Here, we report on the development of a custom thermal simulation platform that addresses the limitations of currently available tools. Our IMPALA framework brings quasielastic modelling capabilities to realistic TCAD settings. The solvers perform Monte Carlo simulation of 2D and 3D modular geometries using a hybrid materials modeling approach. The latter enables us to tackle, within one seamless particle-based simulation environment, the three types of compounds typically encountered in complex structures. Firstly, for semiconductors we employ wavevector-resolved phonon dispersions and scattering rates computed from first principles. These inherently capture the less efficient heat removal that arises in thin layers and around small active junctions. Secondly, metal contacts and electrodes are treated under the isotropic grey-medium BTE using estimated or measured values for the electron mean free path. Doing so naturally captures the size-dependent excess resistivity observed in narrow lines. Finally, heat flow in amorphous regions such as passivation/insulation layers is simulated by Brownian motion, thereby replicating diffusive transport at nominal bulk conductivity.

Practical applications for analysing front-end and back-end of line (FEOL/BEOL) self-heating and resulting thermal cross-talk in state-of-the-art finFET architectures will be discussed. 2D simulations already suggest the quasiballistic heat flow to have intricate repercussions on FEOL and BEOL reliability. The suppressed thermal performance of the transistor fins induces both a substantial increase in junction thermal resistance and stronger heat spreading along the drain electrodes. In turn, this raises the temperature in overhead metal lines, even near idle devices. Simulations of 3D structures, which are currently underway, can further elucidate the resulting impact on electromigration in the BEOL.

Understanding the Lattice Thermal Conductivity and Lorenz Number in Tungsten from First Principles
Yani Chen, Jinlong Ma and Wu Li; Shenzhen University, Shenzhen, China.

Tungsten is known to have a Lorentz number L larger than the Sommerfeld value Ls by 30%. By performing fully first-principles calculations, we are able to calculate the electronic conductivity (β) and quantify the electronic (κe) and lattice (κl) contributions to the thermal conductivity with a high accuracy. We show that the deviation of L is entirely due to κl. At room temperature κl is 46 W/m-K, one order of magnitude larger than that in other metals even with smaller atomic mass and higher Debye temperature, and likely the largest of all metals. The large κl is ascribed to the surprisingly weak anharmonic phonon scattering. The weak anharmonic phonon scattering is facilitated with the large atomic mass, leading to small thermal displacement.

Non-Cured Thermal Interface Materials with High Graphene Loading
Sahar Naghibi, Fariborz Kargar, Zahra Barani, Ruben Salgado, Dylan Wright and Alexander A. Balandin; Phonon Optimized Engineered Materials (POEM) Center, Department of Electrical and Computer Engineering, Materials Science and Engineering Program, Bourns College of Engineering, University of California., Riverside, California, United States.

Reliable affordable thermal management technologies remain a major packaging challenge driven by the continuous miniaturization of integrated circuits, increase of functionality of mobile devices, and growing computing density in data centers. Development of the next generations of thermal interface materials (TIMs) is important for packaging and thermal management of all electronic and optoelectronic devices. The discovery of the unique heat conduction properties of graphene [1] motivated numerous studies on the use of graphene and few-layer graphene in various composites. The most recent studies of thermal composites with graphene have been limited to curing epoxy-based composites [2-3]. However, TIM applications in thermal management of computers and other electronic gadgets, require non-cured TIMs. The Semiconductor Research Corporation (SRC) target for the thermal conductivity of TIMs is ~10 W/mK near room temperature. Despite substantial efforts and investments in research of new TIMs in the last couple of decades, there is no commercial thermal greases available with the verifiable thermal conductivity above 10 W/mK and the thermal interface resistances below 10 Kmm2/W. Commercial TIMs filled with conventional thermal conductive particles require large filler loading, >50% to achieve the thermal conductivity of the composite in the range of ~0.5 – 6 W/mK. In this presentation we report on development of the exfoliation and mixing techniques for preparation of the non-cured mineral-oil based composite with the commercially produced graphene flakes. The viscosity of the composites was kept in the range required for easy dispersion on the surfaces of interest. The lateral sizes of the few-atomic-layer fillers of graphene ranged from ~2 µm to ~15 µm while the thickness varied from single atomic planes of 0.35 nm to ~12 nm. The thermal conductivity of TIMs was determined using two types of industry standard TIM Testers (Longwin LW-9389 and Analysis Tech, Inc.), following the ASTM D5470-06 standard. It was found that the thermal conductivity of the graphene-based non-cured TIMs can exceed that of the best commercially available TIMs at substantially lower loading fraction. We will discuss the dependence of the thermal conductivity on the graphene loading characteristics, below and above the thermal percolation threshold. Brillouin – Mandelstam spectroscopy was used to determine the acoustic phonon velocities before and after graphene incorporation. Taking into account recent technological developments in the liquid phase exfoliation of graphene and various methods of reduction of graphene oxide, we argue that our results can open up new application domain for graphene in non-cured TIMs.

This work was supported, in part, by the National Science Foundation (NSF) through the Emerging Frontiers of Research Initiative (EFRI) 2-DARE award 1433395, and by the UC – National Laboratory Collaborative Research and Training Program LFR-17-47723.

Strong Phonon Anharmonicity of Type-I Clathrate Compounds
Masato Ohnishi1, Terumasa Tadano2, Shinji Tsuneyuki1 and Junichiro Shionoi1; 1The University of Tokyo, Tokyo, Japan; 2National Institute of Materials Science, Tsukuba, Japan.

Clathrate compounds are promising candidates for thermoelectric materials in terms of the “electron-crystal phonon-glass” concept. Because of strong anharmonic potential of guest atoms in cage structures of type-I clathrates, guest phonon modes lead to strong phonon scattering. Recently, first-principles simulations of phonon properties of a clathrate have been first demonstrated with using self-consistent phonon (SCP) theory that can include temperature-dependent fourth-order anharmonic interatomic force constants (IFCs) into harmonic IFCs [Tadano et al. Phys. Rev. Lett 120, 105901 (2018)]. Here, we reveal unusual anharmonic effects of phonons by comparing phonon properties of type-I Ba8Ga5O12X0.5 (X = Si, Ge, Sn, BGX) with first-principles simulations. We have first succeeded to calculate temperature-dependent thermal conductivities of BGXn with first-principles approach, which has the minimum thermal conductivity among the reported values of clathrates. Because the selection of atoms composing cage structures, namely Si, Ge, or Sn, manipulates the degree of anharmonicity, we have clearly observed effects of anharmonicity of phonons in clathrates. For example, we have observed an unusual effect of grain boundaries on phonon transport in BGXn; polycrystallization decreases a thermal conductivity of BGXn more at higher temperature.
Multi-Carrier Thermal Coupling at Heterogeneous Interfaces

Energy and mass transport across grain boundary determines the physical property of materials. The emerging grain boundary engineering methods coupled with laser-based acoustic spectroscopy and thermal transport could offer a new route to study the microstructure of polycrystalline ceramics for novel applications. Here, we employ the time-domain Brillouin spectroscopy (TDBS) to non-invasively monitor acoustic phonon propagation inside individual grains and detect the microstructure of polycrystalline cera, an important electrolyte material in solid oxide fuel cells. TDBS employs a conventional pump-probe technique based on femtosecond laser. The pump beam launches bulk acoustic waves propagating away from the surface and a time-delayed probe beam detects propagation of these acoustic waves. Strong longitudinal waves are readily observed whose velocity agrees with theoretical calculations. Large amplitude shear waves are generated through mode conversion when a thin layer of gold is deposited with matched acoustic impedance. Amplitude of measured shear phonon exhibits strong dependence on optical polarization of the probe beam. A theoretical model that accounts for the generation, propagation, and detection of acoustic phonons is developed to explain these observations. Additionally, the capability of TDBS to image grain microstructure non-destructively through deep substrate measurement of Brillouin oscillation frequency is demonstrated. The grain orientations at the surface are obtained and compared with the results from electron backscatter diffraction technique (EBSD). The subsurface morphology of grain boundary is constructed in 3D nondestructively, unlike traditionally used EBSD that requires destructive sequential analysis. The current work paves the path for future study on phonon/grain boundary interaction and offers guidance for material design in advanced energy systems.

Giant Effect of Spin-Lattice Coupling on the Thermal Transport in Two-Dimensional Ferromagnetic CrI

Recently, two-dimensional monolayer chromium triiodide (CrI) with intrinsic magnetism was experimentally discovered, which shows promising applications in many technologies ranging from sensing to data storage where thermal transport plays a critical role. However, so far, the effect of spin-lattice coupling on the thermal transport properties has not been explored yet. In this talk, we present the giant effect of spin-lattice coupling on the lattice thermal conductivity ($\kappa$) of monolayer CrI. The lattice thermal conductivity is more than two orders of magnitude enhanced by considering the spin-lattice coupling. The effect is found to be especially stronger for the acoustic phonon modes, which dominates thermal transport with spin-lattice coupling. The mechanism lies in the weakened phonon anharmonicity by spin-lattice coupling. The bond angle and atomic position are changed due to the spin-lattice coupling, making the structure much stiffer and more symmetric, which lead to the weaker phonon anharmonicity, and thus the enhanced thermal conductivity. This study uncovers the effect of spin-lattice coupling on the thermal transport, which would deepen our understanding on thermal transport and shed light on future research of thermal transport in magnetic materials.

