the heat carriers (atormistic vibration modes) in amorphous solids are diffusons, which are expected to have very short effective mean free paths that comparable to interatomic spacings and therefore can be hardly influenced by the size effect [2]. However, there still exist long-wave-length or low-frequency heat carriers (propagons), which propagate at the speed of sound, can have effective mean free paths exceeding tens of nanometers, and thus contribute to significant proportion exceed the total \(k\), especially their tiny density of states [3]. Therefore, it should be possible to tune \(k\) by scattering propagons with phononic structures. To validate the above reasoning, we firstly prepared several a-PnCs samples for amorphous silicon, silicon and silicon nitride, which are 70 nm thick 2D thin films with periodic cylindrical holes of different diameters. Then, the effective mean free paths of propagons and diffusions are obtained by combining Allen-Feldman theory and normal-mode decomposition method [3,4]. Boundary scattering effects for propagons and diffusions are evaluated by Monte Carlo Raytracing method [5]. The results show that \(k\) of these a-PnCs can be as low as ~0.3 W/m K when the neck sizes between the holes reduced below 10 nm. The low \(k\) suggests that a-PnCs can be used as an effective way for tuning thermal transport in amorphous solids. We will also discuss coherent effect in a-PnCs at low temperatures, where thermal transport is dominated by long-wave-length propagons.

Solid-state thermal rectification, a mechanism in which the magnitude of heat transfer depends on the direction of heat flow, has novel applications in thermal management and nanoscale radiation-based information processing. Several material systems were proposed to achieve this high thermal rectification through radiation. Of particular interest has been the possibility of using phase-transition materials in the thermal near-field. In this talk, we will describe how we demonstrated thermal rectification at the nanoscale between doped Si and VO$_3$ surfaces. In specific, we will show that large differences in heat flow are possible due to the metal-insulator phase transition of VO$_2$. We further show that this rectification increases at systematically controlled nanoscale separations, with a maximum rectification coefficient exceeding 50% at ~140 nm gaps and a temperature difference of 70 K. Our modeling indicates that this high rectification coefficient is due to broadband enhancement of heat transfer between Si and metallic VO$_3$, as compared to narrower-band exchange when VO$_2$ transitions to its insulting state. The results and approaches developed in our work have important implications for probing near-field thermal devices such as diodes and transistors.

Phonon Properties of Confined Thin Films Predicted from a Two-Dimensional Lattice Dynamics Framework. Hyun-Young M. King, Bo Fu, Kevin Parrish and Alan McGaughey.

Thermal transport by phonons in thin films can be rigorously described using a two-dimensional (2D) lattice dynamics (LD) framework. This treatment contrasts the standard approach of assuming that the bulk phonon modes obtained from a three-dimensional (3D) treatment exist in the film and of modifying their mean free paths with a phenomenological boundary scattering model.

A mapping algorithm was developed to directly compare 2D and 3D phonon modes and was applied to Lennard-Jones (LJ) argon and multi-layer graphene films described by an optimized Tersoff potential. The algorithm applies a Fourier transform to the polarization vectors of the 2D modes and projects the results onto the cross-plane wave vectors of the 3D modes. A near one-to-one correspondence was discovered at thicknesses of greater than 20 atomic layers for argon and at all thicknesses for graphene. Deviations for the few-layer argon films are attributed to the inherent differences between the 2D and 3D phonon modes, which is primarily caused by the emergence of anisotropy.

Thermal transport in films built from LJ argon and Tersoff silicon was then investigated in the 2D LD framework. Molecular dynamics (MD) simulations were also performed as a benchmark. Thermal conductivity decreases with decreasing film thickness for both the LD and MD calculations, until the thickness reaches eight atomic layers for argon and twelve for silicon. At this point, thermal conductivity increases with a further reduction in thickness due to the increase in low-frequency modes in the phonon density of states. This finding is opposite to the monotonically decreasing trend predicted from the 3D/boundary scattering model approach.
An alternative approach, the Anharmonic Lattice Dynamics (ALD), implementation of the Boltzmann Transport Equation (BTE) has been successfully adopted for the calculation of thermal properties of semiconductors. In this approach, boundary scattering is customarily modeled through Matthiesen’s rule.

Comparing ALD and NEMD on carbon nanostructures, we show that Matthiesen’s rule fails for modeling phonon transport in the quasi-ballistic regime. We then show how implementing boundary conditions in BTE and enhancing the theory with a systematic treatment of the scattering term one can achieve an excellent agreement between NEMD and ALD results. Finally, we demonstrate how accounting for the effects of spatially resolved out of equilibrium phonon distribution, can provide a detailed physical picture of heat transport in the quasi-ballistic regime.

Sub-Continuum Air Conduction Measurement Between Si Plates with Surface Features Mohammad Ghashami, James R. Bailey and Keunhan Park; Mechanical Engineering, University of Utah, Salt Lake City, Utah, United States.

The conventional mechanism of heat conduction in the continuum regime is by diffusion processes through random collisions of heat carriers, such as electrons, phonons and molecules. However, when the length scale of a heat transfer domain becomes comparable to or smaller than the mean free path of heat carriers (i.e., sub-continuum regime), ballistic energy transport and boundary scattering behaviours of heat carriers significantly alter the heat conduction mechanism [S. Hamian et al., Int. J. Heat Mass Transf. 80 (2015): 781].

In the present work, we experimentally investigate the diffusive-ballistic heat conduction of air molecules between large planar structures when the gap distance is in the sub-continuum regime. In this regime, heat conduction becomes saturated due to ballistic features while thermal radiation is greatly enhanced due to near-field effects such as photon tunnelling and surface phonon polaritons [R. Messina et al., Phys. Rev. B. 94 (2016): 121410]. The precision measurement of the two heat transfer mechanisms should be made in two scenarios: (1) when there is no participating medium between them (vacuum condition), and (2) when air molecules are present in the gap between the two bodies. The differences in the heat transfer rate between case (1) and (2) should result from the contribution of heat conduction through air molecules. To this end, we will be using an experimental setup based on a nanopositioning platform composed of three piezo-motors, providing six degrees of freedom in x-, y- and z-directions and 1 nm-precision rotational resolution [M. Ghashami et al., Phys. Rev. Lett. 120 (2018): 175901]. The net exchanged power (Qth) can be measured from Pth (i.e., power supply to the heater) required to maintain desired temperature at the hot sample (Tth) for different gap distances while Tc (i.e., cold side temperature) can be maintained by the thermoelectric cooler (TEC) at the bottom. The experimental setup is housed in a vacuum chamber that is capable of controlling the partial vacuum pressure precisely. Varying a partial vacuum pressure can change the mean free path of air molecules, which can demonstrate the role of sub-continuum air conduction in planar configurations. Additionally, the role of the surface condition can be further investigated by manipulating the surface roughness on the samples. The obtained results will help us fundamentally understand the sub-continuum heat conduction physics in a nanoscale gap and its competing effect with the near-field radiative heat transfer.

11:30 AM QN04.14.04

Observations of quasiballistic transport behavior, which occurs if a temperature gradient exists over a length scale comparable to the phonon mean free paths, have recently been reported in numerous thermal characterization experiments using ultrafast laser spectroscopies. However, a precise mapping from these observations to mode-dependent information of phonons is challenging. Here, we will first present a generalized Fourier’s law based on Peierls-Boltzmann transport equation that is able to capture quasiballistic transport behavior in experiments. We will show that misinterpreting the generalized Fourier’s law in experiments would lead to erroneous microscopic information of phonons. Second, we will use this derived generalized Fourier’s law to extract phonon transmission coefficients at solid interfaces using a combination of first principles phonon transport and time-domain thermo-refractance technique. Our work provides a useful perspective on how first principles transport theory can be coupled to experiments to develop deeper physical insights into phonon behaviors.

SESSION QN04.15: Near- and Far-Field Radiation

Scanning Thermal Microscopy—Probing Temperature and Heat Dissipation Down to the Few-Nanometers Scale Eloise Guen1, Antonin M. Massoud1, Ali Alkurdı1, Christophe Lucchesi1, Rodolphe Vailllon1, Valeria Lacatena1, Maciej Haras2, Jean-François Rohillard4, Elyes Nezfaouis3, Jean-Marie Bluet1, Sérène Gomès1 and Pierre-Olivier Chapuis1; 1-CNRS - INSA Lyon, Villeurbanne, France; 2, IES, Madrid, Spain; 3, EMM, Lille, France; 4, ESSEE - ESYCOM, Noisy-le-Grand (Paris region), France.

Scanning thermal microscopy (SThM), a technique derived from atomic force microscopy, is applied with different thermoresistive tips, providing down to 10 nm spatial, few mK temperature, and pW/K thermal conductance resolutions [1].

We first discuss original physical features of the technique. In ambient conditions [2], approach curves unambiguously demonstrate ballistic thermal transport in air. In vacuum, the sample exchange behavior is characterized by means of near-field thermal radiation, however this contribution is observed only under certain particular circumstances which will be discussed. In contact with the sample, SThM is found to be especially applicable for characterizing materials with thermal conductivity lower than 3 W.m-1.K-1, but reduced sample area, as in the case of suspended phononic nanomembranes, can allow characterizing thermal conductivity up to ~50 W.m-1.K-1 [3].

In a second step, recent thermal conductivity and thermal boundary resistance results obtained for various set of samples are highlighted, including thin oxide amorphous films down to the native-oxide case and phononic membranes with partially-perforated holes. Thermal transport mechanisms are discussed, in particular when ballistic phonon dissipation takes place and that simulations based on the Boltzmann transport equation for phonons support the experimental results.

The support of projects QUANTIHEAT (FP7-2012 604668), EFINED (H2020-FETOPEN-1-2016-2017 766853), TIPTOP (ANR-16-CE09-0023), DEMO-NFR-TPV (ANR-16-CE05-0013), THERMOS (INSA-BQR-2017) is acknowledged.

2:00 PM QN04.15.02
Thermal Transport Across Nanoscale Vacuum Gaps—Insights From Lattice Dynamics Calculations Combined with Ab Initio Force Constants Merabia Samy1,2, Ali Alkurdı12, Christophe Adessi1 and Konstantinos Termentzidis2; 1Universite de Lyon, CNRS, UCBL, ILM, Villeurbanne, France; 2INSA Lyon, Villeurbanne, France; CNRS, Villeurbanne, France.

Thermal boundary conductance is basically dictated by phonon transmission at interfaces [1], and an accurate prediction at nanoscale is of a great importance for many applications where thermal management is a vital issue. In microelectronics there is a strong need to know how energy can be exchanged across small vacuum gaps having separation distances of few nanometers. Recent experimental studies reported giant heat flux transfer between gold surfaces at nanometer separation distance [2]. Theoretically, it is expected that at such nanometer distances, heat is exchanged primarily by acoustic waves [3], while radiative heat transfer dominates when the gap is larger than a few nanometers [3].

Thermal transport in the quasi-ballistic regime.

Friday Afternoon, April 26, 2019
PCC North, 100 Level, Room 124 A
We have developed a new computational method to probe phonon scattering at interfaces between FCC or diamond like structure materials [4,5]. The idea is to combine lattice dynamics calculations with inputs from ab-initio calculations. Lattice dynamics has been already successfully applied to describe interfacial thermal conductance, but it relies on semi-empirical potentials and lacks the accuracy to describe phonon dispersion curves of bulk materials. Coupling lattice dynamics with interatomic force constants calculated using ab initio calculations opens the way to an accurate description of modal phonon transmission at interfaces.

We used the calculations to probe heat transfer across nanoscale vacuum gaps. We first characterize the thermal conductance due to phonons for silicon/vacuum/silicon and gold/vacuum/gold interfaces [6]. We show that for subnanometric gaps, phonons dominate by far thermal transport even in the presence of air molecules in the gap. Moreover, we demonstrate the major role played by phonon scattering as compared with electron/phonon processes at interfaces [7]. Finally, we compare our ab-initio lattice dynamics results with simplified acoustic mismatch models. We clearly demonstrate that these models fail by several orders of magnitude to describe the thermal conductance across nanoscale gaps. We show that these discrepancies originate from the contribution of intermediate phonon frequencies which are not accurately described by acoustic models.

near-field radiative heat transfer measurements where a set of important parameters are investigated: temperature, geometry and materials. We first consider the configuration of an emitter and a substrate both made of silica, which was already studied in the past but with smaller temperature differences. The large temperature differences (from 100 K to 500 K) allow observing the temperature dependence of near-field radiative heat transfer. Measurements of the near-field conductance are compared to results of the proximity flux (also called Derjaguin) approximation. It is highlighted that the temperature dependence of the exchanged power in the near field is very different to that of the far field, which is another key feature of near field in addition to the distance dependence of the flux.

In a second step, we focus on the influence of the geometry of the substrate on the near-field radiative heat transfer. To do this, we use different patterns (cylinders, lines or grids for examples) etched on a silica substrate, with etching depths ranging from 1 µm to 10 µm, so as to build emitter-substrate distances where the near-field contribution around the patterns is expected to be varying. This experimental work contributes to understanding the behavior of near-field radiation with micron-sized objects smaller than the emitting sphere.

Finally, we investigate the impact of the materials. In particular, indium antimonide (InSb) is investigated as substrate and graphite as emitter. This configuration is attractive for TPV conversion with moderate emitter temperatures (<1000 K) since InSb is a low-energy bandgap material which can be considered for TPV cells [6].

References
substances, the energy transfer picture based on the lattice vibration, that is, phonon propagation, can be effective like in the ordered solid materials. So far, Sääskilahti, K. et al. (Phys. Rev. B, 90 (2014), 134312; Phys. Rev. E, 93 (2016), 052141) and Zhou, Y. et al. (Phys. Rev. B, 92 (2015), 192505) introduced the spectral decomposition of heat current inside solid materials and the solid-liquid interface for the abovementioned purpose. We newly extended the previous expression for spectral decomposition of heat flux in a frequency regime, which is consistent with the MoP (method of plane) expression for heat flux at a control surface proposed by Torii, D. et al. (J. Chem. Phys., 128 (2008), 044504). Thus, our formulation can be applied to arbitrary molecular systems including soft matters, liquids, and “soft” interfaces like the SAM. In order to validate our formulation, we performed molecular dynamics (MD) simulations on the alkanethiolate SAM and water interface, and the proposed spectrum description of heat flux was applied to this system. As a demonstration, the control surface was located at the middle of the SAM, at which multi-body interactions work among covalently bonded atom sets. It was found that thermal energy is mostly exchanged in the lower frequency bands under 15 THz, in which the characteristic vibrational spectrum of atoms is observed from the VDOS analysis. The cumulative heat flux, which is defined by the spectral heat flux integrated over a frequency, converges to the partial heat flux which is the energy transfer associated with inter- and intramolecular interactions. This fact shows our formulation is consistent with the MoP expression at the control surface as expected. We also applied our method with varying the location of the control surface in the SAM-water system and examined microscopic heat conduction mechanisms in the interface systems in a spectral domain.

Spectroscopic Measurements of Heat Transfer at Hybrid Interfaces Using Infrared Pump, Electronic Probe (IPEP) Spectroscopy
Benjamin T. Diroll, Peijun Guo and Richard D. Schaller; NST, Argonne National Laboratory, Lemont, Illinois, United States.

The transfer of thermal energy from the ligand passivating layer to the inorganic core of colloidal nanocrystals is observed using infrared-pump, electronic-probe (IPEP) spectroscopy. Inorganic nanocrystals are excellent model systems for organic-inorganic hybrid interfaces as they have much larger surface-to-volume ratios than bulk solids, which facilitate spectroscopic measurements of weak signals. Such interfaces between disparate materials are challenging to probe by traditional methods. Here, resonant excitation of the hydrocarbon ligand vibrational absorptions results in a transient red-shift of the CdSe nanocrystal excitonic features consistent with heating, as demonstrated by steady-state absorption measurements. The temperature rise can be quantitatively estimated with static absorption/reflection measurements. The time constant associated with heating ranges from 10 ps to 30 ps depending on the sample morphology, static temperature, input fluence, and environment. Although applied here to nanocrystals to measure interfacial heat transfer, IPEP spectroscopy is readily applicable to measure heat transfer with sub-picosecond resolution for any heterogeneous system in which one component has spectrally-isolated molecular vibrations or lattice phonons.

TUTORIAL: Building Understanding of Phonon Transport—Calculations and Experiment
April 22 - April 22, 2019

* Invited Paper

TUTORIAL
Building Understanding of Phonon Transport—Calculations and Experiment
Monday Afternoon, April 22, 2019
PCC North, 100 Level, Room 124 B

This two-part (theoretical and experimental) afternoon tutorial will dive into topics related to: (1) lattice dynamics and phonon thermal transport calculations and (2) measurements of thermal transport that inform our understanding of underlying phonon behaviors. This tutorial is meant to provide background of state-of-the-art theoretical and experimental techniques used to describe thermal transport in materials.

1:30 PM
Theoretical and Numerical Aspects of Phonon and Lattice Transport Calculations
Lucas R. Lindsay; Oak Ridge National Laboratory

Dr. Lucas Lindsay will cover some of the underlying techniques and challenges of describing lattice thermal transport via Peierls-Boltzmann equation methods coupled with density functional theory. A brief discussion of the development and application of these tools will be given, followed by a deeper dive into the numerics involved and highlights of progress toward addressing current challenges (e.g., temperature and disorder).

3:00 PM BREAK

3:30 PM
Techniques and Challenges Associated with Thermal Transport Measurements Spanning Different Length and Time Scales
Amy Marconnet; Purdue University

Dr. Amy Marconnet will provide an introduction to thermal transport measurement techniques spanning a range of length and time scales. A brief discussion of recent key experimental results that have guided our understanding of phonon transport will be emphasized. Open challenges in the field will be highlighted.

Thermal Studies of Nanoporous Thin Films with Increased Periodic Nanopores

Dongehao Xu, Fabian Medina, Yue Xiao and Qing Hao; University of Arizona, Tucson, Arizona, United States.

Nanomaterials introduce new opportunities in tuning the thermal transport for various applications. Among various nanostructured materials, phonon transport within periodic porous structures has been intensively studied for potential applications in thermal management. It is now acknowledged that wave effects of lattice vibrations, i.e., phononic effects, are only important for ultrathin nanoporous structures and at cryogenic temperatures. Experimental evidence is usually found by comparing the thermal conductivities of periodic and aperiodic nanoporous Si films,1,4,5 for measuring the specific heat to justify the phonon dispersion variation.6

In this work, a new approach is proposed to validate the wave effects, simply by comparing the thermal conductivity of the same Si thin film with increased number of nanopores. When phononic effects exist, it is anticipated that the thermal resistance can be largely increased from single to multiple rows of nanopores. Without phononic effects, the thermal resistance of a patterned Si film should linearly increase with the number of nanopore rows. The measured thermal conductivities are compared to frequency-dependent phonon Monte Carlo simulations that assumes incoherent phonon transport and diffusive pore-edge and film-surface phonon scattering.

Identifying Diels-Alder Reactions for Aqueous Thermal Storage Using Density Functional Theory

Evangelos W. Spotte-Smith1, Peiyuan Yu1, Anubhav Jain4 and Ravi Prasher1,2; 1Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Mechanical Engineering, University of California, Berkeley, California, United States.

Thermal storage offers the potential to reduce the amount of waste heat generated by thermal processes and improve overall energy efficiency. Thermochemical storage using reversible reactions has shown considerable potential for high energy density. However, most current thermochemical systems involve the use of at least one gas phase, thus requiring large volumes and reducing energy density. Condensed-phase, particularly all-liquid, thermochemical storage systems are thus highly desirable in order to improve energy density. In this study, we present a computational search for all-liquid thermochemical storage materials based on the Diels-Alder ([4+2] cycloaddition reactions. Using high-throughput density functional theory (DFT) calculations, we determined the enthalpy change $\Delta H_{\text{rxn}}$, entropy change $\Delta S_{\text{rxn}}$, and turning temperature ($T^* = \Delta H_{\text{rxn}} / \Delta S_{\text{rxn}}$) of 54 Diels-Alder reactions that had been performed in an aqueous solvent in the literature. We screened this test set for turning temperature, identifying nine reactions with a turning temperature close to the working temperature range of water (50 - 150 degrees Celsius). Several of these reactions (the exo-reaction between furen and maleimide and the reaction between furan and acrylonitrile) were selectively modified using functional group substitution to generate additional reactions for study. These modified reactions were predicted to display exceptional thermal properties, increasing the heat capacity of water by as much as 58.7% and improving the thermal energy density of water by as much as 33.8%. Graviometric energy densities as high as 0.5598 MJ/kg were predicted. Experimental work to verify the predicted properties of Diels-Alder reactions are ongoing.

Coherent Phonon Transport in a Two-Dimensional Graphene Superstructure

Usama Choudhry, Shengying Yue and Bolin Liao; University of California, Santa Barbara, Santa Barbara, California, United States.

Coherent wave effects of thermal phonons hold promise of transformative opportunities in thermal transport control, but remain largely unexplored due to the small wavelength of thermal phonons, typically below a few nanometers. This small length scale indicates that, instead of artificial phononic crystals, a more promising direction is to examine the wave properties of thermal phonons within hierarchical superstructures matching the thermal phonon wavelength. In this work, we characterize the thermal properties of dodecagraphene (D-[BL1] graphene), a previously unstudied two-dimensional carbon allotrope based upon the traditional graphene structure but containing a secondary, in-plane periodicity. We use density functional theory (DFT) to calculate harmonic and anharmonic interatomic force constants (IFCs), which were then used to calculate the phonon dispersion, scattering rates, group velocities, and lattice thermal conductivity via an iterative solution to the linearized Boltzmann Transport Equation (BTE). We find that despite a very similar atomic structure, D-graphene possesses significantly different thermal properties than that of pristine graphene. At room temperature the calculated thermal conductivity of D-graphene is 600 Wm$^{-1}$K$^{-1}$ compared to 3000 Wm$^{-1}$K$^{-1}$ for graphene. The out of plane acoustic (ZA) mode contribution decreases from 84% in graphene to 47% in D-graphene. We also report a much smaller thermal transport of the presence of three naturally occurring, low frequency optical phonon modes that possess characteristics of phonon answered to arise from a folding of the new acoustic modes and the associated frequency gap opening, a phenomenon also found in superlattices where an out of plane periodicity is introduced. The optical modes make a significant contribution to the thermal conductivity due to enhanced dispersion, comprising over 18% of the thermal conductivity, while the three coherent branches contribute 9% of the total conductivity. The construction of the D-graphene unit cell presents a new method with which the thermal conductivity of 2D materials can be reduced without making drastic changes to its fundamental composition and demonstrates the potential of using coherent phonon effects to significantly modify thermal transport. This work is supported by a Department of Energy Early Career Research Program under award number DE-SC0019244.

The Effect of Doping, Vacancies and Isotopes on the Thermal Conductivity of 2D Materials

Kai Xiao, Xufan Li, Yiling Yu, Liangbo Liang, Mina Yoon, Alexander Puretzky, Christopher M. Rouleau and David B. Geohegan; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

The heterogeneities such as defects and dopants can give rise to exotic electronic properties in 2D transition metal dichalcogenides (TMDs), but to this date, there is no detailed study to illustrate how heterogeneities can be engineered to tailor their thermal properties. Here, through combined experimental and theoretical approaches, we have explored the effect of defects, doping, and metal isotopes on the thermal transport of monolayer 2D TMDs grown by chemical vapor deposition (CVD). We found that doping and defects in a CVD-grown monolayers 2D crystals can significantly affect their thermal conductivity due to the mass induced kinetic energy and potential energy difference. Furthermore, we...
find the isotopically pure monolayer 2D crystals synthesized by CVD can significantly boost their in-plane thermal conductivity resulting from combined effects of the reduced isotope disorder and a reduction in defect-related scattering. Our work demonstrates that heterogeneity engineering can effectively tune the thermal conductivity of 2D TMDs, which is important for thermal properties development and thermal management in 2D electronic and optoelectronic building blocks.

Synthesis science was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences (BES), Materials Sciences and Engineering Division. Characterizations were performed at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.

9:45 AM QN05.01.05
Heat Transport of Anisotropic Nanocellulose Foams Varvara Apostolopoulou Kalkavoura1, Nathalie Lavoine2, Pierre Manier1, Furuta Makito1, Shigian Hu3, Junichiro Shiomi4 and Lennart Bergström1; 1Department of Materials and Environmental Chemistry, Stockholm University, Stockholm, Sweden; 2Department of Forest Biomaterials, College of Natural Resources, North Carolina State University, Raleigh, North Carolina, United States; 3Department of Mechanical Engineering, The University of Tokyo, Tokyo, Japan.

Efficient thermal insulation using materials with a small environmental footprint is essential for sustainable thermal management in buildings. Nanocellulose produced from wood cellulose fibers is a nanosized, renewable, light weight cellulose particle of high aspect ratio which exhibits tunable surface properties and low thermal conductivity. We have previously shown that anisotropic nanocellulose foams prepared by directional freezing exhibit lower thermal conductivity than air (=25 mW/mK) perpendicular to the fibers direction at room temperature.

Here, we will present the heat transfer of anisotropic nanocellulose foams as a function of relative humidity (RH) and temperature (T). Hence, we measure the axial and radial thermal conductivities of anisotropic freeze-casted nanocellulose foams by using a customized hot disk thermal constant analyzer at controlled RH and T. Thermal conductivity measurements have been combined with X-ray diffraction and modelling. The strong dependence of the thermal conductivity on the RH will be related to the interaction of the hygroscopic nanocellulose fibrils with water and humidity-dependence of the directional interfacial thermal resistance. We will also address the effect of the crystallinity and alignment of nanocellulose on the thermal conductivity of anisotropic nanocellulose foams.

SESSION QN05.02: Nanoengineering for Energy Conversion
Session Chairs: Yongjie Hu, Yee Kan Koh, Lucas Lindsay and Amy Marconnet
Monday Morning, April 22, 2019
PCC North, 100 Level, Room 124 B

10:30 AM *QN05.02.01
Transport of Heat, Mass and Charge in Nanostructured Materials Arun Majumdar; Stanford University, Stanford, California, United States.

When materials are nanostructured in the 1-100 nm range, fundamental length scales related to transport are often crossed. In the case of heat transport by phonons, the dominant wavelength at room temperature is typically in the 1-10 nm range. Hence, by nanostructuring to this length scale, thermal transport can be modulated in unprecedented ways. Here I will discuss our observations to reduce thermal conductivity below the “alloy limit” as well as reaching the upper limits of phonon conductance. What has eluded the community is the lower limit, which is likely to occur due to Anderson localization. That is the focus of our current work.

The van der Waals, electrostatic or steric forces between liquid molecules and between liquid-solid interfaces fall in the range of 1-10 nm. When liquids are confined to these length scales, they undergo a variety of transitions that control the liquid, ionic and macromolecular transport, as well as liquid-vapor phase transitions. This talk will discuss what we discovered in nanofluidics, which is forming the basis for new research to probe ions, solvation shells and macromolecules in nanofluidic channels.

Finally, I will discuss our current research to use a new class of oxide material for catalysis of a few redox reactions that are important in energy science. This research will also underscore the need for new experimental probes to study catalysis and surface reactions at nanoscales.

11:00 AM QN05.02.02
On-Sun Testing of a Solar-Thermal Aerogel Receiver Bikram Bhattacharya, Thomas Cooper, Lee Weinstein, Lin Zhao, Elise M. Strobach, Sungwoo Yang, Gang Chen and Evelyn Wang; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The performance of line-focus concentrating solar power (CSP) systems, operating at concentrations <100 suns, is limited by receiver thermal losses. Existing linear CSP receivers rely on spectrally selective surfaces enclosed within cylindrical vacuum tubes to minimize heat loss due to radiation and convection. However, using spectrally selective coatings and maintaining a high-quality vacuum at high temperatures (up to 400 °C) increases cost, reduces durability, and restricts receiver geometry to a cylindrical shape. We have developed a solar thermal aerogel receiver comprising of custom-fabricated highly-transparent thermally-insulating silica aerogels that allow transmission of concentrated sunlight, minimization of thermal losses and enables operation in air. We demonstrate the on-sun performance of the prototype aerogel receiver with a 1 m×10 cm aperture area. The prototype receiver consists of seven monolithic solar-transparent aerogel tiles that cover the solar-absorber consisting of a nanopipe loop connected in series and coated with black Pyronark paint. The receiver is paired with a 6 m×6 m linear Fresnel reflector (LFR) array capable of achieving concentration up to 30 suns. Pressurized Dowtherm A is used as the heat transfer fluid which is heated to temperatures up to 350 °C before entering the receiver section. We performed on-sun measurements for different receiver inlet temperatures and incident flux conditions, and report a peak receiver thermal efficiency >65%.

11:15 AM QN05.02.03
All-Ceramic Multilayer Selective Solar Absorbers for Concentrated Solar Power Yang Li, Chongjia Lin, Dezha Li, Shihe Yang and Baoling Huang; HKUST, Kowloon, Hong Kong.

Concentrated solar power (CSP), also known as high-temperature solar-thermal energy conversion, is a promising solar energy harvesting technology due to its efficient sunlight utilization, and high availability in energy storage. For the sake of higher Carnot efficiency and greater cost reduction, next-generation CSP plants are expected to operate at higher temperatures (≥900 K) than those conventional systems. Selective solar absorbers, as the key components in CSP systems, are required to offer high stability and great selectivity at such high temperatures. Selective solar absorbers based on multilayer metal/ceramic thin films are a kind of low-cost and scalable absorbers fabricated by facile processes such as sputtering deposition. However, their thermal stability and spectral selectivity fall behind those state-of-the-art cermets and photonic absorbers. Previously works demonstrated that multilayer absorbers suffered from a variety of high-temperature degradation cases associated with the metal/ceramic interfaces, including delamination, surface oxidation, and atom diffusion.

In this work, we introduced a TiN IR reflector into the multilayer absorbers to replace refractory metals (W, Ta, Mo, etc.) used in conventional designs; meanwhile, another ceramic material, titanium oxy-nitride (TiNO), was utilized as the absorptive layer due to its tunable absorption properties and excellent compatibility with TiN. Two ceramic anti-reflection layers, ZrO2 and SiO2, with gradient refractive indexes were adopted to reduce the surface reflection, and enhance the sunlight absorption. The fabricated all-ceramic absorber displayed highly selective absorption with a high solar absorptance of 91.2% and an ultralow IR emittance of 15.7% at 1000 K. Consequently, a high solar-thermal
conversion efficiency of 82.1% was achieved under the irradiation of 100 suns. This value is on par with or exceeds the record of state-of-the-art selective absorbers. As expected, the all-ceramic absorber was able to sustain its superior performance at high temperatures up to 800 °C. Both SIM-EDX and depth profiles of elements result reveal that the diffusion and oxidation were effectively suppressed in the all-ceramic structure. Moreover, the delamination was also avoided in the ceramic/ceramic interfaces. Compared with previous multilayer absorbers, this all-ceramic absorber boosted the operating temperature of such low-cost multilayer absorbers by ~300 °C, rendering it suitable for the high-temperature applications in next-generation CSP plants.

11:30 AM QN05.02.04
Rational Surface Nanoengineering for Condensation—From Power Generation to Sunlight-Enabled Anti-fogging of Transparent Materials Dimos Poulikakos; Mechanical and Process Engineering, ETH Zurich, Zurich, Switzerland.

Thermal processes and materials involving phase change, are practically omnipresent in nature and technology. Viewed in the direction of decreasing temperature, the encountered phase transitions are condensation, freezing and de-sublimation. All share significant scientific challenges in terms of material/surface engineering to control nucleation and growth of the generated phase on a surface, and assure its continuous and facile, passive removal from the surface, to maintain surface functionality and robust performance at a high level, depending on the application of interest. Here, I will focus on the rational, physics-derived, surface nanoengineering, for condensation applications, ranging from power generation targeting high efficiency, to sunlight-driven fogging retardation and rapid defogging of transparent materials.