Multi-Carrier Thermal Coupling at Heterogeneous Interfaces

Efficient heat transfer is one of the major concerns in the design of micro- and nano-scale materials and devices. In metals, electrons and phonons both carry significant thermal energy, whereas in semiconductors and dielectrics phonons are the dominant carriers. Therefore, for metal-semiconductor composite structures, heat can transfer across an interface by coupling either between phonons in metal and dielectric or by direct coupling between electrons in metal and phonons in dielectric through electron-interface scattering. Phonon-phonon coupling at interfaces has been well studied, mainly by the acoustic mismatch model (AMM) and the diffuse mismatch model (DMM). For electron-phonon coupling at and near hetero-interfaces, a number of different viewpoints exist. Some studies have assumed that electron-phonon coupling across a metal-dielectric interface is negligible, and heat transfer occurs as electron-phonon coupling within metal and then phonon-phonon coupling across the interface. Electron-phonon coupling at metal-dielectric interfaces has been measured to exhibit negligible apparent thermal resistance in some cases, yet other times it has been suggested to be important [e.g., for Pd-diamond]. In recent work we have shown that, with accurate definition and understanding of atomic structure, the electron-phonon coupling across silicide-silicon interfaces must include rigorous first-principles understanding of electron-phonon coupling (e.g., via the Eliashberg function) both within the metal and in the near-interface region of the semiconductor in order to obtain close quantitative agreement with experiments [1], [2]. In summarizing the current state of this topic, it would be reasonable to conclude that some qualitative understanding is emerging on cross-interface electron-phonon coupling, but that quantitative models validated by experiments remain scarce. Here, we discuss a new innovation – namely interfaces with tunable interfacial heat transfer characteristics to assess the relative contributions of different carriers and coupling mechanisms. As another example, electron-phonon coupling in bilayer graphene controls its unique photoconduction response. We find that, in contrast to single-layer graphene, $\Gamma$ point LA’ and TA’ modes in bilayer graphene couple strongly with electrons with energies lower than 200 meV, while optical modes dominate in the high electronic energy range. A Drude model of photoconductivity provides good agreement with experiments for both the real and imaginary components. Finally, we discuss a rigorous temperature-dependent approach involving Green-Kubo equilibrium spiral and atomic dynamical properties to assess phonon-magnon interactions in magnetic solids. Resulting predictions of the non-electronic thermal conductivity of iron show very good agreement with experimental measurements. By computing the modal phonon-magnon scattering rates, the high-frequency phonon-magnon scattering rates are found to be one order magnitude larger than those at low frequencies regions due to energy conserving rules and the high density of states. This new framework fills existing gaps in simulating thermal transport across the ferro/para-magnetic transition.

References
the wave vector. A force constant is a derivative of the total potential energy of the system with respect to the displacement of a given atom. Accurate methods to compute these quantities are needed without the approximations inherent in finite difference methods.

In this paper, we present the automatic code differentiation technique to perform unintrusive sensitivity analysis and derivative computation in nanoscale phonon transport simulations. This method exploits the concepts of templating and operator overloading in C++ and other similar programming languages to unintrusively convert existing codes into those yielding derivatives of arbitrary order. The idea is demonstrated through the computation of phonon properties such as second and third order force constants, the Gruneisen parameter, group velocities, and the temperature sensitivity of specific heat for graphene nanoribbons. Derivative values so computed are compared with those obtained using finite difference approaches or with analytical values. The method is found to yield derivative values to machine accuracy, with none of the round-off issues associated with finite difference approaches.

Deducing Phonon Modes from Atomistic Simulations
Antan Raj and Jacob Eapen; Nuclear Engineering, North Carolina State University, Raleigh, North Carolina, United States.

Normal modes are non-interacting, non-decaying collective excitations of atomic vibrations. Many-body atomistic dynamics with an arbitrarily accurate anharmonic Hamiltonian provides a direct approach for probing the interactions among the crystal normal modes. The traditional normal mode analysis (NMA) framework, which employs complex normal mode coordinates, does not, however, distinguish the non-resistive normal (N) phonon interactions from the resistive Umklapp (U) interactions. By adopting a set of real asymmetric normal mode coordinates, we show that both N and U processes can be resolved directly from atomistic simulations.

Although the normal modes exchange energy continuously, they are localized in the reciprocal space and engage in discrete interactions. Interestingly, we observe that the harmonic and anharmonic energies do not remain constant. The time-dependent Hamiltonians, which is an intrinsic property of all anharmonic lattices even at low temperatures, can allow a multitude of normal mode interactions that are not possible with constant anharmonic energies. Using graphene as a model material, we show the emergence of normal modes that are created and annihilated simultaneously. We anticipate that such additional scattering channels can be discovered with more complex Hamiltonians using the current approach. Finally, we discuss the correspondence between the normal modes extracted from atomistic simulations and the quantum phonon modes that are employed in Boltzmann transport equation (BTE).

Unconventional Impact of Thermal Phonon Coupling in Film-On-Substrate Systems
Kartik S. Kothari, Abhinav Malhotra and Martin Maldovan; Georgia Institute of Technology, Atlanta, Georgia, United States.

An accurate determination of thermal transport in thin film-on-substrate (FOS) architectures is crucial to optimum performance of nanostructured devices. A rigorous treatment of the nanoscale interfacial thermal coupling between materials accounting for dispersion mismatch, interfacial roughness and shadowing effects is imperative in studying the impact of substrates on thin-film conduction. We demonstrate novel thermal functionality in FOS systems, creating a new paradigm for thermal management in optoelectronic applications. In a breakthrough finding, we discover an increase in thermal conductivity with a reduction in thin-film thickness attributed to phonon injection from the substrate layer. We examine the in-plane and cross-plane configurations of thermal conduction in Ge and Al_{0.5}Ga_{0.5}As thin-films mounted over Si and GaAs substrates respectively. We provide an extensive analysis of phononic coupling and contrast the results with bulk and isolated thin film values. We present a detailed microscopic and spectral analysis by investigating the spatial thermal flux distribution, modal thermal conductivity, and mean free path and frequency spectra in the FOS architecture. We elucidate how interlayer phonon coupling opens new avenues for thermal conductivity manipulation in nanostructures and achieves desired thermal properties for rational thermal material design in microelectronics and optoelectronics.

3D Silicon Meta-Lattices with Low Thermal Conductivity and Bulk Electrical Transport

Nanostructured thermoelectrics are currently emerging as promising materials for energy generation due to their improved thermoelectric efficiency via increasing contribution of complex nano-interfaces to the decreasing thermal transport through them. However, lack of 3D order and connectivity restricts the flow of electrons and phonons through the structure. But, theoretical predictions of electrical and thermal properties through periodically arranged nanoporous silicon suggests significant improvement in performance of such thermoelectric devices. In the present work, a 3D ordered and precisely doped Si nanostructure, namely an inverse opal metalattice, with periodicities on the order of 1-100 nm is synthesized using unique infiltration of Si into the voids of closely packed silica spheres nanotemplates through high pressure confined chemical vapor deposition. Subsequently, Time domain thermoreflectance method is utilized to measure the thermal transport through these structures as a function of sphere size ranging from 14-100nm and observe the effect of interfacial thermal resistance and appropriately control it to strive towards higher thermoelectric figure of merit. Initial data on intrinsic Si inverse opals show a significant reduction in thermal conductivity with values lying close to or lower than fused silica indicating a dominant interface effect on phonon transport through these structures. Secondly, occurrence of a minima at 20nm sphere size further points towards the role that geometry has on phonon scattering mechanism while travelling through them. Theoretical understanding of the phonon transport mechanism and subsequent studies of thermal transport with respect to variation of geometry, composition and porosity will be performed to aim towards potential thermoelectric applications of these structures.

Engineered Particle-Particle Contacts for High Thermal Conductivity Soft Polymer Composites
Matthew Ralphs, Wilson Kong, Robert Wang and Konrad Rykaczewski; Arizona State University, Tempe, Arizona, United States.

Thermal interface materials (TIMs) are arguably the solution to faster and smaller computer chips. As integrated circuits get faster and smaller, it becomes more difficult and paramount to remove the excess heat. TIMs accomplish this by dramatically reducing the contact resistance between IC components so heat can be better conducted away from the chip. The most common way to make a TIM is to add high conductivity particles to a polymer matrix, which boosts the thermal properties of the base polymer material. However, the interfacial thermal boundary resistances between the particles and matrix ($R_{pp}$) and the particles themselves (particle-particle resistance, $R_{pp}$) prevent the high k particles from passing heat through the matrix effectively. In this presentation, we will discuss a two-step process for resolving this issue: inducing particle percolation using magnetic alignment and engineering of their contacts using shell structures that minimize $R_{pp}$. Maximum particle-particle contact is achieved by magnetically aligning the fill material in the polymer matrix. The applied magnetic field seggregates particles into aligned columns within the polymer matrix, enforcing percolation and ensuring good contact between particles. We show that magnetic alignment of the particles alone doubles the thermal conductivity of the composite ($k$) over the unaligned composites, even without any special consideration for the particle-particle interfaces. With the particles in good contact with one another, particle contact engineering can then have the greatest effect in boosting $k$. We use silver and liquid metal particle coatings to decrease $R_{pp}$ of solid nickel particle fill by providing a layer that can plastically deform and increase the particle-particle contact
area. Dry powder beds show a decrease of more than 4× in thermal resistance with a silver shell thickness of only a few hundred nanometer and 500 kPa force to “sinter” the powders together. Similarly, liquid metal is used as a coating for the nickel particles and shows a similar decrease in thermal resistance but requiring a larger amount of liquid metal for an equivalent reduction in thermal resistance.

Applying these engineered contacts in a magnetically aligned polymer composite maximizes the benefits of the silver and liquid metal coatings by enforcing good particle-particle contacts throughout the polymer matrix. We demonstrate that the magnetically aligned silver coated nickel particles produce almost an extra 2× increase in k over the aligned nickel particles at volumetric fill ratios of 0.4 and 0.5 with an 8vol% silver shell. The aligned liquid metal coated nickel show small increases in k over the aligned nickel particles until the volume of liquid metal to Ni reaches 50%, where a 2.5× increase is achieved over the aligned nickel composite at a particle volume fill fraction of only 0.3. The mechanisms are discussed and a full parameter space is explored to fully evaluate these engineered contacts and minimize Rp/n.