Enhancing the thermal efficiency of a broad range of condenser devices requires means of achieving sustainable dropwise condensation on metallic surfaces, where heat transfer can be further enhanced by facilitating a reduction in the droplet departure diameter. I will present a novel approach, based on sunlight absorbing metasurfaces, which goes well-beyond state-of-the-art anti-fogging methods such as superhydrophilic coatings. We rationally nanoengineer such transparent metasurfaces, by varying the concentration of embedded plasmonically enhanced light absorbing nanoparticles in an ultra-thin titania film to achieve broadband absorption with tunable transparency. Such surfaces upon illumination induce significant heating at the air-substrate interface where fog is most likely to form and can rapidly de-fog or completely inhibit fog nucleation altogether, Ref. 3. For the same environmental conditions, we demonstrate that such metasurfaces are able to reduce defogging time by up to four-fold compared to reference samples and markedly outperform the most widely implemented solution in anti-fogging, namely, superhydrophilic surfaces. This approach works paves the way for large-scale, low-cost manufacturing that can be applied to a versatile range of materials, including polymers and other flexible substrates, which can further be combined with state-of-the-art technology to overcome remaining impracticalities, safety, and energy-related costs related to fogging.

SESSION QN05.03/QN04.01: Joint Session: Nanoscale and Nonequilibrium Thermal Transport
Session Chair: Ali Shakouri
Tuesday Morning, April 23, 2019
PCC North, 100 Level, Room 124 B

10:30 AM QN05.03.01/QN04.01.01
Nanoscale Thermal Metrology Using SEM, TEM and Confocal Microscopy Chris Dames 1,2; 1University of California, Berkeley, Berkeley, California, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

I will review several collaborative efforts at developing new non-contact methods for heating and thermometry at the nanometer scale. Examples include techniques based on SEM (e-beam as a point heater; secondary electron yield as a thermometer), TEM (thermometry using the Debye-Waller effect), and confocal microscopy (luminescence thermometry of individual nanoparticles).

11:00 AM QN05.03.02/QN04.01.02
A Multi-Temperature Model for Non-Equilibrium Thermal Transport Xiulin Ruan; Purdue University, West Lafayette, Indiana, United States.

Conventionally, the two-temperature model has been widely used for electron-phonon coupled non-equilibrium thermal transport. However, many recent applications have shown that different phonon branches can be in strong thermal non-equilibrium. Therefore, assuming a local equilibrium lattice can lead to misleading or wrong results. Here, we present a multi-temperature model to capture the non-equilibrium among different phonon branches, and demonstrate its advantages over the conventional two-temperature model for bulk materials and across interfaces.

11:15 AM QN05.03.03/QN04.01.03
Specular Reflection Creates Lowest Thermal Phonon Conductivity Martin Maldovan; Georgia Institute of Technology, Atlanta, Georgia, United States.

The thermal conductivity of materials is not a fixed physical property but can be manipulated by controlling the transport properties of thermal phonons. Recently, a large number of experiments have been introduced where thermal conduction is reduced by orders of magnitude via phonon mean free path reduction through diffuse surface scattering. In contrast to established work that use the diffuse surface scattering of phonons as the physical mechanism to reduce the thermal conductivities, in this talk we show that the largest reduction of thin film heat conduction is achieved via specular scattering. Our results thus create a new paradigm for heat conduction manipulation since smooth surfaces – in contrast to rough surfaces – can be more effective on suppressing thin film phonon heat conduction.

11:30 AM QN05.03.04/QN04.01.04
Phonon Heat Conduction and Nanoscale Disorder—From Scatterings to Localizations Sebastian Volz; CNRS–University of Tokyo, Tokyo, Japan.

Effect of structural disorder on phonon thermal conduction remains an open question with a large spectrum of physical effects, as the plane-wave description of atomic vibrations is expected to become irrelevant. In a first stage, atomic scale disorder will be investigated in various systems – silicon [1], SiGe nanowires [2], partial-crystal partial-liquid [3], 2D [4,5] - with atomic scale simulations. Secondly, thermal properties of nanoscale random materials [6,7] will be presented to raise the question of the eventual impact of localization on heat conduction.

Molecular Engineered Polymer with High Thermal Conductivity

Polymers have entered almost every aspect of modern life, from packaging and soft robotics to aerospace sector and 3D printing. Traditional polymers are both electrically and thermally insulating. The discovery and development of electrically conductive polymers has led to innovative electronic applications such as flexible displays, wearable biosensors and lightweight photovoltaics. As in the case of electrically conductive polymers, the development of thermally conductive polymers would open up a range of advanced thermal applications including an emerging self-cooling system to existing electronics casings. This talk will summarize our recent work on improving thermal conductivity of polymers. We developed scalable polyethylene films with thermal conductivity ~62 W/mK by extrusion and roll-to-roll drawing processes. Structural studies and thermal modeling reveal that the film consists of nanoparticles with crystalline and amorphous regions, and the amorphous region has a remarkably high thermal conductivity of ~16 W/mK. We grew thermally conductive conjugated polymer by bottom-up oxidative chemical vapor deposition technique, and realized high thermal conductivity ~2.2 W/mK in conjugated polymer (P3HT) thin film by engineering both inter- and intramolecular interactions and taking advantage of both strong C=C covalent bonding along the extended polymer chain and strong π-π stacking noncovalent interactions between chains. We will also discuss our current work on enhancing heat conduction in hydrogels. This work is supported by Department of Energy—Basic Energy Sciences under award number DE-FG02-02ER45977.

Optical phonon linewidth is crucial to infrared dielectric function of polar materials and thermal conductivity of certain materials that have a large number of optical phonon branches. The current understanding of optical phonon linewidth is associated with three-phonon scattering. In this work, however, we show that four-phonon scattering can dominate the optical phonon linewidth and infrared optical properties at elevated temperatures for a range of important materials, including cubic boron arsenide (BAs), cubic silicon carbide (3C-SiC), and α-quartz. Strikingly, in large band gap-materials, e.g., BAs and AlSb, four-phonon scattering rates are found to be orders of magnitude higher than three-phonon scattering rates even at room temperature. The predicted infrared optical properties of α-quartz after including four-phonon scattering can well explain experimental measurements.

Heat dissipation has become an increasingly important technological challenge in modern electronics. Discovering new high thermal conductivity materials that can efficiently dissipate heat from hot spots and improve device performance are urgently needed. In this talk, I will describe our recent progress in developing emerging high thermal conductivity semiconductors including boron arsenide (BAs) and boron phosphide (BP). We synthesized BAs and BP single crystals without detectable defects, and measured a room temperature thermal conductivity of 1300 W/mK [1] and 500 W/mK [2] respectively. Our ultrafast spectroscopy study in conjunction with atomistic theory reveals that the unique band structure of BAs allows for very long phonon mean free paths and strong high-order anharmonicity through the four-phonon process. The single-crystal BAs has the highest thermal properties among all common metals and semiconductors. In addition, I will briefly discuss our efforts in characterizing thermal boundary resistance and integrating BAs and BP with high-power electronics for near-junction thermal management applications through the combination of measurement and atomistic simulations. Our study establishes BAs and BP as new benchmark materials for thermal management applications, and exemplifies the power of combining experiments and ab initio theory in new materials discovery.

Condensation and boiling are integral processes in many industrial applications including power generation, HVAC, and thermal management of electronic systems. Current efforts aimed at increasing heat transfer during these processes predominantly focus on altering either the chemistry or the texture of the solid-fluid interface. In this talk we will expand beyond these two design variables and will discuss how softening of these surfaces impacts droptime condensation [1] and nucleate boiling [2]. An intriguing component of these phase change processes on soft surfaces is that both microscale droplets and bubbles can significantly deform such materials through Laplace pressure and capillary force at the triple phase contact line. We first discuss how these elastocapillary processes impact heat transfer during condensation across individual droplets as well as their nucleation, growth, and shedding. By integrating these trends over droplet population, we show that softening of the surfaces below shear modulus of about 500 kPa is detrimental to dropwise condensation. In contrast, we use theoretical arguments to show that softening of the surface could significantly facilitate onset of nucleate boiling (ONB). Specifically, we use classic kinetic theory to show that softening of a smooth-surface could mildly decrease superheat needed for ONB. We also discuss a close-form model of vapor trapping and bubble seeding from soft surfaces with conical cavities to show that superheat needed for ONB decreases linearly with shear modulus of the surface. Thus, our work shows that boiling could be manipulated using mechanical properties of the surface. We will also briefly discuss practicalities involved in implementing soft surfaces in boilers and some of the remaining outstanding fundamental questions.

A novel solar heating (SH) and radiative cooling (RC) system based on black surface with selective cover (BS-S) is proposed. This system can provide heat via photothermal conversion and obtain cooling energy by radiative cooling. Photonic approach is applied to design selective cover for SH-RC system. The selective rigid cover consists of a 500 μm-thick zinc sulfide (ZnS) substrate and alternating layers of ZnS and ytterbium fluoride (YbF3) with varying thicknesses. It has strong and remarkably spectral selective characteristics. The transmissivity in SH band (i.e., 0.3–2.5 μm) and RC band (i.e., 8–13 μm) is approximately 0.85, the reflectivity in wavelength band 3–8 μm is approximately 0.70. With the selective rigid cover, air pressure between the cover and black surface could be low (maybe even vacuum) to suppress heat conduction and heat conduction. Numerical analysis demonstrates that in SH process, when surface temperature is 80 °C, the vacuum BS-S case shows a thermal efficiency of 45.9%, approximately 11.5% higher than that of the typical air pocket BS-S case. In RC process, the equilibrium temperature of the vacuum BS-S case and the typical air pocket BS-S case are lower than those of ambient air by approximately 28.9 °C and 22.5 °C, respectively. This selective rigid cover provides an alternative choice for integrating combined SH-RC system and has potential to enhance the performance of the diurnal solar heating and nocturnal radiative cooling processes.

Liquid-vapor phase change is essential in many applications including water purification, power generation, and thermal management. However, effectively utilizing these processes requires detailed understanding and manipulation of interfacial transport. In the first part of the talk, we discuss evaporation from ultra-thin nanoporous membranes.
Tunable Thermal Transport and Reversible Thermal Conductivity Switching in Topologically Networked Bio-Inspired Materials

simultaneously when coated on various IR reflectors, including Au, stainless steel, Al, and TiN. Particularly, the absorbers with Au reflectors exhibited a high solar absorptance of perhydropolysilazane (PHPS) solution, acted as the protection and anti-reflection coating. Both full-spectrum sunlight absorption and strong IR reflection were achieved resonance wavelengths. Due to the in-plane plasmonic coupling of adjacent TiN nanoparticles, the resonance wavelength was able to red-shift to near-infrared (NIR) range. As a switch, offering the possibility of engineering thermally conductive biological materials with dynamic responsivity to heat. This on/off ratio in thermal conductivity switching is over a factor of three larger than the current state-of-the-art thermal atomic vibrations. By varying the network topology, or crosslinked structure, of squid ring teeth-based bio-polymers through tandem-repetition of DNA sequences, we show that modulate the thermal conductivity of topologically networked materials by nearly a factor of four following hydration, through manipulation of the displacement amplitude of conductivity switches have resulted in only modest on/off ratios, since only a relatively narrow portion of the phononic spectrum is impacted. Here, we report on the ability to augment the thermal conductivity of topologically networked materials with dynamic responsivity to heat.

A Framework for Continuum Simulations of Interfacial Phase Change Processes Anirban Chandra1, Pawel Keblinski1, Onkar Sahni1 and Assad A. Oberai2; Rensselaer Polytechnic Institute, Troy, New York, United States; University of Southern California, Los Angeles, California, United States.

Continuum-scale simulations of phase change processes are essential for assisting the design of engineering systems, such as heat pipes and combustion chambers. To quantitatively predict the rate of the phase change in micro-scale systems it is imperative to properly account for the boundary conditions at the interface between phases. For example, in liquid-vapor phase change simulations, the typical continuum assumptions are, a) temperature is continuous at the interface, and b) vapor density near the interface is equal to the saturated density. Results of molecular dynamics (MD) simulations have indicated that in many situations such assumptions are not satisfied. To address these issues, we present a framework for continuum simulations capable of relaxing the aforementioned assumptions. We use finite elements to solve the Navier-Stokes equations while correctly accounting for the flux jump conditions at the interface. Expressions for phase change rates and temperature jumps are obtained from theoretical considerations and augmented by MD simulations. Problems including the burning of solid propellants and evaporation/condensation of liquids are discussed.

High-Performance Solution-Processed TiN/SiOx Selective Absorbers for Solar Thermophotovoltaic Energy Conversion Yang Li, Chongjia Lin and Baoling Huang; Mechanical and Aerospace Engineering, The Hong Kong University of Science and Technology, Kowloon, Hong Kong.

Solar thermophotovoltaic (STPV) systems, which leverage the benefits of both solar-thermal and photovoltaic (PV) technologies, involve efficient and dispachable approaches to generating electricity. The key components in a STPV system include a selective solar absorber, a selective emitter, and a solar cell at least. The total input power of a STPV system is determined by the sunlight absorption efficiency of the selective absorber. Considering the high operating temperatures of STPV systems, selective absorbers are required to maintain high absorption for solar radiation and low emission beyond a cut-off wavelength in the infrared region to avoid thermal re-radiation even at elevated temperatures. To date, almost all the state-of-the-art selective absorbers/emitters such as cermets and photonic crystals with superior performance (i.e., high selectivity and high thermal stability) were generally manufactured with complicated and expensive micro-fabrication or nano-fabrication techniques, leading to high cost and challenges for large-scale production. Moreover, the obtained absorbers/emitters often encounter problems when being integrated with solution-processed solar cells. Therefore, developing high-performance solution-processed absorbers/emitters is urgently demanded.

Tunable Thermal Transport and Reversible Thermal Conductivity Switching in Topologically Networked Bio-Inspired Materials John A. Temple1, Abdon Pena-Francesch2, Huhun Jung2, Madhusudan Tyagi3, Benjamin Allen2, Melik Demirel2 and Patrick Hopkins1; 1University of Virginia, Charlottesville, Virginia, United States; 2The Pennsylvania State University, University Park, Pennsylvania, United States; 3Max Planck Institute for Intelligent Systems, Stuttgart, Germany; 4NIST Center for Neutron Research, Gaithersburg, Maryland, United States.

The dynamic control of thermal transport properties in solids must satisfy the fact that phonons are inherently broad-band. Thus, efforts to create reversible thermal conductivity switches have resulted in only modest on/off ratios, since only a relatively narrow portion of the phononic spectrum is impacted. Here, we report on the ability to modulate the thermal conductivity of topologically networked materials nearly by a factor of four following hydration, through manipulation of the displacement amplitude of atomic vibrations. By varying the network topology, or crosslinked structure, of squid ring teeth-based bio-polymers through tandem-replication of DNA sequences, we show that this thermal switching ratio can be directly programmed. This on/off ratio in thermal conductivity switching is over a factor of three larger than the current state-of-the-art thermal switch, offering the possibility of engineering thermally conductive biological materials with dynamic responsivity to heat.

Effective system energy management and cooling solutions is critical for a range of increasingly complex systems and missions. Various industries and agencies seek technologies and design techniques to cool ultra-high heat fluxes in various applications, and thereby increase system energy efficiencies in future advanced lasers, radars and power electronics. There has been an increasing interest in exploiting the use of additive manufacturing in developing nontraditional cooling schemes to be built directly into components. This study investigates the heat transfer and pressure loss performance of additively manufactured micro-channel heat exchanger. A heat exchanger of 30 micro-sized channels was manufactured via the Direct Metal Laser Sintering (DMLS) method and tested at a range of Reynolds numbers. Same test setup and configurations have been used to test the DMLS manufactured micro-channel heat exchanger, and the results are compared to the mini-channel heat exchanger of similar dimension but manufactured traditionally. The results have shown that although DMLS manufactured micro-channel heat exchanger yield a higher-pressure loss, it has shown significantly improved convective heat transfer compared to the mini-channel heat exchanger tested under same conditions but fabricated traditionally. It is likely that non-post processed surface of the DMLS manufactured micro-channels is the main contributor of this augmented heat transfer. Future study is needed to further understand the mechanisms behind the phenomena observed here.
Lithium-ion batteries (LIB) have found a wide range of applications in many consumer products in the last 25 years. In particular, Navy and Marine Corps has various applications using LIB and safe battery technologies are critically needed. One of the most important safety considerations for LIB cells is thermal stability under various abuses such as exposure to heat, nail penetration, external short circuit, crushing, and so on. Several exothermic reactions can occur as the inner cell temperature is increasing, and if the heat generation is larger than the dissipated heat to the surroundings, this leads to heat accumulation in the cell and acceleration of the chemical reactions, which can then lead to a thermal runaway. Since the behavior of batteries is strongly affected by the interaction of physics on varying length and time scales: a multi-physics and multi-scale model is needed to simulate this process. While many approaches have been reported in literature, they are not directly applicable in large-format LIB cells and the development of multi-scale and multi-physics models are relatively limited and still computational expensive. For example, in large formatted battery cells, the uniformity of the electrical potential along the current collectors in the cell composites is no longer given. Additionally, due to the inhomogeneity of the distribution of the temperature field with respect to the cell geometry, thermal dynamics must also be taken into account. This study reports the recently developed multi-scale and multi-physics model for simulating the thermal runaway inside a large-format Lithium-ion battery using COMSOL software. For the electrochemical processes, the porous electrode theory with contributions coming from exothermic side reactions is used to model abuse mechanisms, which could lead to a thermal runaway. For the thermal-mechanical processes, models of thermal abuse reactions that occur at specific elevated temperatures have been simulated. Prior experimental data on a large-scale lithium-ion battery tested at NSWCCD has been used to construct and validate the model with good agreement.