Work has been conducted on the laser patterning of graphene and 2D thin transition metal dichalcogenide (TMDC) films. Laser thinning has been performed in conjunction on-line diagnostics to precisely control the film thickness. Tuning the properties of atomic layer films by modulating the free carrier type and density and composition can offer an exciting new pathway to various practical nanoscale electronics. Our laser induced doping process is spatially local and selective, and the doping level is widely tunable by varying the duty cycle and laser irradiation. Moreover, laser doping can be digitally controlled and is an air-stable process for achieving fabrication of high-quality, high-fidelity nanodevices. Sharp and high quality P-N junctions have been demonstrated, and using laser thinning of liquid metal nanodevices has been developed, aiming at decoupling the vacancy formation, precursor gas decomposition and dopant incorporation processes. Controlled doping of graphene and TMDC films has been demonstrated via this approach. Time-resolved probing with femtosecond resolution has been conducted to understand the transport properties of the ultrathin films and the effects of doping and defect formation.

The transient thermal grating (TTG) technique, in which two crossed laser pulses produce a spatially periodic temperature profile whose decay is monitored with a probe laser beam, is widely used for thermal transport measurements. On the one hand, this technique provides a non-contact method of measuring thermal diffusivity with intrinsically high absolute accuracy. On the other hand, it offers a tool for studying heat transport at small distances without the need to fabricate nanostructures, with the heat transfer distance controlled by the TTG period. However, the latter cannot be made smaller than half the optical wavelength, thus limiting the ability to study thermal transport on the nanometer scale. This difficulty can be circumvented by using an extreme ultra-violet (EUV) laser source. TTG measurements in the EUV range (13-50 nm) are now possible at the FERMI free electron laser facility (Elettra, Trieste, Italy). In this report, we will describe the first measurements of thermal transport with thermal gratings produced by EUV light performed at FERMI. In the initial series of measurements, we used EUV excitation (12.7 nm) and optical probe (400 nm) to study thermal transport in single crystal silicon and diamond sample at a TTG period of 280 nm, corresponding to a heat transfer distance of ~90 nm. We find that in silicon the heat transport is strongly non-diffusive but still does not reach the ballistic limit. In diamond the heat transport is found to be close to the purely ballistic regime. The results will be compared with calculations based on the Peierls-Boltzmann phonon transport equation using scattering rates calculated from first principles. We will also describe the first measurements with EUV light used for both excitation and probing, which made it possible to shrink the TTG period to 25 nm (heat transfer distance ~8 nm). The EUV probe has an additional advantage of being insensitive to electronic excitations, which simplifies the interpretation of the measurements. Further prospects for using EUV transient gratings to study thermal transport on the single-digit nanometer scale will be discussed.

Thermal energy dissipation and transport processes influence the physical properties of matter, control the kinetics of chemical reactions, and trigger bio-molecular mechanisms in living organism. Understanding how thermal phenomena arise and change as the characteristic length scale of structures becomes comparable to or even shorter than the mean free path of energy carriers such as electrons and phonons is therefore on of the key challenges in the physical sciences. In this talk, we will first provide an overview of the numerous scanning probe based thermal nano-imaging and spectroscopy methods developed to quantify local energy dissipation and thermal transport phenomena in nanoscale systems and molecular structures. We will highlight the unique capabilities of thermal scanning probe techniques to unravel local dissipation processes down to few-nanometer length scales, and discuss prospects to extend existing thermal imaging approaches towards characterization of collective dissipation processes in quantum material systems. Secondly, we will present recent experiments extending traditional scanning thermal microscopy towards nanoscale spectroscopy. We will illustrate how local photo-thermal forces in tip-sample nanocavities enable to study energy dissipation in molecular systems with simultaneous chemical specificity. We will illustrate how to separate thermally induced expansion from optical forces and provide guidelines for the development of new thermal nanoimaging modalities combining local scanning probe with tunable laser excitation.

Individual luminous nanoparticles enable temperature measurements with sub-diffraction limited spatial resolution. While single-particle measurements require excitation intensities orders of magnitude higher than nanoparticle ensembles, potential single-particle self-heating effects remain largely uninvestigated because thermal models predict negligible self-heating. We show that the common “ratiometric” thermometry single of individual 50 x 50 x 50 nm3NaYF4:Yb3+:Er3+ nanoparticles increases unexpectedly with excitation intensity, implying a temperature rise over 50 K if interpreted as thermal [1]. Luminescence lifetime thermometry results indicate a similar temperature rise. We resolve this apparent contradiction between model and experiment by systematically varying the nanoparticle’s thermal environment: the substrate thermal conductivity, nanoparticle-substrate contact resistance, and nanoparticle size. The apparent self-heating remains the same in all cases, demonstrating that this effect is an artifact rather than a true temperature rise. Using established rate equation models, we show that this artifact is instead due to increased radiative and non-radiative relaxation from higher energy Er3+ manifolds.

Following calibration of this apparent self-heating effect, individual NaYF4:Yb3+:Er3+ nanoparticles can be employed as accurate nanothermometers. We demonstrate the ability of 50 x 50 x 50 nm3 NaYF4:Yb3+:Er3+ nanoparticles to characterize nanoscale hotspots and sharp temperature gradients using two different modalities. First, by coating a low thermal
conductivity substrate with an optically absorbing metal film, we can achieve substantial local heating and measure the peak temperature within a laser-heated spot using a single exciting laser beam. Our nanoparticle thermometer minimizes spatial averaging of the temperature profile, thereby increasing the accuracy of this temperature measurement relative to thermometry techniques with coarser resolution. We also measure the spatial temperature variation within the laser-heated spot. Additionally, we Joule heat microfabricated metal structures to create sharp temperature gradients via “current crowding” effects caused by geometric constrictions. We then quantify the temperature variation in these structures. Our measurements demonstrate that individual NaYF₄:Yb³⁺:Er³⁺ nanoparticles can be used as nanoscale thermometers in scenarios ranging from fundamental thermal measurements to device-level applications.

Nanothermometry and Nanocharacterization in Scanning Thermal Microscopy—Approach Curves and Temperature Jumps at Contact Ali Alkuri1, Axel Pic2, Aloise Guen3, Antonin M. Massoud1, Wenyu Zhao1, Jan Martinek1, Christophe Lucchini1, Rodolphe Vaillon1, Sebastien Gallois-Garreignot2, Matthieu Bugnet1, Petr Klapetek1, Jean-Marie Bluet1, Séverine Gomès1 and Pierre-Olivier Chapuis3; 1CNRS - INSA Lyon, Lyon (Villeneuve), France; 2ST Microelectronics, Crolles, France; 3CMi, Brno, Czechia; 4IES, Madrid, Spain.

Scanning thermal microscopy (SThM) is a key thermal characterization tool, where a micro to nanometer-scale probe tip measures the temperature close to a surface. The spatial and temperature resolutions of this technique are limited in particular by the size of the tip, the sample properties, and the various tip-sample heat transfer mechanisms [1] depending on the operation conditions. In this communication, we present a study of heat transfer between a sample surface and a SThM probe based on resistive thermometry: the probe electrical resistance depends on the probe temperature. Such probe operates either in thermometry (passive) mode with a minimal Joule self-heating to enable sample surface temperature measurement or in thermal-property measurement (active) active mode where a significant Joule heating is needed to allow thermal power flowing into the sample, depending on its thermal conductivity.

We first study the hot tip-cold sample (active mode) heat exchange as a function of the tip-sample distance [2]. When the tip is far from the surface (>100 micrometers), it is cooled by heat convection and there is no exchange with the sample. At lower distances, the diffusive heat exchange starts. The exact geometry is required to compute accurately the transfer, which can be done by means of Finite Element Modeling (FEM). In the sub-micrometer distance regime, air conduction cannot be modeled by usual FEM because the air mean free path (~60 nm) is on the order of the average distance between the hot object and the sample. In our simulations, we account for this deviation to the diffusive regime by adding thermal resistances on surfaces, which correspond to the ballistic transfer limit in air. This allows us to reproduce numerically the ballistic leveling off seen experimentally. Depending on the probe considered, a 1D approximation [3] or improved considerations based on the Boltzmann transport equation for air molecules are to be taken into account.

When the tip and the sample are in contact, heat transfer is enhanced, which is described by the contact thermal conductance. It includes contributions from the solid-solid mechanical contact, the water meniscus around the mechanical contact and the constrictions in the heat flux path. In the best cases, this thermal contact is responsible for 5% of the total tip temperature decrease due to the tip-sample exchange. We discuss the impact of various tips with curvature radii ranging from a micron down to 10 nm, especially the ballistic thermal dissipation in the sample, and the impact of vacuum-condition operation, where air transfer is removed. In addition, the modest impact of the applied force on the heat exchange is observed.

In a second step, we consider SThM thermometry (passive mode). There are two key phenomena to account for. First, the probe temperature is not equal to that of the sample, as the cantilever base acts as a heat sink which imposes a temperature distribution in the tip. Second, since the tip acts partially as a heat sink which is placed close to the sample, it modifies the sample temperature distribution. Accounting for this effect can be crucial, as highlighted by experiments performed with samples heated by means of Joule-heated electrically-resistant serpentines.

We believe that this work, where both the understanding of the physical mechanisms responsible for thermal transport between the tip and the samples and precise knowledge of the energy balance of the tip-sample systems are targeted, provides a decisive step for determining quantitative data from the experiments.

Decoupling Phononic and Electron Temperatures in Thermionic Power Converters Nicki Hogan, Shengxiang Wu and Matthew Sheldon; Texas A&M University, College Station, Texas, United States.

Our laboratory is interested in taking advantage of plasmonic properties for thermionic power converters. The benefit to using these metasurfaces comes from the additional population of photo-excited non-thermal ‘hot’ electrons on top of traditional photothermalization. Thermionic emission current increases as a function of temperature, however practically devices are limited by the melting point of the metal. This significantly hinders possible power conversion applications. By decoupling the electronic and phononic temperature in nanostructured films we can increase the electronic temperature to a regime where there is efficient emission without destroying the device.

We show how anti-Stokes Raman spectroscopy can independently measure the phononic and electronic temperature. This allows for us to demonstrate the changes in the electronic temperature in response to excitation wavelength but also changes in nanostructure geometry. Phononic temperatures from the nanostructures under laser excitation vary from 300-500 K, well below the melting point of the structures, while electronic temperatures range above 5000 K. These electronic temperatures are high enough to promote efficient electron emission in a temperature range where the device is still thermally stable.

We verify that device power conversion matches our temperature measurement by constructing a simple thermionic device by pairing the metasurface with an ITO anode and measuring current across the vacuum gap between the two. We demonstrate that a gold film, which has fewer hot electrons at electronic temperatures <2000 K, shows no measurable current. However, nanostructured surfaces lead to a short circuit current of 0.015 A*cm² under continuous wave illumination of 10⁶ W/m². Correlating the temperature and the measurement gives information about the lifetime of a hot electron as well as the electron-phonon coupling that we correlate to other ultra-fast time resolved studies.
Thermoelectric Generators (TEGs) can continuously convert human body heat into electricity. Therefore, they can eliminate the usage of chargeable batteries in wearable devices. The next generation of self-powered devices come up with controlling the performance of thermoelectric materials and device together. For body wearable TEGs the performance is limited by the hot side (skin) and cold side (ambient) heat exchangers as they experience high parasitic resistances to the body [1]. This requires the TEG to be designed with not only careful consideration of material properties, but also specific consideration of module design, particularly the fill factor and contact resistance. Most of current research is focused on improving the thermoelectric material properties to enhance the efficiency of the TEGs while poor design of the TEG module can produce parasitic resistances that can reduce the generating power on body condition.

To improve the performance of the TEG device, the thermal resistance of the module should be much higher than parasitic resistances. The module thermal resistance can be increased by reducing the thermal conductivity of the legs, increasing the aspect ratio of the legs, and reducing the filling factor (number of the legs in unit area) of the module. Designing low fill factor TEGs will reduce the production cost, while it improves the generated output power in comparison to a high fill factor TEGs. The maximum output power for a wearable TEG made of high thermal conductivity materials (~1.5 W/mK) achieves at lower fill factors (<10%), however, making low fill factor modules is quite challenging. In this research, we designed a TEG with very small fill factor (3%) and compared it with other modules with different fill factors. The power generation characteristics of the modules were studied in practical environment. The results confirm the concept of generating high power with low fill factor module [1]. Therefore, the output power per unit mass can be maximized in comparison to the commercial off-the-shelf TEG.

Porous Polymer Coatings with Fluid-Mediated Optical Switching—A Diverse Platform for Optical and Thermal Regulation

Nanorarchitectured metamaterials that enable spatial control of heat flow have innumerable benefits in as daytime radiative cooling, thermal textile, and thermophotovoltaic systems. Their abilities to tune in plane heat transport and out of plane thermal emission has been of tremendous interest in adaptive tuning of optical channels in response to environmental changes.

In this invited talk, I will present our ongoing efforts on nanorarchitectured thermal metamaterials that are enabled by scalable 3D nanofabrication technology. For example, we recently demonstrated an on-site nano-kirigami method by programming the dosages of the ion beam irradiation in one step. A remarkable 3D optical chirality is achieved through the out-of-plane twisting by nano-kirigami, leading to selective angular emission of circularly polarized IR photons several orders of magnitudes higher than that in natural chiral materials. I will also discuss the potential of thermal metamaterials for detection of chemically induced phase transitions and 3D nanophotonic control of thermal radiation.

Ulta-Narrowband Wavelength-Selective Thermal Emitter and Absorber with Multi-Layered Metamaterials Designed by Bayesian Optimization

We computationally designed ultra-narrowband wavelength-selective thermal emitter and absorber via a materials-informatics method alternating between Bayesian optimization and thermal electromagnetic field calculation. For a given target infrared wavelength, the optimal structure was efficiently identified from over 8 billion candidates of multilayers consisting of multiple components (Si, Ge, and SiO$_2$). The resulting optimized structure is an aperiodic multi-layered metamaterial exhibiting high and sharp emissivity with the Q-factor of 273. The designed metamaterials were then fabricated, and reasonable experimental realization of the optimal performance was achieved with the Q-factor of 188, which is significantly higher than those of structures empirically designed and fabricated in the past. This is the first demonstration where metamaterials designed by Bayesian optimization is realized in experiments. The results facilitate the machine-learning-based design of metamaterials and advance our understanding in the narrow-band thermal emission mechanism of aperiodic multi-layered metamaterials.

Porous Polymer Coatings with Fluid-Mediated Optical Switching—A Diverse Platform for Optical and Thermal Regulation

Porous polymers, which vary in their intrinsic electromagnetic behavior and morphology, are a diverse platform for optical and thermal management. For instance, porous poly(vinylidene fluoride-co-hexafluoropropene) (P(Vdf-HFP)) coatings exhibit near-perfect solar reflectance $R_{solar}$ ($>$ 0.96) and long-wave infrared (LWIR) emittance $\varepsilon_{LWIR}$ ($>$ 0.97) for radiative cooling [1], while porous poly(ethylene) (PE) films exhibit high $R_{solar}$ ($>$ 0.8) and LWIR emittance $\varepsilon_{LWIR}$ ($>$ 0.6) useful in thermal management designs with tuneable $\varepsilon_{LWIR}$ [2]. However, making such coatings optically dynamic remains to be explored in detail.

In this presentation, we demonstrate that the optical behaviors of porous polymers can be dramatically altered by reversibly wetting and drying them with index-matched fluids. For porous P(Vdf-HFP), the drastic reduction of the scattering efficiency of the pores upon wetting causes transition from a solar reflective to a transparent state. The coatings, which show remarkable $\Delta R_{solar}$ of 0.74, can be deployed in roofs, walls and windows for large scale adaptive radiative cooling, solar heating and daylighting depending on the time of day or season. Extending the concept to ethyl cellulose, we show that hydrophilic porous polymers can act as water-responsive coatings that can be used for warming houses before rain or in situations requiring applications and underground watercooling. Lastly, we show that porous PE-based designs wetted with IR emissive fluids can achieve large and opposite $\Delta R_{solar}$ of 0.3 and $\Delta \varepsilon_{LWIR} = -0.6$, representing an "ice-house" to "green-house" transition useful for tunable radiative cooling at night and potentially, thermal camouflaging. Promisingly, the optical performances are achieved over a fast switching time ~ 1 min, and are stable over large number of cycles. The performances of the porous polymer coatings are either new, or better than or comparable to notable electrochromic and thermochromic designs [2-4]. However, unlike the latter, they combine a passive functionality with active switching. Importantly, the porous polymers and fluids used are readily available and inexpensive. Given these aspects, porous polymers with fluid-activated optical switching are a promising and sustainable paradigm for optical and thermal regulation.
A fundamental series of thermal conductivity measurements using time domain thermoreflectance (TDTR) have been performed on photonic (phonon-glass) HKUST-1 Metal-Organic Frameworks (HKUST-1 SURMOFs) thin films. We have determined the thermal conductivity of loaded and unloaded (pristine) HKUST-1 thin films in dependence of their film thickness. These monolithic, polycrystalline HKUST-1 SURMOF thin films are grown using liquid phase epitaxy (LPE) grown at different film thicknesses on specially modified Au and Al SiO2 substrates. In addition, infiltrated MOFs have been measured to determine the effect of loading with different organic solvents, water, and TCNQ. The experimental results demonstrate a reduction in the thermal conductivity upon the polar guest molecule infiltration compared to the pristine activated MOFs. The bulk modulus of the thin, pristine HKUST-1 SURMOF was also measured to understand how the negative thermal expansion of this material affects the temperature dependent mechanical and thermal properties. These materials have been presented here as tunable Designer Materials for the generation of novel porous phononic Nanomaterials with unexpected and tailorable physical properties for high-efficient thermoelectric generation and future applications.

9:45 AM QN05.15.06

Colloidal nanocrystal solids are widely used in a variety of applications due to their unique electronic, optical and magnetic properties. However, nanocrystal solids have very low thermal conductivities (0.1-0.5 W m$^{-1}$K$^{-1}$), which presents a challenge for heat dissipation in nanocrystal solid-based electronic and photonic devices. The low thermal conductivity of nanocrystal solids originates from numerous interfaces in their internal structure. The ligand-ligand interfaces between adjacent nanocrystals are especially problematic because of the weak van der Waals (vdW) interactions at these locations.

We show that forming covalent bonds at these ligand-ligand interfaces can significantly increase thermal conductivity in colloidal nanocrystal solids. More specifically, we demonstrate a thermal conductivity increase of 200-300% in iron oxide nanocrystal solids via crosslinking of adjacent oleic acid ligand molecules. Crosslinking of the oleic acid molecules on nanocrystal surface is carried out through a moderate thermal anneal (350 °C) and is confirmed through a combination of x-ray photoelectron spectroscopy, mass spectrometry, and nanoindentation experiments. The nanoindentation experiments demonstrate that this cross-linking process increases the Young’s modulus of the nanocrystal solid from 1.4 GPa to 9.5 GPa. This correlates to a sound velocity increase from 1243 m s$^{-1}$ to 4290 m s$^{-1}$ that in turn helps increase thermal conductivity.

We use the differential 3 omega method to measure the cross-plane thermal conductivity of our nanocrystal solid samples as a function of nanocrystal diameter. These measurements indicate that ligand-cross-linking increases the thermal conductivity of these samples by a factor of 2-3. This is in approximate agreement with effective medium approximation (EMA) modeling that predicts a factor of 3. We also use molecular dynamic simulations to confirm that ligand cross-linking alleviates a key thermal transport bottleneck in these materials. These results collectively suggest that the key to improve the thermal transport in nanocrystal solids lies in improving thermal transport across the ligand-ligand interface.

Modeling and Measurement of Electrothermal Effects in Wide Bandgap Semiconductor Devices Samuel Graham; Georgia Institute of Technology, Atlanta, Georgia, United States.