Manipulating heat conduction is an appealing thermophysical problem with enormous practical implications, which requires insights into the lattice dynamics. Strain engineering is one of the most promising and effective routes towards continuously tuning the thermal transport properties of materials due to the flexibility and robustness. However, previous studies mainly focused on quantifying how the thermal conductivity is affected by strain, while the fundamental understanding on the electronic origin of why the thermal conductivity can be modulated by mechanical strain has yet to be explored. In this talk, I would like to present our comparative study of thermal transport in two-dimensional group III-nitrides (h-BN, h-AlN, h-GaN) and graphene. Although the monolayer group III-nitrides possess similar planar honeycomb structure with graphene, their thermal conductivity is substantially lower and the root reason cannot be intuitively attributed to the mass difference. We then establish a microscopic picture to connect phonon anharmonicity and lone-pair electrons. Direct evidence is provided for the interaction between lone-pair electrons and bonding electrons of adjacent atoms based on the analysis of orbital-projected electronic structures, which demonstrates how nonlinear restoring forces arise from atomic motions and lead to strong phonon anharmonicity. The microscopic picture of lone-pair electrons driving strong phonon anharmonicity provides coherent understanding of the diverse thermal transport properties of the monolayer group III-nitrides compared to graphene. Furthermore, the thermal conductivity (κ) of planar monolayer group III-nitrides is unexpectedly enlarged by up to one order of magnitude with bilateral tensile strain applied, which is in sharp contrast to the strain induced κ reduction in graphene despite their similar planar honeycomb structure. The anomalous positive response of κ to tensile strain is attributed to the attenuated interaction between the lone-pair electrons around N atoms and the bonding electrons of neighboring (B/Al/Ga) atoms, which reduces phonon anharmonicity. The microscopic picture for the lone-pair electrons driving phonon anharmonicity established from the fundamental level of electronic structure deepens our understanding of phonon transport in 2D materials and would also have great impact on future research in micro-/nanoscale thermal transport such as materials design with targeted thermal transport properties.

We report the electrothermal properties of AZO/Ag/AZO (AAA) trilayer on PET, which helped us develop a low cost high performance transparent flexible electrode and heater (TFEH) using RF magnetron sputtering. The thickness of the Ag interlayer (~5-7.5 nm) in the AAA trilayer was varied, and its electrical, optical and structural properties was thoroughly investigated. At optimized Ag interlayer thickness of 5 nm, the AAA trilayer based TFEH yielded saturation temperatures beyond 100 °C at 10 V which makes it a suitable energy efficient device. The time dependent temperature profile along with its highly stable and reversible thermal behavior demonstrated that it is a promising low cost TFEH device that can be developed industrially on large areas using RF magnetron sputtering. Most importantly the AAA trilayer based TFEH provides a high-performance alternative to the conventional ITO electrodes at a much lower cost.

We present new composite with significantly improved Thermal Conductivity (TC) that comprises a continuous network of thermally conductive fillers and a natural polyl. The network of thermally conductive filler, in this case boron nitride nanosheets (BNNS), was an aerogel that was fabricated with the ice template method. Subsequently, the aerogel was carbonized and filled with xylitol with help of vacuum infiltration of liquefied xylitol. The aerogel provided a 3D thermal conductive pathway and also acted as a scaffold to form a network of thermally conductive filler, in this case boron nitride nanosheets (BNNS), was an aerogel that was fabricated with the ice template method. Subsequently, the aerogel was carbonized and filled with xylitol with help of vacuum infiltration of liquefied xylitol. The aerogel provided a 3D thermal conductive pathway and also acted as a scaffold to provide the oriented crystallization of xylitol. Our results demonstrate that the BNNS scaffold and packing of oriented xylitol crystals play a key role in improving TC of the composite. With BNNS content of 18.16 wt% (6.14 vol %) TC of above 4.5 W/mK, which is higher than that reported in recent literatures, was obtained.

Van der Waals Confinement Enhances Phonon Transport by Reducing Atomic Thermal Displacement Magnitudes Xiaoxiang Yu1, Dengke Ma1, Chengcheng Deng1, Xiao Wan1, Meng An1, Han Meng1, Xiaobo Li1, Xiaoming Huang1, and Nuo Yang1; 1Huazhong University of Science and Technology, Wuhan, China; 2Shaanxi University of Science and Technology, Xi’an, China.

The van der Waals (vdW) interactions exist in reality universally and play an important role in physics. Here, we show the study on the mechanism of vdW interactions on phonon transport in atomic scale, which would boost developments in heat management and energy conversion. Commonly, the vdw interactions are regarded as a hindrance in phonon...
transport. Here, we propose that the vdW confinement will enhance phonon transport. Through molecular dynamics simulations, it shows that the vdW confinement makes more than two-fold enhancement on thermal conductivity of both polyeleynyl single chain and graphene nanoribbon. The quantitative analyses of morphology, local vdW potential energy and dynamical properties are carried out to reveal the underlying physical mechanism. It is found that the confined vdW potential barriers reduce the atomic thermal displacement magnitudes, thus lead to less phonon scattering and facilitate thermal transport. Our study offers a new strategy to modulate the heat transport.

QN05.06.11
Effect of Pressure on Thermal Conductivity of Oxide Glasses Jihui Nie, Siddharth Sundararaman, Liping Huang and Pawel Keblinski; Rensselaer Polytechnic Institute, Troy, New York, United States.

We use molecular dynamics simulations to determine the pressure-induced structural changes in several oxide glasses including permanent densification and the effect of these changes on thermal properties. We show that densified glass structures exhibit increased thermal conductivity, which may be attributed to the increased density and elastic modulus. The local properties analysis reveals that the higher-pressure treatment reduces elastic heterogeneities, which might also contribute to higher thermal conductivity of densified glasses.

QN05.06.12
Electrical, Optical and Thermal Properties of Different Metal Doped Zinc Oxide Thin Film for Flexible Transparent Heater Jasmine Beckford, Monree K. Roul, Makkes K. Behera, Kelsey Yarbrough, Sangram K. Pradhan and Messiah Bahoura; Norfolk State University, Norfolk, Virginia, United States.

Gallium doped zinc oxide (GZO) and Aluminum doped zinc oxide (AZO) thin films were often grown on substrates such as glass, flexible polyethylene terephthalate substrate through using physical vapor deposition technique. The thin films were ultra-smooth in nature and showed outstanding optical, and electrical properties. Highly compact and dense PLD target was made in the laboratory fromAl2O3, Ga2O3 and ZnO powder in an appropriate proportion with a less than 10 atomic weight percentages of Ga and Al followed by isotropic press as well as high temperature annealing (1200 °C) for 12 hours. AZO thin films show stable and reproducible Joule heating effect of more than 100°C by the application of low (~10 V) voltages. GZO transparent heater also showed a stable and reproducible Joule heating effect and the temperature can reach easily close to the 100°C by the application of low input (8V) voltages. The samples showed low resistivity of about 2.6×10⁻³ Ω cm and 3.7×10⁻³ Ω cm and also exhibited high optical transparency value in the visible region of the electromagnetic spectrum. The temperature dependent resistivity behavior of the films were investigated using four-point probe technique. This exciting results encourages the use of GZO and AZO transparent oxide in different optoelectronics device application.

QN05.06.13
Thermal Conductivity Tuning in Drilling Fluid by Bentonite Functionalization SungHyun Hong and Soo Young Kim; Chung-Ang University, Seoul, Korea (the Republic of).

Advances in nanotechnology have contributed to dramatically increasing the thermal conductivity of fluids. Nanoparticles with high thermal conductivity have a high surface area relative to their mass and thus increase the thermal conductivity of the fluid more efficiently with a small amount of addition. However, unlike a pure solution such as DI water, complex fluids such as drilling mud have a large influence of other components so not too much increase the thermal conductivity through the addition of nanoparticles. Therefore, we do not simply add nanoparticles but use a method to increase the thermal conductivity by growing ceramics with high thermal conductivity directly on the solid particle surface added to the complex fluid. Synthesis of nanoparticles using the conventional bottom-up method was inferior in terms of cost and yield compared to synthesizing nanoparticles in a top-down method. But it is expected that only small amounts of nanoparticles will have a great effect, if the particles are synthesized only on the surface of the other particles by the bottom-up method. We made drilling mud after functionalization of ceramics (BN, SiC, MoS₂, WS₂) with high thermal conductivity on bentonite surface which is the most important additive substance to drilling mud. Thermal conductivity of the drilling mud was compared with the conventional method in which the same amounts of nanoparticles were simply mixed in the conventional method in which the same amounts of nanoparticles were simply mixed in the drilling mud. We also measured the FE-SEM, RAMAN, and XPS to check the growth of the particles on the bentonite surface and measured the viscosity according to the flow rate to confirm the performance as a drilling mud. We report how to increase the thermal conductivity of a complex fluid in a different way than previously.

QN05.06.14
Thermal Properties of Binary Filler Composites with Graphene and Boron Nitride Jacob S. Lewis, Andres Sanchez Magana, Sahar Naghibi, Zahra Barani, Ruben Salgado, Fariborz Kargar and Alexander A. Balandin; Phonon Optimized Engineered Materials (POEM) Center, Department of Electrical and Computer Engineering, Materials Science and Engineering Program, Bourns College of Engineering, University of California, Riverside, California, United States.

The exceptionally high thermal conductivity of graphene has driven interest toward its applications in thermal interface materials (TIMs) [1-3]. In addition to its unique heat conduction properties, graphene is also a strong conductor of electricity, which is problematic for certain TIM applications where electrical insulation is paramount. A common strategy for the optimization of composite materials is to combine two or more different thermally conductive fillers. Typically, work along this vein employs fillers of disparate size, shape, and aspect ratios with the larger-sized fillers providing the greatest contribution of overall thermal transport and the smaller fillers improving the interstitial thermal transport between the larger fillers. Unlike much of the previous work into binary fillers, we report on polymer composites filled with few-layer graphene and hexagonal boron nitride (h-BN) of similar lateral dimensions, thicknesses, and aspect ratios. In each filler material, phonons are the primary heat carrier, necessitating the selection of lateral dimensions larger than the “gray” phonon mean free path (MFP) in the micrometer distance range. The composition and structure of the resulting epoxy-based composites were verified using scanning electron microscopy (SEM), Raman, and Brillouin spectroscopy. Thermal measurements were conducted using the “laser flash” techniques. It was found that the use of electrically conductive graphene and electrically insulating h-BN fillers of similar physical dimensions can be complementarily leveraged to achieve an independent control of the thermal and electrical conductivity of the TIM. Varying the constituent fraction of graphene in composites with ~44% filler loading can tune the thermal conductivity enhancement from a factor of ~15 to ~34 while changing the electrical resistivity from 3×10⁴ Ω-mm to 10⁵ Ω-mm, i.e. spanning the resistivity range from an insulator to a conductor. We offer an analytical model of a factor that describes the experimental thermal conductivity data of the binary filler composites. The obtained results are illustrative of a promising strategy for the development of next-generation thermal interface materials with specific control of electrical properties, allowing for the expression of electrically insulating or electrically grounding behaviors.

QN05.06.15
Phononic Topological Insulators Based on Six-Petal Holley Silicon Zao Yu, Ren Ren and Jaeho Lee; University of California, Irvine, Irvine, California, United States.

Since the discovery of the Quantum Spin Hall Effect, electronic and photonic topological insulators have made substantial progress, but phononic topological insulators in solids have received relatively little attention due to challenges in realizing topological states without spin-like degrees of freedom and with transverse photon polarizations. Here we present a holley silicon-based phononic topological insulator design, in which simple geometric control enables topologically protected in-plane elastic wave propagation up to GHz ranges when the unit cell reaches submicron scales. By incorporating a hexagonal lattice of six small holes with one large hole in the center and by creating a hexagonal lattice by themselves, the six-petal holley silicon, which has C₆ symmetry, induces zone folding to form a double Dirac cone. Based on the hole dimensions, breaking the discrete translational symmetry allows the six-petal holey silicon to achieve the topological phase transition, yielding two topologically distinct phononic crystals. Based on the unit cell periodicity, the transition readily shifts from low- to high-frequency ranges. Our numerical simulations confirm inverted band structures and show backscattering-immune elastic wave transmission up to 90% at 14.83 GHz through defects including a cavity, a disorder, and sharp bends when the unit cell periodicity is 500x3 nm. The six-petal holey silicon design also offers robustness against geometric errors and potential fabrication issues such as over- or under-etching. The simulations of the six-petal holey silicon with the same periodicity show up to 90 % transmission of elastic waves at 13.8 and 15.37 GHz even when the holes are under-sized by 5 % or over-sized by 2.5 %, respectively, in which the shift of bandgap is led by the change of porosity. These findings provide a detailed understanding of the relationship between geometry and topological properties and pave the way for the development of next-generation elastic wave devices.
Spectral emissivity control is critical for optical and thermal management in the ambient environment because solar irradiance and atmospheric transmissions occur at distinct wavelength regions. For instance, selective emitters with low emissivity in the solar spectrum but high emissivity in the mid-infrared can lead to significant radiative cooling. Ambient variations require not only spectral control but also a mechanism to adjust the emissivity. However, most selective emitters are fixed to specific wavelength ranges and lack dynamic control mechanisms. Here we show ultraviolet to mid-infrared emissivity control by mechanically reconfiguring graphene, in which stretching and releasing induce dynamic topographic changes. We fabricate crumpled graphenes with pitches ranging from 40 nm to 10 μm using deformable substrates. Our measurements and computations show that 290-nm-pitch crumpled graphene offers ultraviolet emissivity control in 200-300 nm wavelengths whereas 10-μm-pitch crumpled graphene offers mid-infrared emissivity control in 7-19 μm wavelengths. Significant emissivity changes arise from interference induced by the periodic topography and selective transmissivity reductions. Dynamic stretching and releasing of 290-nm- and 10-μm-pitch crumpled graphene show reversible emissivity peak changes at 250 nm and at 9.9 μm wavelengths, respectively. This work demonstrates the unique potential of crumpled graphene as a reconfigurable optical and thermal management platform.

Plasmonic nanostructures generate heat via the photothermal effect when excited with a specific wavelength of light, where optically excited surface plasmons decay to produce hot electrons that subsequently couple to the lattice vibrations. Photothermal cancer therapy shows promise as an application using this effect, where local hyperthermia leads to cell death. However, noble metal nanoparticles traditionally used in plasmonic applications exhibit surface plasmon resonance in the lower-wavelength visible range, where human tissue is not transparent. As a result, recent research efforts have pushed new plasmonic nanostructures and materials into the near- and mid-infrared ranges by using anisotropic geometries. Gold nanorods are extensively used due to their wavelength tunability of the plasmon resonance and their ability to be modified and functionalized for specific binding, enhanced detection, and drug delivery. The thermal transport of this system at the cellular level is not heavily studied, therefore we experimentally measure the thermal transport in a system of cancer cells infiltrated with gold nanorods in vitro at various concentrations, to understand the minimum illumination intensities and durations required for cancer cell death. We report, for the first time, the interfacial thermal conductance between gold nanorods and the ovarian cancer cellular environment as measured by ultrafast pump-probe laser techniques. We also report the thermal conductivity and heat capacity of the cancer cells. By understanding the thermal properties of this system, more defined and tailored photothermal therapy regimens are made possible. This study also provides an experimental framework for measuring the thermal properties of other photothermal therapy agents in cellular environments in the future.