Wide bandgap electronics made from nitrides (e.g., Gallium Nitride (GaN)) and oxides (e.g., Hafnium Oxide (HfO2) and Gallium Oxide (Ga2O3)) are currently under development due to their potential to create some of the most advanced RF, power electronic, and neuromorphic computing devices in the world. However, the thermal response of these devices under applied electric fields can create large power densities (RF and power electronics) or highly non-linear behavior (neuromorphic devices) that must be understood.

For many of these devices, the electrothermal response plays a strong role in both the acceptable operation or long-term failure and reliability of the devices. Thus, tools that can help elucidate these responses and provide a method to help design better devices is of critical need for this field.

In this talk we will discuss advancements in modeling and thermal characterization techniques that have allowed new insights into electrothermal behavior in HfO2, GaN and Ga2O3 materials and devices. Specifically, a focus on the role of device architecture and material processing will be addressed. For GaN and Ga2O3 RF and power electronics, the role of thermal interfaces in the heat dissipation of both lateral and vertical device architectures will be discussed. Unique thermoreflectance imaging of cross sectioned devices will show for the first time the experimental picture of the electrothermal response of devices such as pn diodes as current and heat flow through the electrical contacts. For neuromorphic devices, the use of electrically driven filament formation will be elucidated through multiphysics modeling and high spatial resolution thermal imaging. These models will be used to determine methods in which low power formation and operation of neuromorphic devices can be obtained.

Thermal Boundary Conductance Across Heteroepitaxial GaN Interfaces—Scattering Mechanisms and Assessment of the Phonon Gas Model Patrick Hopkins1, John Gaskins2, George Kotsonis3, Ashutosh Giri1, Samuel Graham1, Tengfei Luo4, Asegun Henry5, Mark S. Goorsky5, Junichiro Shiom3 and Jon-Paul Maria5; 1University of Virginia, Charlottesville, Virginia, United States; 2The Pennsylvania State University, State College, Pennsylvania, United States; 3Georgia Institute of Technology, Atlanta, Georgia, United States; 4University of Notre Dame, Notre Dame, Indiana, United States; 5Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 6University of California, Los Angeles, Los Angeles, California, United States; 7The University of Tokyo, Tokyo, Japan.

We present experimental measurements of the thermal boundary conductance (TBC) from 78 – 500 K across isolated heteroepitaxially grown ZnO films on GaN substrates. This data provides an assessment of the underlying assumptions driving phonon gas based models, such as the diffuse mismatch model (DMM), and atomistic Green’s function (AGF)
formalisms used to predict TBC. Our measurements, when compared to previous experimental data, suggest that TBC can be influenced by long wavelength, zone center modes in a material on one side of the interface as opposed to the “vibrational mismatch” concept assumed in the DMM; this disagreement is pronounced at high temperatures. At room temperature, we measure the ZnO/GaN TBC as 490[+150, −110] MW m−2 K−1. The disagreement among the DMM and AGF, and the experimental data at elevated temperatures, suggests a non-negligible contribution from other types of modes that are not accounted for in the fundamental assumptions of these harmonic based formalisms, which may rely on anharmonicity. Given the high quality of these ZnO/GaN interfaces, these results provide an invaluable, critical, and quantitative assessment of the accuracy of assumptions in the current state of the art computational approaches used to predict phonon TBC across interfaces. We then extend our understanding to measurements across other interfaces of GaN.

11:15 AM QN05.16.03
Nonstructured Interfaces by Random Nanopillars Enhance Interfacial Thermal Transport Eunghyu Lee, Erezdhep Menumerov, Robert Hughes, Svetlana Nerusina and Tangfei Lu; University of Notre Dame, Notre Dame, Indiana, United States.

Solid-state interfaces are pivotal to the high performance in semiconducting electronic devices ranging from GaN-based high-electron mobility transistors to light-emitting diodes. While unprecedented electrical loads are on such electronic devices to maximize their capability, the interfaces usually impede efficient heat removal with large thermal boundary conductance (TBC). For example, in power electronics, generated heat fluxes from semiconducting channels have reached (or exceeded) 1 GW/m². It leads to temperature rises in the channels up to 100 °C, where half of the temperature rise can be from various interfaces. Recently, it has been reported that nonstructured interfaces with periodic nanopillar arrays significantly increase thermal transport across semiconductor/metal interfaces. In this study, we demonstrate that random-distributed nanopillars interfaces fabricated by low-cost Au islands metallic etching masks can enhance TBC of semiconductor/metal interfaces, where the Au islands mask is prepared by thermal solid-state dewetting (TSSD) properties of Au on solid substrates. We first confirm that Si/Al nonstructured interfaces with randomly and periodically distributed Si nanopillars have similar enhanced thermal transport across the interfaces when their interfacial area enhancement -- which are accurately controlled by electron-beam lithography -- are almost same. Such finding suggests distribution of nanopillars at interfaces are not critical to thermal transport enhancement, motivating us to find low cost methods to fabricate randomly distributed nanopillars on solid substrates. As a result, we apply the TSSD method to prepare random nanostructured Si surfaces where the Si nanopillars have characteristic lengths ranging from 10 nm to 70 nm. By capping these nanostructured Si surfaces with Al layer, it is found that the TBC of these randomly nanostructured Si/Al interfaces is ~ 90% higher than that of planar interfaces. In addition, the nonstructured Si/Al interfaces maintain the enhancement at a temperature range from 30 °C to 110 °C, in which semiconducting electronics usually work. Moreover, we successfully extend the TSSD technique to GaN surfaces and demonstrate thermal transport enhancement across GaN/Al interfaces similar to the cases for Si/Al interfaces. The TSSD technique can potentially reduce the cost to achieve random nanostructured interfaces over large areas. Commercial applications can take advantage of our results in enhanced interfacial thermal transport to improve thermal management.

11:30 AM QN05.16.04
Thermal Management in Silicon Integration Fabric (Si-IF) Umaesh Mogera and Timothy Fisher; Henry Samueli School of Engineering, University of California, Los Angeles, Los Angeles, California, United States.

Moore’s law of packaging calls for several innovations in advanced packaging. One approach is the direct placement of silicon dies, heterogeneously, on a single interconnected platform, termed ‘Silicon Interconnect Fabric’ (Si-IF) [1-2]. In this approach, interconnect pitch can be reduced by almost 100 times (~10 µm) [3], which is impossible to achieve by conventional packaging technologies. However, such high placement density of dies requires enormous power density (~1-10 W mm²) which in turn generates huge heat load on the system. Therefore, such a dense but large system will need efficient thermal dissipation to avoid thermal degradation of performance and to ensure reliability. This calls for an efficient power interconnect architecture to the Si-IF that delivers not only power but also manages thermal loads generated in Si-IF. Here, we propose an approach, called PowerTherm that combines these two functions uniquely and efficiently. The PowerTherm concept involves a network of current-delivering blocks with built-in cooling that is dynamic and addressable. The architecture of PowerTherm consists of metallic terminal blocks such as Cu bonded to Si-IF by thermo-compression bonding and optimized copper-filled electrically insulated through-wafer-vias (TWVs) that pass through the entire thickness of the Si-IF (500 µm) to contact the terminal block. For thermal management, macroscopic channels are constructed into the metallic terminal blocks through which cooled liquid is passed. We use a dynamic and ultra-high-flux capable flash cooling method with two-phase coolants that produces peak heat transfer coefficients of 50,000 W/m²K [4]. For testing of thermal management of Si-IF by flash cooling, we developed a dynamically controlled flow loop. The loop has been designed to be flexible and robust at various test conditions to quantify and benchmark the flash cooling of Si-IF. A detailed characterization of heat dissipation density and transient thermal response of the Si-IF were carried out in this study.

Thermal Conductance Across Heterogeneous GaO3-Diamond Interfaces Zhe Cheng1, Marko J. Tadijer2, Virginia D. Wheeler3, Jingjing Shi1, Luke Yates1, Mark S. Goorsky1, Karl D. Hobart2, 3 and Samuel Graham1; 1Georgia Institute of Technology, Atlanta, Georgia, United States; 2U.S. Naval Research Laboratory, Washington, District of Columbia, United States; 3Materials Science and Engineering, University of California, Los Angeles, Los Angeles, California, United States.

Because of its ultra-wide bandgap, high electrical breakdown strength, and potential for large area substrates, b-GaO3 has attracted great attention recently for applications of high power electronics. However, its thermal conductivity is at least an order of magnitude lower than that of other wide bandgap semiconductors, such as SiC, GaN, AlN, and diamond. Proper thermal management is essential to avoid device degradation for high-voltage applications. A possible solution is to integrate thin GaO3 layer to fabricate GaO3-on-diamond devices by taking advantage of the ultra-high thermal conductivity of diamond as a heat spreader and wide bandgap dielectric substrate. When dissipating heat generated in a device through a diamond substrate, the thermal boundary resistance (TBR) of the GaO3-diamond interface can play an important role in the thermal response. The contribution of the TBR in this heterostructure has not been studied yet. In this work, we study thermal transport across several GaO3-diamond interfaces, including exfoliated GaO3-single crystal (SC) diamond van der Waals interface, chemical-vapor-deposited diamond grown on a sc (~201)GaO3-commercial substrate (Tamara Corp.), as well as atomic-layer-deposited GaO3 on SC diamond. The thermal boundary conductance (TBC) of these interfaces were measured by time-domain thermoreflectance (TDT) and the structures of these interfaces are studied with transmission electron microscopy (TEM). For instance, the TBC of exfoliated GaO3-SC diamond van der Waals interface is measured to be 17 MW/m²K. To understand the measured TBC values of different GaO3-diamond interfaces, a Landauer approach is used to calculate the theoretical TBC of GaO3-diamond interfaces. An electron energy loss spectroscopy (EELS) study is performed across the GaO3-diamond interfaces with nanometer spatial resolution to probe the vibrational mode. Our work is the first study to perform thermal conductance across different GaO3-diamond interfaces. These experimental and theoretical studies would not only contribute to developing new theories of interfacial thermal transport, but also impact applications such as high power electronics.

SESSION QN05.17: Thermal Transport in Nanomaterials
Session Chairs: Yongjie Hu, Yee Kan Koh, Lucas Lindsay and Amy Marconnet
Friday Afternoon, April 26, 2019
PCC North, 100 Level, Room 124 B

A novel fabrication method for an imperceptible transparent electrode based on copper random micro patterns is introduced in this work. This fabrication method enables minimum spot size of 2.4-μm and elimination of Motre and starburst effect by employing the randomness of the pattern, in turn an imperceptible transparent electrode especially for display devices or thermoelectric devices can be made. The cost of fabrication of the transparent electrode introduced in this study is much lower than other well-known fabrication methods which use noble materials such as silver nanowires since the process is all solution based process and only Cu nanoparticles are used as a conducting medium. Thermal conducting layer is introduced to successfully sinter Cu nanoparticles. The performance of imperceptible transparent electrode based on copper random nanopatterns made by fabrication method introduced in this work, a resistive type touch panel application and defroster application is also demonstrated.

1:45 PM QN05.17.02
Energy Sensitivity Studies of Charge-Carrier Scattering in Graphene Antidot Lattices Dongchao Xu1, Samuel Tang2, Xu Du1 and Qing Hao1; 1University of Arizona, Tucson, Arizona, United States; 2SUNY Poly, New York, New York, United States; 3Department of Physics & Astronomy, Stony Brook University, Stony Brook, New York, United States.

Understanding the scattering mechanisms of charge carrier is critical to the electrical properties of two-dimensional materials such as graphene, transition metal dichalcogenide monolayers, black phosphorene, and tellurene. Beyond pristine two-dimensional materials, further tailored properties can be achieved by nanoporous patterns such as nanor- or atomic-scale pores (antidots) across the material. As one example, structure-dependent electrical/optical properties for graphene antidot lattices (GALs) have been studied in recent years. However, detailed charge carrier scattering mechanism is still not fully understood, which hinders the future improvement and potential applications of such metamaterials. In this work, the energy sensitivity of charge-carrier scattering and thus the dominant scattering mechanisms are revealed for GALs by analyzing the maximum Seebeck coefficient with a tuned gate voltage and thus shifted Fermi level. It is found that charge carriers are mainly scattered by the potential field due to edge-trapped charged, particularly at elevated temperatures. For thermoelectric interests, the gate-voltage-dependent power factor of different GAL samples are measured and can reach 554 at 400 K for a GAL with the square pattern. For on-chip cooling applications, such a high power factor is improved by more than one order of magnitude from the values for the state-of-the-art bulk thermoelectric materials. With their high thermal conductivities and power factors, these GALs can be well suitable for “active coolers” within electronic devices, where heat generated at the hot spot can be removed with both passive heat conduction and active Peltier cooling.

2:00 PM QN05.17.03
Substrate Effects on Thermal Transport in Single-Layer MoS2 Alexander J. Gaborie1, Saurabh V. Suryavanshi1, Amir Barati Farimani1 and Eric Pop1,2; 1Electrical Engineering, Stanford University, Stanford, California, United States; 2Materials Science & Engineering, Stanford University, Stanford, California, United States; 3Mechanical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

Two-dimensional (2D) semiconducting MoS2 is a promising material for end-of-roadmap technologies [1], flexible and transparent electronics [2], and thermoelectric applications [3]. However, it is known that electrical and thermal conductivities in other 2D materials, like graphene, degrade when in contact with a substrate, e.g. due to scattering with substrate impurities or phonons [4, 5]. Such insulating substrates cannot be avoided in modern electronics; therefore, understanding the role of the substrate is crucial to know the realistic thermal limitations of 2D semiconductors like MoS2.

Here, we present a detailed molecular dynamics (MD) study on the effects of an amorphous SiO2 (a-SiO2) substrate on the in-plane thermal conductivity of single-layer MoS2. Unlike continuum models, the atomistic nature of MD accurately captures phonon scattering physics in 2D materials and their interfaces. The GPUMD package [6, 7] is used for all MD computations and thermal conductivity calculations use the recently-developed homogenous non-equilibrium MD (HNEMD) method [8]. HNEMD results are consistent with the equilibrium Green-Kubo and non-equilibrium MD methods but require fewer computational resources. The in-plane thermal conductivity is decomposed into its in-plane and out-of-plane contributions to elucidate which phonons are suppressed. We also present a spectral decomposition of the thermal conductivity for insight into the phonon wavelengths affected by the substrate.

To facilitate comparison, we compute the in-plane thermal conductivity of both isolated, single-layer MoS2 and single-layer MoS2 on an a-SiO2 substrate. The simulation cell area is 10 × 10 nm², the single-layer MoS2 is 6.15 Å thick, and the a-SiO2 substrate is 5.4 nm thick. The in-plane dimensions are periodic, with vacuum in the out-of-plane direction. All simulations are at 300 K with a time step of 0.5 fs.

Running 20 independent simulations for each structure, we first calculate the suspended single-layer MoS2 in-plane thermal conductivity to be ~115 Wm⁻¹K⁻¹ (consistent with experimental measurements on bulk MoS2) [9] with the in- and out-of-plane contributions as ~84 Wm⁻¹K⁻¹ and ~31 Wm⁻¹K⁻¹ respectively. The in-plane thermal conductivity of MoS2 supported by an a-SiO2 substrate is calculated to be ~29 Wm⁻¹K⁻¹ (~74% decrease) with the in- and out-of-plane contributions as ~25 Wm⁻¹K⁻¹ (~70% decrease) and ~4.7 Wm⁻¹K⁻¹ (~85% decrease) respectively. While a greater proportion of the out-of-plane component is suppressed on a-SiO2, the in-plane component’s reduction drives the overall reduction in thermal conductivity. This contrasts the suppression of the in-plane thermal conductivity of graphene on a-SiO2, which suffers ~91% degradation mostly from the suppression of the out-of-plane component [10]. Our results underscore the strong effect of the substrate on thermal conductivity of single-layer 2D semiconductors like MoS2 for the first time.

2:15 PM QN05.17.04
Heat at the Nanoscale—A Comprehensive Experiment Testing Specific Thermal Behavior from Nanoparticles Mengistie L. Debasu1,1, Artemi Skripka2, Carlos Brites1, Antonio Benayas1,1, Fiorenzo Vetrone3 and Luis Carlos4; 1Physics, CICECO, Aveiro, Portugal; 2EMT, INRS, Varennes, Quebec, Canada; 3Radiology -MIPS, Stanford School of Medicine, Stanford, California, United States.

Nowadays, there is an ever-growing wave of reports providing cumulative evidence about a behavior of heat transport in solids at nanoscale that may substantially divert from the well-known physical laws governing thermal conductivity at macroscopic (bulk) size range.1 Thus, the opportunity is wide open to unveil a much more comprehensive insight on how the adage “more is different” can work also in the opposite direction. If so, a scientific turning point lies ahead, once ascertained if certain laws of nature may work through a different path when considered at ultrashort range domain.

In the other hand, luminescent nanothermometry has become a powerful investigative tool able to report temperature real-time, from inside complex systems in a smart non-contact way. Based on a thorough understanding of how emission lines from the luminescent nanoparticles change depending on temperature variations, these so-called nanothermometers report local temperature readouts grasped from the spectroscopic measurement of the light emitted from them, upon optical excitation. This research field has produced substantial progress and applications, especially at the biomedical sensing arena.

In this work, we present a simple nanothermometry set up -already used for successful studies on brownian movement- to measure the average time profile of temperature changes inside a given kind of luminescent nanoparticles. Appropriately, the nanoparticles have been engineered to constitute high-resolution nanothermometers, able to distinguish in real-time the differentiated temperature from two physically separated points, at the inside of the nanoparticles. Thus, that described framework allows us to record the (averaged) time evolution of the temperature inside the nanoparticles.

A quartz cuvette containing core-shell nanoparticles suspended in water was heated from one side in thermal contact with a thermofoil heater. The temperature of the suspension was increased by adjusting the temperature of the heater and the evolution of corresponding upconversion emission spectra of the suspended nanoparticles was recorded upon excitation with a 980nm-laser. The core and shell temperature profiles were determined, respectively, by using the integrated intensity ratios of the Er\(^{3+}\):\(H_{5/2}\rightarrow3I_{7/2}\) and \(G_{5/2}\rightarrow3H_{5/2}\) transitions as thermometric parameters, with temperature resolution \(<0.5K\) and relative thermal sensitivity up to \(1.25%K^{-1}\). Hence, this experimental procedure allows to measure precisely two distinct onset times with delay time up to 250 sec the core and shell temperature increments when a core-shell nanoparticle is heated by an external heating source and to thoroughly study the corresponding thermal transport dynamics in nanosystems. The experimental process is also gifted with high repeatability of the measure values. The data mining, once carefully treated with error correction numerical protocols, translates into a great wealth of heat transport insight (20-50 nm distance through crystalline lattice).

The conclusions produced from the collected data will undoubtedly help clarifying trends on the different behavior of the thermal diffusivity at nanoscale in solids, compared to the one foreseeably expected from the (macroscopic) heat diffusion laws in solids. This presented method paves the way for adapting new theoretical formulations of heat transport, also featuring different implications spread into physics, microelectronics and biology.

Materials with tunable phonon transport are a key ingredient to achieve logic operations using heat currents. Moreover, the corresponding variation of the thermal conductivity can be used to greatly enhance the thermoelectric properties and, therefore, promoting the development of new thermoelectric materials. In this regard, ferroelectrics are excellent candidates to be explored as they possess intrinsic interfaces –domain walls– which effectively act as phonon scattering centers and their distribution and type can be engineered, for instance, by epitaxial strain. In pursuit of this goal, we report the effect of the strain-engineered domain and superdomain structures in ferroelectric PbTiO\(_3\) on the thermal conductivity.