Anisotropic Thermal Conductivity in the Polycrystalline Environmental Barrier Coating γ-YSi3O7: David Olson, Cory Parkers, Valentina Avincolatri, John Gaskis, Elizabeth Opilar and Patrick Hopkins; 1University of Virginias, Charlottesville, Virginia, United States; 2Materials Science and Engineering, University of Virginia, Charlottesville, Virginia, United States; 3Physics, University of Virginia, Charlottesville, Virginia, United States.

Aerospace applications in which high heat fluxes are reached necessitate the use of unique materials to withstand these harsh environments. The need for environmental barrier coatings (EBCs) are of particular importance in limiting the oxidation of aerospace components and the volatility of the SiO2 scale commonly found in silicon-based ceramic coatings. Rare earth mono- and disilicates have been identified as promising EBCs due to their ease of application via various plasma spray processes. However, a robust examination of the insulating thermal properties of these systems has yet to be performed. To better understand the thermal processes and anisotropy associated with these disilicates, we examine the commonly used polymorph of yttrium disilicate, γ-YSi3O7. Using a combination of time- and frequency-domain thermoreflectance, we compare the extracted thermal conductivity maps to associated electron backscatter diffraction micrographs. The thermal conductivity maps exhibit strong anisotropy in the monoclinic structure, in good agreement with other anisotropic features of the system. The results are significant in that they are the first experimental measurements of the anisotropic thermal conductivity in a thermal barrier coating, and should provide a basis for plasma-based applications in which the potential for texturing is strong.

Tunable Functionality of High Entropy Carbide Thin Films via Carbon Stoichiometry: Christina Rost, Trent Bormann, Mohammad Hossain, Jon-Paul Marzia and Patrick Hopkins; 1University of Virginia, Charlottesville, Virginia, United States; 2Materials Science & Engineering, The Pennsylvania State University, State College, Pennsylvania, United States.

Materials science is challenged with developing new materials in order to meet the demands of technological innovation. Consequently, this opens the door to novel or complex properties awaiting exploration. High entropy carbides (HECs) continue to demonstrate the viability of materials engineering using configurational entropy to aid in phase development. Using two compositions, Hf-Nb-Ta-Ti-Zr-C (HEC3) and Hf-Mo-Ta-W-Zr-C (HEC6), we explore the thermal transport properties of these systems as carbon stoichiometry is varied. Using time domain thermoreflectance (TDR), we measure thermal conductivity of both the HEC3 and HEC6 thin film series and then relate trends to other observed characteristics of each system such as electrical conductivity, crystallinity, and modulus. Total thermal conductivity systematically varies with increasing deposition flow rate of methane, while the electrical contribution to the thermal conductivity decreases. Results are discussed in terms of various scattering mechanisms from different types of defects, emphasizing understanding of thermal properties from both a local and a global structural perspective. In this talk we focus on the experimental process of elimination using several metrology techniques in conjunction with TDR to gain meaningful perspective on configurationally disordered, highly crystalline systems.

Observation of Second Sound in Graphite At Temperatures Up to 100 K Bryan A. Duncan, Samuel Huberman, Ke Chen, Bai Song, Vazrik Chiloyan, Zhiwei Ding, Alexei Maznev, Gang Chen and Keith Nelson; 1Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Wave-like thermal transport in solids, referred to as second sound, has until now been a exotic phenomenon limited to a handful of materials at low temperatures. This has restricted interest in its occurrence and in its potential applications. Through time-resolved optical measurements of thermal transport on 5-20 μm length scales in graphite, we have made direct observations of second sound at temperatures above 100 K. The results are in qualitative agreement with ab initio calculations that predict wavelike phonon hydrodynamics on ~ 1-μm length scale up to almost room temperature. The results suggest an important role of second sound in microscale transient heat transport in two-dimensional and layered materials in a wide temperature range.

Mitigation of Point-Contact Thermal Boundary Resistance in Elastomeric Composites Through Liquid Metal-Bridged Tungsten Fillers Wilson Kong, Matthew Ralphs, Robert Wang and Konrad Rykaczewski; Arizona State University, Tempe, Arizona, United States.

As increasingly powerful microelectronic chips shrink in size and scale, inadequate waste heat dissipation ultimately results in poor computational performance or early device failure. Therefore, advances in thermal interface materials (TIMs) are necessary in combating detrimental heating issues by providing improved avenues for thermal transport. Many types of polymer-filler combinations for TIMs have been explored to maximize the composite thermal conductivity, while only leading to thermal conductivities of up to 2 W m-1K-1. One of the primary limitations to efficient thermal transport in TIMs lies in the boundary resistance generated by the point-contact of filler particles. Additionally, the thermally conductive inclusions are often rigid particles which can lower the elasticity of the composite at high fill factors. Increasing the effective contact area between filler materials could potentially result in much higher composite thermal conductivities [1,2]. Previous work done by Ralphs et al. has shown a substantial increase in thermal conductivity by up to 17 W m-1K-1 with copper particles bridged by liquid metals in a PDMS matrix [3].
In this work, multi-phase fillers comprised of a solid metal core with a liquid metal shell are proposed as a promising solution to reducing point-contact boundary resistance. Liquid metals form a self-limiting oxide layer that encapsulates the liquid metal and can rupture under applied pressure, therefore allowing liquid metal coated particles to connect. Due to the tendency of liquid metal to alloy with and/or embrittle many metals, tungsten is selected as the core material for its relative inertness towards liquid metals. In addition, tungsten particles coated with liquid metals can also be mechanically processed to increase the effective contact area between adjacent particles. The novel combination of deformable liquid shells and highly thermally conductive solid particles can potentially lead to composite materials that facilitate more efficient heat transport and are still stretchable. This research seeks to demonstrate a reduction in thermal boundary resistance that improves TIMs through novel materials processing methods.

Nanoscale Thermal Transport in Lithiated Si Anode Films
Azat Abdullaev1, Talgat Yakupov2, Aliya Mukanova1, Assiya Yermekambetova1, Zhumbabay Bakenov1 and Zhandos Utegulov2; 1Department of Chemical Engineering, School of Chemistry, Nazarbayev University, Astana, Kazakhstan; 2Department of Physics, School of Science and Technology, Nazarbayev University, Astana, Kazakhstan.

Rechargeable Li-ion batteries (LIBs) are very promising candidates for electrochemical energy storage in electrical vehichles. Electrical conduction properties in these systems are strongly affected by thermal transport properties during electrochemical cycling. Therefore, thermal management in these systems is very crucial for the control of electrical properties of these storage devices [1]. Si-based anode is a very attractive material because of potentially large achievable capacity of 3700 mAhg−1 [2] that is ten times more than that for graphite carbon, which is mainly used as an anode material in LIBs. However it is well known that Si electrodes suffer from volumetric change during the electrochemical cycling/recycling processes, which in turn leads to change in mechanical and electrical properties. But little research has been done on thermal conductivity variation in Si films during the lithiation. In this work we aim to study nanoscale thermal transport in this nanoscale-thick material using ex situ picosecond time-domain thermoreflectance (TDTTR) approach [3]. RF magnetron sputtering was used to deposit a ~300 nm thick Si films on glass substrate. A 50 nm thick Al was deposited on top of Si serving as an optical absorber and efficient heat transducer in TDTTR experiments. The lithiation of films has been performed in the beaker cell with lithium hexafluorophosphate (LiPF6) in the solution of ethylene, diethyl carbonate and ethyl methyl carbonates (EC:DC:EMC = 1:1:1, v/v) using a constant current of 25 µA up to 0.05 V. Thermal transport measurements were done for non-lithiated and lithiated samples. The results show that for non-lithiated amorphous Si films the thermal conductivity value is ~1.4 W/m*K, which is very close to literature value [4]. After electrochemical lithiation process, the thermal conductivity of lithiated amorphous Si was in the range between 1.3 to 2.2 W/m*K. This sizeable thermal transport fluctuation was likely due to inhomogeneous lateral Li ion distribution on the near-surface region. We also have done measurements on Young’s elastic modulus of these thin film materials using nanosecond laser pulse-induced surface acoustic waves. The results showed the decrease in Young’s modulus after lithiation as it is expected because of volumetric expansion of Si crystal.

Solid-Solid Phase Change Composite for Thermal Energy Harvesting and Storage
Waseem Afzal1, Talgat Yakupov2, Aliya Mukanova1, Assiya Yermekambetova1, Zhumbabay Bakenov1 and Zhandos Utegulov2; 1Department of Chemical Engineering, School of Chemistry, Nazarbayev University, Astana, Kazakhstan; 2Department of Physics, School of Science and Technology, Nazarbayev University, Astana, Kazakhstan.

The phase change materials (PCMs) provide state-of-the-art thermal energy storage capability and offer enormous potential for the development of sustainable energy infrastructure. However, the widespread utilization of PCMs in real life applications is often limited by the intrinsic material problems including shape instability, structural rigidity, low conductivity as well as the lack of multi-charging modes. Therefore, the functionality of PCMs in order to overcome the aforementioned issues has remained an elusive goal. In current study, we developed nano-pore confined solid-solid phase change composites (PCCs) by infiltrating polyurethane into the pores of carbon nanotube sponge (CNTs). Our fabricated composite structure is dual formable, flexible, highly conductive and more importantly can store thermal energy by mean of low voltage as well as sunlight irradiation, which overcomes the intermittency of input energy source. To the best of our knowledge, we achieved the highest energy conversion efficiencies (94.5 %) for both electro and photo to thermal energy storage among all functionalized PCMs. This high-energy storage efficiency is attributed to the excellent energy conversion/transfer performance of aligned carbon nanotubes (CNTs) network, which remains unaffected over 100 cycles owing to the solid-state phase transition of confined PCM. Moreover, the alignment of CNTs results in anisotropy in thermal transport, which has potential in harvesting/transferring energy in favorable direction. Furthermore, our devised composite with 90 wt% of PCM presents energy storage density 132 J g−1 which is close to solid-liquid PCMs and higher than all the solid-solid PCMs. The combination of multiple features is realized in one single structure, which sets our work apart from previously reported PCCs. Therefore, the presented study will provide breakthrough towards the development of real life applicable PCCs for thermal energy applications.

Radiative Cooling Device Design Boosted by Machine Learning
Guo Jiang1, Shenghong Ju1,2 and Junichiro Shiomi1,2,3; 1Mechanical Engineering, The University of Tokyo, Tokyo, Japan; 2Center for Materials Research by Information Integration, National Institute for Materials Science (NIMS), Tokyo, Japan; 3Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Agency (JST), Tokyo, Japan.

Due to the major concern on global warming and energy crises issues, radiative cooling devices which utilize the unattapped cold space as potential heat sink, has attracted intense attention again with the newly development in nanotechnology. Many successful experiment results on radiative cooling have focused on blocking the solar energy absorption (0.4−4 µm) and maximizing the thermal radiation loss (~4 µm) to the surrounding simultaneously, which shows exciting temperature drop even under the direct sunshine. However, this design policy may suffer from absorbing too much downward atmospheric radiation in hot and humid regions, thus could be less effective in cooling. Selective emitter which only emit or absorb thermal energy within the 8-13 µm-atmospheric window can tap the most potential of the transparency of atmosphere and get lower stagnation temperature. To our best knowledge, there is no reported work which shows perfect selective emissivity property matching with the atmospheric window.

In this work, we combined the traditional grating and multi-layer structure, aiming to get ideal optical response for radiative cooling purpose. The machine learning optimization was based on Bayesian algorithm and the optical property of the selective coating was calculated by the rigorous coupled wave analysis (RCWA) method. For the design, the ideal optical response property should only have unity emissivity in the 8-13 um wavelength range and unity reflectance outside the transparency window. We employed the typical polar material SiO2 as the grating material on the top to excite the surface phonon polariton. The multi-layer structure consists of Si3N4, Al2O3, SiC and Si with various thickness and sequence was used to manipulate the resonance position. We used silver thin film with sufficient thickness as substrate to totally reflect the solar energy. The periodic length, thickness and filling ratio of the top grating layer, the sequence and thickness of the multilayer structure were optimized by Bayesian and Alex Greaney. We obtain the optimal structure with nearly unity emissivity only in the atmospheric window.

QN05.06.25
Modeling Thermal Resistance Across Contacting Interfaces Including Surface Characteristics
Seshu Nimmala1, Aria Hosseini2, Jackson Harter2, Todd Palmer2, Eric Lenz1 and Alex Greeney1; 1Lam Research Corporation, Tualatin, Oregon, United States; 2University of California, Riverside, Riverside, California, United States; 3Oregon State University, Corvallis, Oregon, United States.

Thermal resistance across the interface between touching surfaces is critical for many industrial applications. Contacting interfaces are fractally rough, with locally intimate contact separated by regions with a wider gas filled boundary gap. Heat flow across the interface is heterogeneous and thus the contact model is based on a network of thermal resistors representing boundary resistance at local contacts and the access resistance for lateral transport to contacts. In a previous work [1], we developed a network model to predict the macroscopic thermal resistance of mechanically contacting surfaces. The results of molecular dynamics simulations to characterize boundary resistance of Silicon Alumina.
interfaces and the Boltzmann transport simulations of access resistance in Si in the ballistic transport regime were presented. In the present work, we review some of the current state-of-the-art and highlight the advanced models developed including surface characteristics such as roughness at interfaces. Additionally, we report some of the results of analyses when the components are subjected to variables such as pressure and temperature. This study is of practical significance in understanding the influence of surface roughness in thermal transport across interfaces at nanoscale to macroscale (i.e., multiscale) for applications such as thin films in the semiconductor industry, and mechanical components in industrial equipment.

Formation of Three-Dimensional Segregated Network of Nanofillers for Epoxy Composites of High Thermal Conductivity
Sung-Ryong Kim and Vu M. Cung; Korea National University of Transportation, Chungju, Korea (the Republic of).

The development of the electronic devices towards smaller design, higher power consumption, and multiple functions requires an effective heat dissipation during operation. The self-assembled carbon nanotubes (oCNTs), hexagonal boron nitrides (hBN) and graphene oxide v were prepared to improve the thermal conductivity while maintaining the electrical insulation properties of the epoxy composites. The oCNTs and graphene oxide were separately immobilized on the edges of hexagonal boron nitride, which prevent oCNTs from continuously contacting with each other. The thermal conductivity the hybrid nanofiller/epoxy composites were measured and compared with the bare epoxy. The thermal conductivity of the epoxy composites containing 20 vol% of oCNTs@hBN10 was 1.26 W/m·K, which is higher than 600% compared to that of bare epoxy and the volume resistivity of the epoxy composites was in an insulating region even at high content of nanofiller. The significant improvement in thermal conductivity was attributed to the formation of linkages between oCNTs and hBN and the good compatibility of the hybrid filler in the epoxy matrix. This work was supported by Korea National University of Transportation in 2018.

Reducing Thermal Conductivity Through Lattice Softening
Riley C. Hanus, G. J. Snyder and Matthias T. Agne; Northwestern University, Chicago, Illinois, United States.

Two fundamentally different avenues for controlling a materials thermal conductivity are phonon scattering and lattice softening. In the phonon scattering picture, the phonon dispersion relation and group velocities are assumed to be fixed and lattice defects reduce lattice thermal conductivity ($\kappa_L$) by introducing phonon scattering centers. Lattice softening recognizes that lattice defects alter the phonon dispersion relation and thus reduce $\kappa_L$ by reducing phonon frequencies and group velocities. Here, I will present experimental data on several systems (Si, PbTe, and SnTe) which demonstrate that microstructural defects such as grain boundaries, dislocations, and vacancies can significantly soften a materials lattice, reducing the materials speed of sound and elastic moduli. By analyzing the data on elasticity and thermal conductivity through standard transport modeling, it is shown that lattice softening is a dominate mechanism for the reduction of $\kappa_L$ in these systems. Additionally, it will be shown that lattice softening is theoretically expected to be more effective than phonon scattering effects in anharmonic materials and at high temperatures. This work demonstrates how lattice softening is emerging as an important mechanism for controlling a materials thermal conductivity, and provides new avenues to engineer a materials $\kappa_L$, beyond phonon scattering.

Design of Microporous Copper Inverse Opal Wicks for Capillary-Driven Boiling
Chi Zhang1, James W. Palko1,2, Michael Barako1,2, Mehdi Asheghi2, Juan G. Santiago2 and Kenneth Goodson1; 1Stanford University, Stanford, California, United States; 2University of California, Merced, Merced, California, United States; "NG Next Basic Research Laboratory, Redondo Beach, California, United States.

Rising power densities have presented thermal management challenges to a number of industrial applications such as power electronics, laser diodes, microprocessors, and defense and space systems. These high-performance devices, however, can generate hotspots with extreme heat fluxes (exceeding 500 W cm$^{-2}$) within a small area (typically submillimeter by submillimeter), leading to local temperature spikes. Accordingly, significant research attention has focused on efficient heat dissipation from local hotspots to reduce device temperature and ensure performance and system reliability. Liquid to vapor phase-change process provides an attractive approach for hotspot thermal management by utilizing the latent heat of working fluid during vaporization.

Microporous metals are promising for applications that require simultaneous transport of fluid through the pore space and heat conduction through the matrix to a surface where they interact. They are common as wick structures in two-phase thermal management systems such as vapor chambers and micro heat pipes due to their potential to reduce the transport resistance associated with the heat supply, liquid replenishing, and vapor removal. Passive microporous structures depend on capillary pressure to supply liquid to the phase-change surface where the working fluid evaporates. The low thermal resistance characteristics of such two-phase operating mechanisms are enabled by the latent heat exchange at nearly constant evaporator temperatures. Inverse opals (IO) are ordered porous media that consist of uniform pores arranged periodically to form a fluid permeable structure. The regular order of these porous structures makes it feasible to accurately predict the fluid transport property using single unit cell analyses and also to fine tune the structural features such as pore diameter and porosity.

We experimentally characterize capillary-driven boiling in well-defined copper inverse opal wicks that consist of uniform pores with diameter ranging from 3 $\mu$m to 10 $\mu$m. Template sintering is utilized to improve the IO permeability by over an order of magnitude, leading to a concomitant increase in boiling critical heat fluxes (CHF). Liquid wicking distances and capillary wick thicknesses are also systematically varied to investigate their effect on the CHF. A semi-analytical model is developed to account for both liquid and vapor transport within the microporous wicks, which predicts the CHF with ±30% accuracy compared to our experimental data. Understanding the characteristics of boiling process in capillary wicking structures is essential to wick design optimization in high-performance vapor chambers, thermal ground planes, and other two-phase heat spreaders.

Role of Gallium Oxide on Thermal Performance of Liquid Metal Droplet Based Thermal Interface Materials
Matthew Ralphs, Wilson Kong, Robert Wang and Konrad Rykaczewski; Arizona State University, Tempe, Arizona, United States.

Gallium-based room temperature liquid metals have become a hot topic in the thermal management of traditional semiconductor packaging and stretchable electronics. However, the native gallium oxide shell on these liquids both facilitates many unique processing techniques as well as hinders others, making it a force that needs to be reckoned with. Some studies have been done on chemically and mechanically altering the oxide layer, but very few have focused on the thermal ramifications of the oxide and its rupture. In this work, we present a comprehensive set of experiments on parameters controlling fracturing of the oxide shell on micro and nanoscale liquid metal droplets and the resulting thermal conductivity of the droplet ensemble. Specifically, we fabricate liquid metal droplets with diameters ranging from hundreds of nanometers to ten micrometers and pack them into macroscopic films. We then compress the films while measuring thermal resistance, pressure, and electrical resistance in situ through and beyond oxide rupture. This allows us to interrogate the mechanical role of the oxide layer and the thermal ramifications of the oxide shells when dealing with liquid metal droplets. Various sizes of liquid metal droplets are investigated as well as mixtures of liquid metal droplets and solid metal particles. The inclusion of solid and liquid metal particles together gives insight into the role of particle packing and how it relates to thermal resistance and oxide failure. The measured thermal properties and how they relate to the mechanics of the rupturing oxide will be explained. Additionally, this work will lead to insights on using liquid metal coated solid metal particles in a polymer composite to reduce the thermal boundary resistance between particles and greatly enhance the thermal conductivity of such composites.

**QN05.06.30**
Modeling of a Water-Harvesting Thermal Battery with a NIPAAm Hydrogel Sorbent
Jordan Kocher, Yanan Zhang and Robert Wang; Arizona State University, Tempe, Arizona, United States.

Thermal energy storage devices (i.e., “thermal batteries”) are utilized in scenarios where thermal energy is available at certain times but required for use at a later time. The amount of energy that can be stored within a thermal energy storage device depends on both the storage material and the mode of storage. Systems that incorporate thermochemical processes are often able to store significantly more energy than sensible and latent heat thermal energy storage systems.
This presentation focuses on the use of N-isopropylacrylamide (NIPAAm) for sorption thermal energy storage. NIPAAm is a thermoresponsive polymer that transitions from hydrophilic to hydrophobic upon crossing its critical temperature (typically 32 °C). In addition, NIPAAm has the ability to absorb water vapor (i.e. humidity) and expel liquid water. This creates huge energy savings potential during sorbent regeneration that is equivalent to the enthalpy of vaporization of water. The energy density of NIPAAm is also particularly attractive because it can be used in conjunction with hydrogels that can store up to 40 times the gel's dehydrated mass in water.

To explore the potential of NIPAAm for cooling applications, we conduct system-level modeling of sorption systems utilizing this novel material. This system charges up by absorbing water from humid air that is passed through the device. When cooling is desired, the NIPAAm is heated above to 32 °C to expel liquid water that is then evaporated to cool the system. This sorption process can potentially exceed the energy density of traditional latent heat systems (e.g. cold thermal storage with ice) because the enthalpy of vaporization significantly exceeds the enthalpy of melting. The presentation on sorption system modeling with NIPAAm will highlight the exciting opportunities for this novel material in thermal energy storage applications.

**Advanced Building-Envelope Component Materials for Optimal Energy Retrofiting Measures of Office Building Façades**

Abantika Sengupta1 and Tivasa Ray1; 1Arizona State University, Tempe, Arizona, United States; 2Politecnico di Milano, Milano, Italy.

Built environment accounts for most of the overall life cycle energy consumption and greenhouse gas emissions. Buildings are a major source of global energy demand and materials, that in return produces large carbon footprint and GHG (Green House Gases) as the by-product. The 2030 Carbon emission reduction challenge sets aggressive goals for slowing down the growth rate of GHG and reducing the Carbon Footprint of the buildings to address climate change. A major sustainable challenge for the buildings is to be resilient during their Life Cycle, for which they need maintenance from time to time within this period to prevent their performance degradation. The building should perform in terms of functionality and energy demands. Buildings which do not meet the energy standards require extensive renovation including façade retrofit, to meet the energy performance and carbon reduction goals for the future. As a reasonable retrofit of the façade, materials play a very important role. With the advancement in material technology and the use of smart materials connected to the building automation systems, zero energy or minimizing the energy demand of the buildings are in trends. Usage of smart or advanced materials should also be weighed with the initial cost, environmental impact, market value, life cycle analysis, maintenance cost along with the sustainable use of local materials. The significance of retrofitting of building façades lies not only in enhancing the energy efficiency or energy-based models but also in the creation of construction markets and business models. Creating value and value proposition for the building retrofit are key to encourage more buildings to adopt this kind of method. Retrofit and refurbishment systems create possibilities to add value to the customers outside the economic area and reduce energy consumption. This creates co-benefits. The major significance of retrofitting of the existing building lies in the analysis of cost reduction incurred as compared to a newly built structure. Abatement in systems cost can also be achieved from attrition of wastage of materials and surplus materials control. Since buildings consume a significant amount of energy (40 per cent of the nation's total U.S. energy consumption) and the existing ones comprise the largest segment of the built environment, retrofitting offers significant opportunities in terms of customization according to the climate, orientation and typology of the building and energy efficiency improvement. Hence sustainability can be achieved in this sector at lower costs and higher uptake rates. The article will propose retrofitting of the façade system of an office building in Giosa, Milan, Italy, additionally adding a static shading element. The study focuses on the diverse façade system and the typology of shading elements for each of them along with the materials used. Apart from energy conservation, retrofitting the existing office building also yields to the key design objectives which include illumination and daylight factor analysis and impact of the façade components on the structural system. This project emphasizes especially on the thermal analysis of the façade system-thermal bridges, water and air permeability, resistance against impact and fire resistivity of the materials in use. Use of advanced materials, its impact on the environment and the analysis of the energy consumption and energy savings form the framework for the retrofit project along with the goal of carbon footprint reduction.

QN05.06.32
**Design and Optimization of the Advanced Silica Nanofiber Insulator Material Properties via Coarse-Grain Molecular Dynamics Simulation Method**

Gorakh Pawar, Bjorn Vaegensmith and Tamnie Borders; Idaho National Laboratory, Idaho Falls, Idaho, United States.

The role of the computational material modeling and simulations is indispensable in the design and development of advanced materials with superior material properties. Here we present a coarse-grained molecular dynamics (CGMD) simulations-based investigation to understand a melting behavior of the mesoscopic electro-spon silica-nanofiber based insulator materials, and subsequently elucidate the silica nanofiber size-melting temperature relationship. A coarse-grained bead, which is equivalent to the spherical (SiO2)6 silica atomic structure, was used to construct the several mesoscopic silica nanofiber structures with sizes \( \sim 100 \text{ nm} \) that were consequently simulated for several hundred nanoseconds. The temporal bead trajectory information was used to decipher the melting behavior of the silica nanofibers. The silica nanofiber size-melting temperature dependency evaluated through CGMD simulations could provide some valuable guidelines for the further optimization of the silica nanofiber manufacturing processes.

QN05.06.33
**Energy Conversion Using Ferroelectric Properties of Barium Titanate**

Mariana Verdugo1, 2, Ashley Bucsek3, William Nun3, 2, Bharat Jalan2 and Richard D. James2; 1University of California, Berkeley, Berkeley, California, United States; 2University of Minnesota Twin Cities, Minneapolis, Minnesota, United States.

In the United States, nearly 68% of the primary energy produced each year is wasted as heat. A couple tangible examples of this wasted energy is the heat that radiates from laptops and air conditioning units that remove heat from air and release it into the environment. It would be efficient to convert this waste heat into a better source of energy such as current. Using the ferroelectric properties of BaTiO3, this energy conversion can be done.

BaTiO3 undergoes structural transitions when heat is applied at its curie temperature, approximately 120-130°C. During this structural transition, BaTiO3 goes from paraelectric to ferroelectric. While in its ferroelectric state, BaTiO3 behaves like a very good capacitor and during its paraelectric state, it behaves like a poor capacitor. Consequently, we can attach BaTiO3 to a circuit with a reference capacitor (ordinary capacitor), and we can charge this circuit to equilibrium and remove all energy sources. As BaTiO3 is heated and cooled, current flows from the reference capacitor to the activate BaTiO3 capacitor. Experimentally, we have observed the current flows consistently as the heat oscillates in the curie temperature range.

Converting waste heat to current is an efficient energy conversion method.

QN05.06.34
**Effects of Chemical Intercalation, Strain and Phase Transition on Thermal Transport in Bulk and Single-Layer MoS2**

Shanla Chen1, Aditya Sood3, Bin Ouyang2, Shinbyoung Xuong1, Eric Pop3, Kenneth Goodson2 and Davide Donadio1; 1University of California Davis, Davis, California, United States; 2Stanford University, Standford, California, United States; 3University of California, Berkeley, Berkeley, California, United States; 4Soochow University, Suzhou, China.

The possibility of tuning the vibrational properties and the thermal conductivity of layered van der Waals materials either chemically or mechanically would open a way to significant advances in nanoscale heat management, which is of importance for potential applications in energy storage, nanoelectronics and optoelectronics. Here we investigate the effects of lithium intercalation, cross-plane strain and phase transition on thermal transport in bulk and single-layer MoS2, by first principles calculations. Our well converged, parameter-free calculations resolve discrepancies in the literature about the thermal conductivity of MoS2, predict the strong modulation effects by mechanical strain, lithium intercalation and phase transition, and provide a detailed microscopic interpretation of recent experiments and benchmarks for future ones. Our findings can be exploited to design novel phononic devices, as well as for thermal management in MoS2-based electronics and optoelectronic systems.

QN05.06.35
**Magnetothermal Transport Behavior in Ferromagnetic and Semiconductor Thin Films**

Anand Kataliha1, Ravindra G. Bhardwaj1 and Sandeep Kumar2; 1Department of Mechanical Engineering, University of California, Riverside, California, United States; 2Materials Science and Engineering Program, University of California, Riverside, California, United States.
In this work, we present an experimental study on magneto-thermal transport and spin-Seebeck effect behavior in ferromagnetic and semiconductor materials. The magneto-thermal transport measurements are carried out using in-plane self-heating three-omega method. The in-plane three-omega measurement requires a freestanding specimen. We address this challenge using micro-electro-mechanical systems (MEMS) fabrication methods. The measurements are carried out on Py/Au and Py/Si. We also demonstrate giant spin-Seebeck effect in Py/Si bilayer thin films. The magneto-thermal transport measurements on these thin films are essential for the design and development of energy efficient spintronics devices. We employ four point probe configuration for our MEMS device structure to probe mainly the second and third harmonic voltages as well as resistance with respect to changing temperature and applied magnetic field. The results can be related to thermal transport properties of the system using the three-omega method as mentioned above.

**QN05.06.36**

**Quasi-Ballistic Thermal Transport in Amorphous Silicon Using Transient Grating Spectroscopy**

*Taeyong Kim, Jaeyun Moon and Austin J. Minnich; California Institute of Technology, Pasadena, California, United States.*

Disordered media are of special interest due to low thermal conductivity. Amorphous silicon (a-Si) has been widely used due to their low-cost potential. Due to the lack of long-range order, identifying thermal transport in amorphous media has been challenging. For example, mean-free paths (MFPs) distribution of propagon, a propagating delocalized atomic vibrational state, and its contribution to the thermal conductivity have long been contentious. Here, we report measurements of in-plane quasi-ballistic thermal transport from 30 K to 300 K on a 10 μm length for the measured film. The measurements are carried out using in-plane self-heating three-omega method. The in-plane three-omega measurement requires a freestanding specimen. We address this challenge using micro-electro-mechanical systems (MEMS) fabrication methods. The measurements are carried out on Py/Au and Py/Si. We also demonstrate giant spin-Seebeck effect in Py/Si bilayer thin films. The magneto-thermal transport measurements on these thin films are essential for the design and development of energy efficient spintronics devices. We employ four point probe configuration for our MEMS device structure to probe mainly the second and third harmonic voltages as well as resistance with respect to changing temperature and applied magnetic field. The results can be related to thermal transport properties of the system using the three-omega method as mentioned above.

**Investigation on Thermal Conductivity of BAs Monolayer—A First-Principles Study**

*Zhongyang Wang, Lei Liu, Rui Dai, Qiong Nian, Houlong Zhuang and Robert Wang; 1Arizona State University, Tempe, Arizona, United States.*

Cubic boron arsenide (BAs) bulk crystal has been identified to have an ultrahigh thermal conductivity (~1300 Wm⁻¹K⁻¹) both theoretically and experimentally. On the other hand, two-dimensional (2D) stable monolayers of BAs have also been reported to have promising electronic, transport, optical and thermoelectric properties. However, the thermal conductivity of BAs monolayers has not yet been investigated. Does thermal transport in BAs monolayers parallel that of cubic BAs bulk crystals? We present our first-principles study on the thermal conductivity of BAs monolayers.

The vibrational spectra of BAs monolayers have been calculated and are quite different from that of cubic BAs bulk crystals. Two transversal acoustic and optical branches, which correspond to out-of-plane atomic vibrations in BAs monolayers, carry lower energy due to the fact that atoms can more easily vibrate perpendicularly to the plane. The so-called “acoustic bunching” behavior in cubic BAs is also not seen in the vibrational spectra of BAs monolayer due to the presence of these out-of-plane branches. Nonetheless, the giant phononic band gap between the two in-plane optical branches still exists in the vibrational spectra of BAs monolayers. At this point, qualitative analysis of thermal transport based on the vibration spectra is inconclusive. More rigorous computational techniques need to be performed to derive the lattice thermal conductivity of BAs monolayers.