PbTiO\(_3\) thin films were grown by reactive molecular-beam epitaxy on SrTiO\(_3\), DyScO\(_3\), TbScO\(_3\), and SmScO\(_3\) substrates, covering epitaxial strain values from compressive -1.36% to tensile +0.71%. For large compressive strains PbTiO\(_3\) thin films with only c-domains are obtained. At these compressive strain values, the absence of the presence of an electrostatic boundary condition (an epitaxially grown bottom electrode) switches from a \(c\)/up domain architecture to a \(c\)/down configuration with 180° domain walls to a single \(c\)-domain sample that contains no domain walls. On reducing the compressive strain, a gradual increase in the population of \(a\)/domains embedded in a matrix of \(c\)-domains takes place, giving rise to \(a\)/c domain architectures. The density of these \(a\)/c 90° domain walls increases on reducing compressive strain. For tensile strains a competing scenario between \(a\)/c and \(a\)/a superdomains is found in which the ratio between both populations can be tuned by varying strain. This enabled the superdomain architecture to be engineered at will. The density of 90° domain walls between the \(a\) domains within the \(a\)/a2 superdomains was found to increase with increasing tensile strain.

The thermal conductivity of PbTiO\(_3\) thin films is strongly influenced by these designed ferroelectric nanostructures. When no domain walls are present, relatively high thermal conductivity is obtained: \(>3.4\) Wm\(^{-1}\)K\(^{-1}\), similar to bulk values. The thermal conductivity, however, dramatically drops (<70% reduction) when a high \(a\)/a2 domain wall density in an \(a\)/a2 superdomain configuration is achieved. A clear correlation between thermal conductivity and domain wall density/type is found, giving rise to a huge control of further tuning the thermal conductivity of PbTiO\(_3\) through epitaxial-strain-engineered domain configurations. These results agree with the theoretical prediction from phase-field modeling, which were performed without previewing the experimental data. The combination of theory and experiment allows gaining a deeper understanding of this phenomenon that relates strain-designed domain structures and thermal conductivity.

2:45 PM QN05.17.06 Enhancing the Thermal Transport Properties of Soft Materials Using Nanoparticles Merabia Samy1,2, Chenxi Ma1, Haouie Han1, Frédéric Leroy3 and Florian Müller-Plathe1; 1Université de Lyon, CNRS, UCLL, ILM, UMR5306, Villeurbanne, France; 2CNRS, Villeurbanne, France; 3Technische Universität Darmstadt, Darmstadt, Germany.

In this contribution, we shall illustrate through two examples how the addition of a tiny amount of nanoparticles may significantly change the thermal transport properties of soft materials. Of particular importance here are the coupling between phonons in the solid and high frequency vibrations in the liquid [1].

First, we analyze heat transport between gold and a model ethanol nanofluid using molecular dynamics simulations [2]. We show that the presence of the nanoparticles increases the Kapitza resistance typically by a factor 2. Surprisingly, the interfacial resistance is found to depend only weakly on the interactions between the nanoparticles and the gold surface. This increase has important consequences as regards ultrafast explosive boiling, and we report on a significant shift of the nanofluid/gold boiling temperature as compared to pure ethanol. The corresponding superheating shift is found to be strongly correlated with the increase of Kapitza resistance.

Second, we demonstrate how the presence of a few nanoparticles may enhance the thermal conductivity of amphorous polymers [3]. Indeed, polymer are renowned for their low cost, low weight and resistance to corrosion. Yet, a barrier which limits the spread and use of polymers in a wide range of applications, and especially in microelectronics, is their relative poor thermal conduction properties. Dispersing highly conductive nanoobjects in a polymer matrix is a common strategy employed to level off polymer conductivity. However, the results are often mitigated by the high Kapitza resistance between the polymer matrix and the dispersed fillers. Here, we report a significant increase of the bulk conductiviy of polystyrene matrix filled with silica nanoparticles. We show that the relative enhancement is essentially explained by the relative good matching between the vibrational modes of the polymer and the silica nanoparticles. We discuss also the role of polymer chains grafted on the surface of the nanoparticale.

**Unified First Principles Theory for the Thermal Properties of Semiconductors**

The availability of fabricating new mesoporous materials opens the possibility of having materials with tunable properties such as thermal conductivity. In this work, we present two applications of a generalized effective medium approximation that allows modeling of the thermal properties of porous systems.

A simple composite system is made of a homogenous matrix with a fixed number of parallel cylindrical holes of circular cross-section. By defining the two-dimensional depolarization factor for the cross-section of the cylinders, we calculate the effective thermal conductivity. For a system with a fixed number of pores, we show how the heat transport depends on the eccentricity of the pores. This is a full calculation that includes the heat resistance at the pore-matrix interface (Kapitza resistance). The method is applied to deformable porous media. By applying a mechanical stress to the system, the distance between the nanopores changes as well as their shape, initially with a circular cross-section. We find an expression for the effective heat coefficient as a function of the applied mechanical stress.

For a set of layered systems, each layer made of a mesoporous system. In particular, we consider as a second example the calculation of the heat transport coefficient of a stack of a mesoporous TO2 layer and mesoporous SiO2 layer, validating our model with recent measurements. (1)

**Phonon Scattering by an Atomic Vacancy in IV-VI Semiconductors from an Ab Initio Green's Function Method**

Encompassing diffusive, quasi-ballistic and ballistic regimes, heat conduction is inherently a multiscale problem. At the atomistic level, the phonon mean-free-path (MFP) distribution is typically obtained by density functional theory. On the other side, phonon-boundary interaction is conveniently captured by continuum models, such as the Boltzmann transport equation (BTE). Finally, short-MFP phonons will mostly travel diffusively, so they can be accounted for by a standard diffusive solver. OpenBTE [1] attempts bridging these three regimes. Specifically, the MFP distribution, computed by first-principles, is used as input to the MFP-BTE [2], a recently introduced version of the BTE that uses the phonon MFP as a control variable. Then, using a parameter-free multiscale approach, the BTE solver integrates a modified diffusive model that calculates heat carried by short-MFP phonons. After a brief introduction to the software architecture, we will show example applications, including thin films, nanoporous materials, Graphene nanoribbons, Si serpentes, phonon focusing and large-scale screening of nanostructured materials for thermoelectric applications. Conclusions and final remarks will conclude the talk.

**Phonon Scattering from an Atomic Vacancy in IV-VI Semiconductors from an Ab Initio Green’s Function Method**

Defects engineering has been a widely used approach for developing low thermal conductivity materials. Also, for some materials (e.g., IV-VI compound), considerably large amount of vacancies was often observed in single crystalline samples. The atomic vacancy in dilute case was assumed as a point defect that can cause the Rayleigh scattering with its rate proportional to the fourth power of phonon frequency. Due to the large dependence of scattering rate on phonon frequency, a vacancy was considered to only weakly suppress the mode thermal conductivity of low frequency acoustic phonons. We show that this does not hold for IV-VI materials. We compare the phonon scattering by a single vacancy in group IV (diamond and Si) and IV-VI (PtTe and GeTe) crystals using an exact ab initio Green’s function approach. The phonon-vacancy scattering rates in diamond and Si follow the well-known fourth-power dependence on phonon frequency. However, PtTe and GeTe exhibit phonon scattering rates that have much weaker frequency dependence. As a result, a vacancy scatters low frequency acoustic phonons more strongly in PtTe and GeTe than in Si and diamond. This unusual behavior in PtTe and GeTe originates to the significant changes of interatomic force constants that extend up to the distance of 10 angstrom from the vacancy site. Therefore, a vacancy in IV-VI materials cannot be assumed as a point defect but its finite size should be considered for phonon scattering. In contrast, a vacancy in Si and diamond changes interatomic force constants only up to 3 angstrom range. Our study provides new insights on the phonon spectral contribution to thermal transport when vacancies exist in IV-VI materials and will help to develop low thermal conductivity materials by engineering vacancies.

**Unified First Principles Theory for the Thermal Properties of Semiconductors**

In semiconductors, heat is carried by phonons, which are quantized vibrations of the crystal lattice. Standard first principles methods to obtain the thermal properties of solids rely on the phonon quasiparticles being well-defined, and assume that the lowest order interactions among three phonons are sufficient to describe thermal transport. Here we show that this is not the case for strongly anharmonic semiconductors, where phonon scattering is so strong that the standard phonon quasiparticle picture can break down, and three-phonon scattering is insufficient to explain the experiments. To address this issue, we present a novel first principles method that features an anharmonic many-body renormalization scheme to create well-defined phonon quasiparticles with weakened interactions, and rigorously accounts for both three-phonon and four-phonon scattering to obtain thermal transport properties [1]. Using a showcase strongly anharmonic material – sodium chloride (NaCl), we demonstrate that our first-principles method simultaneously captures the apparently contradictory experimental measurements of low thermal conductivity and large lattice thermal expansion of NaCl on the one hand, and the relatively temperature-independent phonon frequencies on the other, while the standard first principles theory fails in all three cases. Furthermore, we show that the higher-order four-phonon scattering significantly lowers the thermal conductivity of NaCl and should be rigorously included for a proper comparison to measurements. Finally, we show that our anharmonic renormalization theory, along with four-phonon scattering, also successfully captures the phonon spectral contribution to thermal transport due to the material’s temperature-dependent thermal transport properties of a weakly anharmonic material – diamond, although the four-phonon scattering and renormalization effects are weak in this material. Our work presents a unified first principles framework to accurately predict the thermal properties of solids with varying bond anharmonicities.