For our computations, we employ density-functional perturbation theory to generate second-order (harmonic) and third-order (anharmonic) interatomic force constants (IFC) for BAs monolayer using the VASP package. The harmonic IFC allows us to derive the vibrational properties, while the anharmonic IFC allows us to determine the three-phonon scattering rates using Fermi’s golden rule. With the only inputs of harmonic and anharmonic IFC, we can derive the lattice thermal conductivity by solving the exact phonon Boltzmann Transport Equation using the ShengBTE package.

**Thermal Conductivity Mapping of High-Entropy Carbides and Diborides**

*Jeffrey Braun, 1David Olson, 2Joshua Gild, 3Tyler Harrington, 4Jian Luo, 2Kenneth Vecchio and 2Patrick Hopkins; 1University of Virginia, Charlottesville, Virginia, United States; 2Materials Science and Engineering, University of California, San Diego, La Jolla, California, United States.*

In aerospace applications operating at very high temperatures (>3000 K), such as hypersonic flight or rocket propulsion systems, there is a critical need for the development of materials which can survive such extreme temperatures. To meet this need, ultra-high temperature ceramics (UHTCs) have proven to be at the forefront of research. While early development of UHTCs were primarily focused on SiC and Si₃N₄ currently there is a strong interest in transition metal diborides such as hafnium diboride (HfB₂) and zirconium diboride (ZrB₂) as well as carbides such as hafnium carbide (HfC) and tantalum carbide (TaC). Looking beyond binary carbides and diborides, materials synthesis of high-entropy ceramics consisting of five or more elements has enabled a new research direction to explore the engineering of thermophysical properties to enable sustainable high-temperature applications.

One of the most critical properties to understand in these systems is thermal conductivity. Nearly temperature independent diffusivity further shows that anharmonic scattering may not be dominant over the temperature range that we studied: 30 (K) to 300 (K). Our non-contact measurement will provide useful insights into studying disordered materials that have been challenging with conventional thermal characterization methods.

**Measuring Ballistic Thermal Resistance within a Nanoslot-Patterned Si Thin Film**

*Dongchao Xu, Yue Xiao, Fabian Medina, Qiyu Chen and Qing Hao; University of Arizona, Tucson, Arizona, United States.*

Phonon transport within nanosporous materials has been widely studied for its potential applications in thermoelectrics, heat waveguides, thermal diodes, and heat imaging. As an alternative to the conventional nanoporous structures, graphene with a patterned row of periodic nanoslots has been proposed for its potential application in tuning the thermal conductivity [1]. Here we report the narrow channel between two adjacent nanoslots functions as a nanoconstriction to restrict the phonon transport. Phonons will transport ballistically through the channel if the phonon mean free paths (MFPs) are much longer than the neck width, subsequently creating a “ballistic thermal resistance” to restrict heat conduction. Some earlier analytical studies on ballistic thermal resistances have been carried out on a heated nanoparticle inside a host medium [2], and nanostructures on a planar substrate [3]. The ballistic thermal resistances have been experimentally observed between nanosized heaters and a substrate [4].

In this work, the ballistic thermal resistance introduced by patterned nanoslots on a Si thin film is systematically studied. With ~10 μm length for the measured film, a single neck of 50 to 200 nm width is fabricated in the middle of the film. Compared with phonon transmission studies across nanoslots patterned on a 1-μm-long bridge between two suspended membranes [5], our measured films can incorporate the thermal conductivity contribution from phonons with much longer MFPs, which becomes more critical at cryogenic temperatures. The measurement results are further compared to predictions by frequency-dependent phonon Monte Carlo simulations. Our technique provides a simple way to justify the ballistic thermal resistance for various film- or flake-like materials.
Our recent experimental study in developing boron arsenide and boron phosphide has led to the synthesis of high quality materials and the observation of ultrahigh thermal conductivity of 3800 W/mK and 500 W/mK respectively. However, when integrated to electronic devices, further investigation is needed to understand thermal transport at multiscales and interfaces. Here we developed multiscale modeling to capture thermal transport from diffusive to ballistic transport and across the high thermal conductivity boron compound interfaces. We derive the interatomic force constants from density functional theory calculations and extract thermal conductivity by solving the steady state Boltzmann transport equation with full collision term beyond relaxation time approximation. We performed a multiscale simulation by solving the time-dependent three-dimensional spectral phonon Boltzmann equation using variance-reduced Monte Carlo method. We proposed a new theory to quantify interfacial phonon transport and the temperature evolution near interface. Our ab initio calculations demonstrate very good consistency with experimental measurements. This study systematically investigated the thermal transport of the newly developed emerging high thermal conductivity boron compounds at varied sizes and near interface. Our development paves the pathway towards establishing the system-level design of advanced thermal management of high-power electronics using these emerging high thermal conductivity semiconductors.

Experimental Study of Solar Thermophotovoltaic Energy Conversion Enhanced with Selective Metalfilm Coatings

Ryan McBurney, Qing Ni and Leping Wang; Arizona State University, Tempe, Arizona, United States.

Theoretical studies have shown that solar thermophotovoltaic (STPV) systems have the potential to produce efficiencies up to 85\%, but current technology has only reported actual efficiencies around 6.8\%. Studies have clearly shown that the major drawbacks in the components of a STPV system are the solar absorber and emitter. Current solar absorbers have shown to have high thermal emission causing heat loss and emitters display a lack in thermal emission above the bandgap of TPV cells. It is desired to have a solar absorber with unit absorbance in the solar spectrum, while having zero emittance in the longer wavelengths. In addition to this, emitters need to have unity emittance only within a narrow band that matches the high quantum efficiency of a specific TPV cell to minimize non-useful photons. Our experimental study will mainly address the issue of high thermal emission of solar absorbers by applying the highly-efficient selective metalfilm coating recently developed in our lab. We propose to use the metalfilm which has demonstrated high temperature thermal stability, as a solar absorber to investigate STPV system energy conversion. We will also address the potential to use such selective coatings as a selective emitter with further structure optimization to further improve STPV systems. The result of our experimental study will produce a better understanding of loss mechanism in STPV systems and bridge the gap between theoretical studies and real application. Our theoretical calculations predict a potential to achieve an STPV efficiency of 10\% or higher with the aforementioned metalfilm selective solar absorber and TPV emitter. In conclusion, this project, by closely examining the inefficiencies of solar absorbers in STPV systems, will bring to light the potential of highly-selective metalfilm enhanced STPV systems.

In Situ Thermal-Mechanical Diagnostics and Extreme-Condition Transport for Battery Thermal Management

Huuduy Nguyen, Ming Ke, Albert Rieck, Joon Sang Kang and Yongjie Hu; University of California, Los Angeles, Los Angeles, California, United States.

Thermal management has become critically important for today's batteries due to safety issues under increasing power and energy density. A clear and straightforward in-situ diagnostic method during the device normal operation process is highly desirable and can elaborate the fundamental materials dynamics for superior performance. We will describe our recent work on the first time demonstration of in situ thermal-electrochemical characterization in a lithium ion battery. We developed a novel approach that integrates ultrafast optical spectroscopy and electrochemical control to investigate the thermal transport in the electrode materials during the battery's normal operation process. The study reveals intriguing anisotropicphonon interactions and highly reversible electrochemical control over the thermal properties. In addition, we investigated state-of-charge dependent ion diffusivity of electrode at the organic-inorganic interfaces and observed significant improvement in ion diffusivity through microscopic structural optimization. Moreover, we explored phase change material for battery temperature control and showed substantial reduction in peak temperature that prevents thermal runaway at extreme conditions. The impact of this study to rational design and improve thermal management of lithium ion batteries working at extreme conditions will also be discussed.

Metasurface Filter Made of Plasmonic Nanodisk Array for Enhancing Thermophotovoltaic Energy Conversion

Rajagopalan Ramesh, Qing Ni, Hassan Alshehri and Leping Wang; Arizona State University, Tempe, Arizona, United States.

A basic thermophotovoltaic (TPV) system consists of a thermal emitter and a photovoltaic cell that converts heat to electricity via infrared photons or thermal radiation. While great progress has been reported recently to achieve spectrally-selective thermal emitters made of photonic crystals, metamaterials and multilayers, a wavelength selective optical filter is another possible route to increase the TPV efficiency by reflecting the photons with energy below the bandgap at longer wavelengths. Optical filters with narrow transmission band right above the bandgap of TPV cells are not restrained by the rigorous thermal reliability as required for the emitters. In this work, we fabricate and characterize a novel metasurface filter made of an aluminum (Al) nanodisc array to achieve spectrally selective transmission above the bandgap of TPV cell. The filter is fabricated by depositing thin Al onto the quartz substrate which is covered by anodized aluminum oxide (AAO) templates. Optical simulations will be carefully performed to determine the appropriate AAO interpore distance, AAO pore diameter and the Al film thickness such that the resulting Al nanodisc array will show narrowband transmission at a wavelength of 1.6 micron, which is the bandgap of a commercial Gallium Antimonide (GaSb) TPV cell. Preliminary simulations indicate that the narrow-band transmission is due to the articular magnetic resonance between neighboring Al nanodiscs, which channels energy through at wavelengths near the resonance. The optical and radiative properties of the Al nanodisc metasurfaces will be characterized by an FTIR spectrometer and a monochromator with an integrating sphere. The external quantum efficiency (EQE) of the commercial GaSb TPV cell will be measured with and without the fabricated metasurface filter covered, aiming to show the narrow-band EQE spectrum right above the cell bandgap due to the spectral filtering. By pairing the filter with a tungsten thin film emitter at 600\°C or higher, the I-V curve from the GaSb TPV cell will be measured and the heat-to-power TPV efficiency will be calculated. Enhanced TPV efficiency is sought to be experimentally demonstrated with the metasurface filter. Theoretical energy analysis for the TPV system will be performed to validate and explain the experimental data.
Regulating Near-Field Radiative Heat Transfer with Tunable Materials

Liping Wang, Xiaoyan Ying and Sydney Taylor; Arizona State University, Tempe, Arizona, United States.

Thermal regulation in solid-state devices has received extensive attention over the years due to its potential applications in thermal management, thermal circuits and thermal computing. Near-field thermal radiation with super-Planckian heat flux beyond Blackbody limit inspired a new route for thermal control with thermal photons, particularly with recent achievements in near-field radiative heat transfer measurements. In this talk, we will first review the theoretical studies on tunable near-field thermal radiation, in particular from our group, such as near-field thermal rectification, thermal switching and thermal modulation based on thermochromic VO₂ and tunable graphene. VO₂, which changes phase between an insulator with strong infrared phonons and a metal with optical phonons around 68degC. Therefore, the near-field coupling due to surface phonon polaritons between VO₂ and another dielectric could be weakened by changing the VO₂ to metallic phase at higher temperatures. As a result, the near-field radiative heat flux can be tuned thermally with the VO₂ temperature. On the other hand, graphene plasmon and its radiative properties can be modulated by chemical doping or electrical gating, such that the near-field coupling strength and resulting radiative heat transfer between graphene surface plasmons can be tuned dynamically. Fabrication and characterization of VO₂ thin films and graphene will be then discussed in detail. By using a plate-plate thermal metrology with nanometer gaps created by sparse polymer posts, we experimentally demonstrate near-field radiative thermal regulation between graphene covered SiO₂/Si plates with 1cm² area for the first time by modulating graphene conductivity through external gating potential. Besides, a near-field radiative thermal rectifier and switch based on VO₂ phase change will be experimentally demonstrated as well. Our work will facilitate the active control of...
near-field thermal radiation in solid-state applications.

Electron-Phonon Coupling and Dimensional Crossover in Quasi-1D van der Waals Crystal NbSe$_2$ Nanowires
Lin Yang, Yang Zhao, Qian Zhang and Deyu Li; Vanderbilt University, Nashville, Tennessee, United States.

During the last two decades, tremendous progress has been made in quantitative understanding of several major phonon scattering mechanisms, including phonon-phonon, phonon-boundary, phonon-defects, as they are the determinant factors in lattice thermal transport that is critical for the proper functioning of various electronic and energy conversion devices. However, the roles of another major scattering mechanism, electron-phonon (e-ph) interactions, remain elusive. This is largely due to the lack of solid experimental data for the effects of e-ph scattering in the lattice thermal conductivity for the material systems studied thus far. Through systematic measurements, we show distinct signatures in the lattice thermal conductivity observed below the charge density wave (CDW) transition temperatures in NbSe$_2$ nanowires, a type of quasi-1D van der Waals (vdW) crystals with covalently bonded molecular chains assembled together through vdW interactions. Owing to the restricted dimensionality, the density of free electrons in NbSe$_2$ spontaneously develops a wave-like variation due to CDW phase transitions. The variation of charge carrier concentration upon the onset of CDW modulates the e-ph scattering strength, resulting in unique features in the lattice thermal conductivity.

In addition, while the measured lattice thermal conductivity demonstrates a decreasing trend as size reduces for wires with diameter $>$26 nm, an unexpected increasing trend was observed as the lateral dimension further reduces. In fact, the room-temperature thermal conductivity of NbSe$_2$ nanowires could be enhanced by more than 20 fold as the diameter reduces, which is attributed to the dimensional crossover from 3D to 1D for phonon transport in thin NbSe$_2$ nanowires. The excised 1D phonons propagate along the molecular chains and contribute to the observed much enhanced thermal conductivity. These studies provide new insights into thermal transport through vdW crystals, which helps to lay the physical foundation of quasi-1D vdW materials in engineering applications.

8:30 AM QN05.07.03
Role of Anharmonicity in Enhancing Interfacial Thermal Conductance by a Bridging Layer
Jingjie Zhang$^1$, Rouzbeh Rastgarkashgorkolaei$^1$, Carlos Polanco$^2$, Nam Q. Le$^3$, Pamela M. Norris$^1$ and Avik W. Ghosh$^1$; 1University of Virginia, Charlottesville, Virginia, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 3JHU Applied Physics Laboratory, Laurel, Maryland, United States.

A bridging layer with matching properties can facilitate phonon transport across interfaces. In this work, we study the role of anharmonicity in such systems. Our results demonstrate the existence of a minimum interfacial thermal conductance $G$ versus layer thickness $L$ with weak anharmonicity and the existence of a maximum $G$ vs. $L$ with strong anharmonicity. The minimum thermal conductance appears at a thin thickness and is due to the competing roles of quantum effect and anharmonicity. The maximum thermal conductance is a result of two contradictory effects of anharmonicity: “re-thermalization” and “umklapp scattering”. Moreover, we present that the effect of anharmonicity on the conductance can be tuned by varying temperature or bridging layer thickness, as both parameters can change the strength of anharmonicity. Additionally, we propose a critical length $\lambda_s$ as a criteria at which the resistance can be separated as resistances in series in the presence of both weak and strong anharmonicity. Additionally, we compared them to the bulk mean free path $\lambda_b$ and demonstrated that $\lambda_s$ is much smaller than $\lambda_b$, hinting that the summation over resistance rule can be used at much smaller length than the bulk mean free path, and a comparison between $\lambda_s$ with L cannot be used to treat boundary resistance or classical size effect for thin films between two materials.

Thermal Materials and Science in Wearable Applications
Yi Cui$^{1,2}$; 1Department of Materials Science and Engineering, Stanford University, Stanford, California, United States; 2Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory, Menlo Park, California, United States.

Wearable applications with multi-function integration afford exciting research opportunities. Among all the functions, effectively regulating the heat flow between human body and environment not only increases thermal comfort but also presents a novel and cost-effective approach for reducing the building energy consumption. Here I will present my group work on thermal consideration and materials design for new generation of textile and wearables. Particularly with regulation of human body infrared radiation, we demonstrated the best heating and cooling textiles. We also develop new concept of bifunctional textile which can switch between heating and cooling mode. In addition, we also demonstrate the cooling textile under the sun.

9:15 AM QN05.07.05
Engineering Thermal Conductivity Through Microstructure
Riley C. Hanus and G. J. Snyder; Northwestern University, Evanston, Illinois, United States.

The flow of heat through materials is a topic of scientific interest and technological importance in fields of microelectronics, power generation, heat management, and thermoelectrics. For example, advancement in microelectronic technologies (e.g. microprocessors, and high-power electronics) demands even more efficient removal of the heat generated in these devices. In contrast, technologies such as thermal barrier coatings and thermoelectric materials are designed to stop the flow of heat. Thus, progress in these fields and many others relies on understanding how microstructural defects such as interfaces, dislocations, and point defects influence a materials thermal conductivity.

In this presentation, I will highlight several experimental and theoretical results which aim to establish a fundamental understanding of heat transport in defective materials. First, I will discuss several studies related to heat conduction across interfaces. Secondly, I will demonstrate in several material systems how defects can soften a materials lattice which reduces the phonon group velocity and thus decreases thermal conductivity. Lattice softening is a fundamentally different avenue to engineer thermal conductivity than phonon-defect scattering. I will then explain why lattice softening is theoretically more effective in anharmonic materials and at high temperatures, and how this is a dominate mechanism at play in several high thermoelectric efficiency (zT>2) PbTe based materials. Finally, I will discuss heat conduction in the ‘fully defective’ or amorphous limit. In this case the lack of sufficient periodicity leads to the concept of a minimum thermal conductivity defined by diffusionasquasiparticles instead of phonons.

Conveyor-Belt Entropy Transport In Weyl Semimetals—A New Concept for All-Solid-State Heat Switches
Joseph P. Heremans$^1$, Dung Vu$^1$, Nandini Trivedi$^1$, Michael Flatté$^2$ and Cuneyt Sahin$^2$; 1The Ohio State University, Columbus, Ohio, United States; 2The University of Iowa, Iowa City, Iowa, United States.

If they existed, solid-state switches with a large switching ratio between their off and on states would have many applications [1]. They would be particularly useful in combination with magnetocaloric engines and adiabatic demagnetization coolers, which are capable of reaching temperatures of 1 to 100 mK. In this talk, a new physical mechanism will be described for magnetically controlled entropy and heat transport based on the topological properties of Weyl semimetals [2]. Weyl semimetals are electrically conducting solids in which the bulk band structure consists of Dirac bands that come in pairs, with the Dirac points of each pair separated by a wavevector $k$. When the Fermi energy is at the Dirac points, charge is carried in the bulk by both electrons and holes. The carriers also have a Berry curvature $\Omega$. The surface states that correspond to this dispersion have themselves a dispersion that forms an arc in k-space, one on each of the top and bottom surfaces. An applied magnetic field normal to these arcs accelerates the carriers and holes, giving rise to a conveyor-belt flow of particles between the top surface, the bulk, the bottom surface, and the bulk again to the top surface. No net charge current flows since the carriers are of equal density and opposite polarity. Thermal transport along this conveyor belt stands in strong contrast to electrical transport. We show how
in the presence of a temperature gradient, these electrons and holes carry a non-zero entropy along the conveyer belt. This leads to an additional field-driven electronic thermal transport through the vdW cross contact between individual copper phthalocyanine (CuPc) nanoribbons. We establish a brand new perspective that neither RUMs nor phonons with negative Gr"uneisen parameters are necessary (or sufficient) in order for a material to undergo NTE. We elucidate the microscopic fundamental driving mechanisms behind NTE remain largely unknown for all but a handful of systems. One mechanism often invoked to explain NTE in inorganic framework materials and was characterized by its thermal conductance and response time. The switching ratio was calculated from the effective conductance between top and bottom surfaces. Experimental data will be shown on semiconducting Bi-Sb alloys, in which band inversion and a Weyl semimetallic state is induced by Zeeman splitting of the Landau levels. The field-induced thermal conductance dominates the electronic thermal conductivity in longitudinal magnetic fields. The effect is macroscopic and visible on millimeter-sized samples up to 200 K.

Two-Channel Thermal Transport in Ordered-Disordered Superionic Ag$_2$Te and Its Traditionally Contradictory Enhancement by Nanotwin Boundary Ming Hu; University of South Carolina, Columbia, South Carolina, United States.

Recent experiment has proved that superionic Ag$_2$Te can achieve a figure of merit as high as 1.39 due to its extremely low thermal conductivity. However, the traditional lattice vibration concept, i.e., phonons regarded as heat carriers, fails to explain the governing mechanism in such structures where anions vibrate around their equilibrium positions while cations flow like a liquid. As a result, the underlying physics for thermal transport properties in superionic Ag$_2$Te is still a mystery. In this study, two-channel heat transport in such ordered–disordered systems (i.e., lattice vibrations and liquid-like mobile ions coexist) is quantitatively characterized on the basis of the heat flux linear response theory. Our results show that the convective thermal conductivity is dominant in the system, which results from the free movement of Ag ions. As a consequence, the total thermal conductivity increases abnormally with temperature due to the strengthened cations’ mobilities at elevated temperatures. Meanwhile, the effect of experimentally observed nanotwin boundaries, which facilitate electrical transport in crystals, on heat carriers are also investigated. In contradiction to the classical heat transport theory, in which heat carriers are hindered by boundaries, the nanotwin boundary in superionic Ag$_2$Te unexpectedly improves thermal transport due to the enhanced movement of Ag ions around the grain boundary. This exhaustive explanation of thermal transport properties in superionic Ag$_2$Te will support the future design of superionic conductors based on thermoelectrics and more broad energy systems composed of ordered–disordered materials.

Giant Caloric Effects in Fast-Ion Conductors—A Promising Route for Ambient Solid-State Cooling Claudio Cazorla; The University of New South Wales, Sydney, New South Wales, Australia.

Solid-state cooling is a sustainable and energy efficient refrigerant technology that exploits field-induced reversible transformations in materials. Solid-state cooling is a promising alternative to traditional refrigeration technologies based on compression cycles of greenhouse gases, which in addition to their obvious environmental threats cannot be scaled down to small sizes (e.g., microchip dimensions). However, most caloric materials known to date (ferroelastic, ferroelectric, and magnetic compounds) display only modest refrigeration performances and/or operate at temperatures that are distant from ambient conditions.

Recently, we have demonstrated with state-of-the-art simulation methods that giant caloric effects occur in fast-ion conductors [1-3], a class of materials with high ionic conductivity below their fusion points that commonly are exploited in electro-chemical devices. The giant caloric effects disclosed in fast-ion conductors can be understood in terms of field-driven changes on their ionic conductivity, which entail large entropy changes and are highly reversible and responsive to external fields. A giant cooling effect of about 20 K has been just measured directly in the archetypal superionic compound AgI [4]. We argue then that solid-state cooling could benefit immensely from the intensive research already undertaken in the field of solid-state batteries.

High Switching Ratio Thermal Switch Using a Peltier Couple Mark A. Verosky$^1$, Michael J. Adams$^1$, Joseph P. Heremans$^{2,3}$, and Mona Zeharjadi$^{4,5}$; $^1$Department of Mechanical and Aerospace Engineering, The Ohio State University, Columbus, Ohio, United States; $^2$Department of Physics, The Ohio State University, Columbus, Ohio, United States; $^3$Department of Materials and Science Engineering, The Ohio State University, Columbus, Ohio, United States; $^4$Department of Electrical and Computer Engineering, University of Virginia, Charlottesville, Virginia, United States; $^5$Department of Materials and Science Engineering, University of Virginia, Charlottesville, Virginia, United States.

A critical design parameter of thermal switches is the ratio of between the thermal conductance in its on and off states; this parameter is denoted as the switching ratio. Most passive thermal switches rely on phase change material and operate only in small temperature regions. Active thermal switches usually require moving parts or vacuum seals. Here we propose an all-solid-state thermal switch with an adjustable switching ratio that can operate over a wide temperature range based on thermoelectric effects.

A switch was constructed from Bi$_2$Te$_3$-based materials and was characterized by its thermal conductance and response time. The switching ratio was calculated from the effective conductance measured in both open (no activation current) and closed switch (optimal activation current) configurations. This switching ratio correlates directly with the thermoelectric figure of merit ZT and diverges at small temperature difference. Switching ratios as large as 100 were found within the temperature range of $-20\,^\circ\text{C}$ to $140\,^\circ\text{C}$. The timed response can be predicted simply from the thermal resistance and capacitance.

Cross Interface Model for Thermal Transport through Cross Contact Xiaoxiang Yu$^1$, Yucheng Xiong$^2$, Dongyan Xu$^2$ and Nuo Yang$^1$; $^1$Huazhong University of Science and Technology, Wuhan, China; $^2$The Chinese University of Hong Kong, Shatin, Hong Kong.

The van der Waals (vdW) contact has emerged as a growingly important role due to their extensive presence in nanostructured materials and systems, such as assembled nanostructure building blocks array and vdW heterostructure, which recently shows massive potential as various functional electronic and optoelectronic devices. These applications require a thorough understanding of thermal transport through the vdW cross contact to address the increasingly severe heat dissipation problem in electronics. Here, we report on a systematic study of thermal transport through the vdW cross contact between individual copper phthalocyanine (CuPc) nanoribbons. We establish a brand new analytic model, cross interface model (CIM), for heat conduction across an interface with overlap, which is similar to the two-temperature model and the two-channel heat transport model, and apply the model to our experiments and numerical simulations. The experimental results by suspended thermal bridge methods reveal that the interfacial thermal conductance per unit area ($G_{th}$) between individual CuPc nanoribbons is on the order of $10^5\,\text{W/m}^2\cdot\text{K}$, which is two to five orders of magnitude smaller than that of the conventional solid-solid interfaces. Molecular dynamics simulations reproduce well the experimental results and suggest that the small $G_{th}$ was ascribed to the weak adhesion strength and the large separation distance of cross contact between CuPc nanoribbons. This work gives an analytic model for heat conduction in cross contact interface and points out that the deteriorative interfacial thermal transport between small molecular nanostructures remains significant bottlenecks for heat dissipation in related electronic devices.

Re-Thinking the Rules for Negative Thermal Expansion from First Principles—The Case Of PbTiO$_3$ Ethan T. Ritz and Nicole A. Benedek; Cornell University, Ithaca, New York, United States.

While most materials expand when heated, materials that exhibit negative thermal expansion (NTE) shrink when heated. NTE materials are critical in applications involving extreme thermal environments, such as inside gas turbine engines, computing hardware and spacecraft. However, while first observed experimentally over a century ago, the fundamental driving mechanisms behind NTE remain largely unknown for all but a handful of systems. One mechanism often invoked to explain NTE in inorganic framework materials and was characterized by its thermal conductance and response time. The switching ratio was calculated from the effective conductance measured in both open (no activation current) and closed switch (optimal activation current) configurations. This switching ratio correlates directly with the thermoelectric figure of merit $ZT$ and diverges at small temperature difference. Switching ratios as large as 100 were found within the temperature range of $-20\,^\circ\text{C}$ to $140\,^\circ\text{C}$. The timed response can be predicted simply from the thermal resistance and capacitance.

even though PbTiO$_3$ contains many RUM-like modes. Indeed, PbTiO$_3$ is unique among well-known NTE materials in that it appears to be the only materials that exhibits volumetric NTE well above room temperature and with positive Grüneisen parameters along all unique crystallographic axes. We find that the symmetry breaking distortion that drives the ferroelectric transition in PbTiO$_3$ also has a significant effect on both the elastic properties and lattice dynamics in general, and the NTE behavior of PbTiO$_3$ in particular. Our work has implications for the understanding of, discovery and design of NTE in perovskites and other families of inorganic materials.

Several experiments have been carried out recently to better understand lattice and electronic thermal transport behaviors in three material systems. Based on steady-state differential measurements, the electronic thermal conductivity of h-BN/graphene/h-BN heterostructures deviate considerably from the Wiedemann-Franz law for both the bi-polar and single carrier type regimes and at both low and high temperatures, and the lattice thermal conductivity of graphene appears to increase when it is encased in h-BN compared to when it is supported on amorphous oxide. In addition, steady state electro-thermal and lock-in Raman thermometry measurements have found that the average thermal conductivity of millimeter size boron arsenide bulk crystals approaches the theoretical limit set by four-phonon scattering. Meanwhile, a multiple probe thermal transport measurements have observed a much weaker length dependence of the thermal conductivity of silicon germanium nanowires compared to a previous report, and the measurement results are in agreement with a first principles calculation.

Electrical and Thermal Transport Properties of Micron-Size Crystals Of Topological Kondo Insulator, Samarium Hexaboride (SmB6) Narayan Poudel1, Daniel Murray1, Jason Jeffries1 and Krzysztof Gofryk1; 1Idaho National Laboratory, Idaho Falls, Idaho, United States; 2Lawrence Livermore National Laboratory, Livermore, California, United States.

In the last 5 years the Kondo insulators have drawn a great interest in the field of strongly correlated systems. Special interest has been devoted to SmB6 that has been proposed to be a topological Kondo insulator at low temperature. Various electrical and thermal measurements have been performed on this material to explore its low-temperature insulating phase. These measurements often gave conflicting results due to the quality of the material used. To overcome these problems, we use micron-size single crystals prepared by plasma Focus Ion Beam (FIB) system and measure the thermal and electrical properties by specially designed experimental configuration. During the talk, I will present our experimental setup focusing on recent transport measurements of micron-size SmB6 crystals at low temperatures and high magnetic fields. I will discuss our results in the context of the presence of metallic surface states in this material. In addition, the thermal conductivity of the micron-size SmB6 crystals, measured by the 3w-method, will be presented and discussed.

Giant Enhancement in Rashba Spin-Seebeck Effect in NiFe/p-Si Thin Films Ravindra G. Bhardwaj2, Paul Lou1 and Sandeep Kumar1, 2; 1Mechanical Engineering, University of California, Riverside, Riverside, California, United States; 2Material Science and Engineering, University of California, Riverside, Riverside, California, United States.

The spin-Seebeck effect mediated thermoelectric energy conversion can provide an efficient alternative to traditional thermoelectrics for waste heat recovery. To achieve this goal, efficient spin to charge conversion using earth-abundant materials is essential. Proximity-induced Rashba effect arises from the charge potential mediated by structural inversion asymmetry, which has been reported in Si thin films and can be manipulated by controlling the thickness of the Rashba layer. We demonstrate a giant Rashba spin-Seebeck effect in NiFe/p-Si (polycrystalline) bilayer thin films. The bilayer thin film specimens have the p-Si layer thickness of 5, 25, and 100nm while keeping the NiFe layer thickness at 25 nm. The Rashba spin-Seebeck coefficient has been estimated to be 0.266 μV/K for 100nm p-Si, and increases by an order of magnitude to 2.11 μV/K for 5 nm p-Si. The measured spin-Seebeck coefficient in 5 nm p-Si specimen is one of the largest coefficients ever reported. The measured voltage of 100.3 μV is one of the largest reported spin-Seebeck voltages, with the smallest area of ~160×10 μm used in any spin-Seebeck measurement. This scientific and technological breakthrough using earth-abundant elements brings the spin mediated thermoelectric energy conversion for waste heat recovery closer to reality.

Nanoscale Simulation of Self Heating and Thermal Crosstalk in 3D finFET Architectures
Bjorn Vermeersch, Erik Bury, Kristof Croes, Herman Oprins, Hamed Kamrani and Geoffrey Pourniotis; imec, Leuven, Belgium.

Heat conduction in confined geometries and around small sources is known to no longer obey standard diffusion models. In contemporary electronic devices, where nanoscale active regions and extremely thin layers are widely prevalent, both effects combine and can induce junction temperatures that substantially exceed conventional predictions. Even so, virtually all commercial TCAD software carries out device-level thermal simulations using classical Fourier diffusion models with either nominal or phenomenologically adjusted thermal conductivities.

Advances in both theoretical understanding and computational power over the past decade have brought refined microscopic treatments within conceptual reach. Computational DFT and phonon Boltzmann codes such as VASP and ShengBTE have enabled researchers to model and predict direction and temperature dependent bulk thermal conductivity for a wide range of semiconductor compounds from first principles. The almaBTE platform subsequently extended these capabilities to analysing the thickness-dependent effective conductivity reduction in thin films and 1D Monte Carlo simulations of multilayer substrates.

In typical device geometries, however, thermal transport has a pronounced multi-dimensional character and occurs through a variety of material systems in which phonons are not always the dominant heat carriers.