**Origin of High Thermal Conductivity in Complex Molecular Crystals—An Ab Initio Study of Polythiophene**

Peishi Cheng, Austin J. Minnich and Nina
Thermally conductive molecular crystals are of fundamental and practical interest in part because they are unlike typical complex crystals, which conduct heat poorly owing to their large phonon scattering phase space. While molecular crystals with high thermal conductivity in the range of tens of Wm\(^{-1}\)K\(^{-1}\) have been known experimentally for decades, the microscopic origin of this property has remained unclear. Ab-initio methods that have been successfully applied to simple crystals have proved difficult to adapt to molecular crystals due to quantum nuclear motion and their complex primitive cells. Here, we report the thermal transport properties of crystalline polythiophene with 28 atoms per primitive cell using an ab-initio approach that rigorously includes finite temperature anharmonicity and quantum nuclear effects. The calculated room temperature thermal conductivity is 176 Wm\(^{-1}\)K\(^{-1}\), a high value that arises from exceptional phonon focusing along the chain for certain branches and despite short lifetimes in the picosecond range. Our finding suggests that many complex molecular crystals with stiff intra-chain bonds are intrinsically good thermal conductors as phonon focusing occurs in any crystal with anisotropic bonds.

**Majorana in Atomic Chains and Topological Hinge States**  
Ali Yazdani; Princeton University, Princeton, New Jersey, United States.

Ettore Majorana famously considered that there may be fermions in nature that are their own antiparticle — and then he mysteriously disappeared just after proposing the idea in 1938. In recent years, following pioneering theoretical work of Kitaev and others, we have learned how to engineer materials that harbor quasiparticles that behave similar to fermions Majorana had envisioned. In particular, there has been a focus on one-dimensional topological superconductor that harbor Majorana zero modes (MZM) that can potentially be used to make fault-tolerant topological quantum computation possible. Recently, we have proposed and implemented a platform for realization of topological superconductivity and MZM in chains of magnetic atoms on the surface of a superconductor [1,2]. In this talk, I will describe this platform and the series of experiments we have performed to establish the presence of these exotic quasi-particle using spectroscopic mapping with the scanning tunneling microscope (STM). [2-4] These include study of the unique spin signature of MZM.[4] Finally, if there is time I will discuss our most recent work on realization of MZM in a platform based on chiral quantum spin Hall edge states [5]. Overall these experiments, illustrate how the power of spectroscopic imaging with the STM can be used to visualize novel quantum states of matter and their exotic quasi-particles.

**Majorana and Andreev Bound States in Proximitized Rashba Quantum Wires**  
Daniel Loss; Department of Physics, University of Basel, Basel, Switzerland.

I will review recent theoretical developments in the field of topological quantum computing, in particular, I will focus on schemes based on Majorana fermions. For Majorana physics, a central ingredient is the proximity effect induced by a superconductor in some attached material. In particular, semiconducting quantum wires defined within 2DEGs and strongly coupled to thin superconducting epitaxial layers have been extensively explored in many experiments as promising platforms to host Majorana bound states. I will present our numerical and analytical studies of such geometries with proximity effects [1-5] where the strong coupling can lead to unwanted ‘metallization’ of the semiconductor host. I will also show that Andreev bound states in absence of any topological phase can mimick the zero-energy behavior of Majorana bound states as function of magnetic field [6].

**Emergence of Majorana States in Engineered Atomic-Scale Hybrid Systems**  
Roland Wiesendanger; Interdisciplinary Nanoscience Center Hamburg, University of Hamburg, Hamburg, Germany.

Majorana states in atomic-scale magnet-superconductor hybrid systems have recently become of great interest because they can encode topological qubits and ultimately provide a new direction in topological quantum computation [1,2]. First, it will be demonstrated how well defined 1D atomic chains of magnetic adatoms on superconducting substrates with high spin-orbit coupling can be artificially fabricated using STM-based atom-manipulation techniques. Spin-polarized STM measurements [3] allow to reveal the presence of non-collinear spin textures, i.e. spin spiral ground states, stabilized by interfacial Dzyaloshinskii-Moriya interactions [4,5]. Simultaneously performed scanning tunneling spectroscopy on the magnetic atom chains on the superconductor substrate reveal the evolution of the spatially and energetically resolved local density of states as well as the emergence of zero-energy bound states at the chain ends above a
critical chain length. Based on the exact knowledge of the geometrical, electronic, and spin structure of the magnetic chain – superconductor hybrid system, the experimental results can be compared rigorously with ab-initio and model-type tight-binding calculations supporting the interpretation of the spectroscopic signatures at the ends of the chains as Majorana bound states [6]. More recently, the atomic-scale design of more complex network structures for Majorana state manipulation, including braiding operations has been in the focus of our research.

Second, we will address experimental and theoretical studies of monolayer topological superconductivity and chiral Majorana edge modes in model-type 2D magnetic islands on elemental superconductors [7]. In particular, we demonstrate that interface engineering by an atomically thin oxide layer is crucial for driving the studied hybrid system into a topologically non-trivial state as confirmed by theoretical calculations of the topological invariant, the Chern number.

Finally, the prospects for studies of Majorana states in skyrmion – superconductor hybrid systems [8] will be highlighted.

This Al-InAs hybrid system shows an induced gap >200µeV. We present structural characterization of superconducting Al layers on MZM structures.

Epitaxial Al-InAs structures are prime candidates for tunable superconducting qubits, the so-called “gatemon” where the Josephson energy can be tuned in-situ with an applied electric field to an InGaAs Josephson junction, eliminating the need for flux tuning in superconducting qubits [1]. Here we have characterized microwave cavity modes needed for coupling to superconducting gatemon qubits. We present resonator quality factors for a fixed design on various levels of the buffer layers used as substrates. We make a comparison to bare InP and Si to establish a comparative baseline. We study the relationship of anharmonicity in gatemon qubits to interface transparency in the Superconductor-Semiconductor structure.

Semiconductor/Ferromagnetic Insulator InAs/EuS Epitaxy Yu Liu and Peter Krogstrup; University of Copenhagen, Copenhagen, Denmark.

Material development holds promise as the basis of topological quantum computing with Majorana fermions. These quasiparticles have been predicted at ends of semiconductor nanowires coupled to conventional superconductors [1-2]. These predictions were followed by a series of experiments providing transport signatures consistent with these theories [3-4]. These early measurements suffered from soft induced superconducting gap, which later was significantly improved by growing epitaxial semiconductor-superconductor (SE-SU) nanowires [5-6]. In order to reach the topological phase, an external magnetic field needed to lift the spin degeneracy in these SE-SU systems, which brings an even larger challenge for achieving scalable solutions. Therefore, in order to integrate and scale up a topological quantum plane, materials that are intrinsically topological (without the need for an external applied field) would be highly preferable. Composite tri-crystals using ferromagnetic insulators (FMI) in close proximity to the SE-SU structure have been proposed as a solution to lift the spin degeneracy [7], where the Zeeman splitting could be induced by the exchange field from the FMI.

In this work, we study hybrid SE-FMI epitaxy of EuS on different InAs crystallographic platforms as the initial basis of tri-crystal SE-SU-FMI NW systems. These SE-FMI systems prove to fulfill key requirements for the realization of topological quantum computing material without need of large external magnetic field:
1. The EuS thin film grown on (100) Zn Blende InAs surface is fully coherent.
2. An exchange field exists by inducing magnetic moments into InAs of about 2 nm.
3. InAs/EuS NWs have strong shape-derived single magnetic domains along the NW length with Curie temperature of 19 K.

The results not only show the InAs/EuS hybrid crystals as promising candidates for topological quantum computing, but also confirm EuS as a promising FMI for various spin applications.

Aluminum oxide (AlO$_x$) is extensively utilized as the tunnel barrier or the gate dielectric in quantum information (QI) devices. However, AlO$_x$ often has a wide distribution of defects originating from the nonequilibrium structure, which affects the electrical stability of devices containing AlO$_x$. One manifestation of the device instability that is often observed on single-electron transistors (SETs) is a time instability named charge offset drift, which is a nanoscale probe of sub-1 e charged defect motion. In this work, we present excellent long-term charge offset stability (very small charge offset drift) measured from two types of SETs containing AlO$_x$: all-metallic AlO$_x$ tunnel junction-based devices and tunable barrier silicon-metal-oxide-semiconductor (MOS) devices. For the all-metallic devices, plasma-oxidized AlO$_x$ is used as the tunnel barrier and the device fine structure is fabricated by double-angle e-beam evaporation. The long-term charge offset stability measured from these devices are better than any other reported metallic SETs, with very small linear charge offset drift of < 0.1 e and standard deviation of < 0.01 e over 7.5 days. For the silicon MOS devices, thermally-oxidized AlO$_x$ is used to electrically isolate overlapping layers of aluminum gates and the devices are made on a silicon-on-insulator (SOI) substrate. These devices display a linear drift of < 0.07 e and standard deviation of < 0.02 e over 7 days. The above results demonstrate good electrical stability using AlO$_x$, which opens the future for large-scale device integration and improving qubit performance.

**Defects in Wide Band Gap Semiconductors for Quantum Computing**

*Panna Biswal* 1,2; Renu Choudhary 3, Bicai Pan 4 and Durga Paudyal 5; 1 Iowa State University, Ames, Iowa, United States; 2DMSE, Ames Laboratory, Ames, Iowa, United States; 3University of Science and Technology of China, Hefei, China.

Many novel materials are being actively considered for quantum information science and for realizing high performance qubit operation at room temperature. It is known that deep defects in wide-band gap semiconductors can have spin states and long coherence times suitable for qubit operation. We theoretically investigate from ab-initio density functional theory (DFT) that the defect states in the hexagonal silicon carbide (4H-SiC) and boron nitride are potential qubit materials. The DFT supercell calculations were performed with the local-orbital and pseudopotential methods utilizing hybrid exchange-correlation functionals. Dv-vacancies in SiC supercells yielded defect levels in the gap consisting of closely spaced doublet just above the valence band edge, and higher levels in the band gap. The divacancy with a spin state of 1 is charge neutral. The divacancy is characterized by C-dangling bonds and a Si-dangling bond. Jahn-Teller distortions and formation energies as a function of the Fermi level will be discussed. Single photon interactions with these defect levels will be discussed. In contrast, the anti-site defects where C, Si are interchanged have high formation energies of 5.4 eV and have just a single shallow defect level close to the valence band edge, with no spin. We will compare results including the defect levels from both the electronic structure approaches. Simulations for BN will be compared with those of SiC. We will also discuss prototypical (s,p) electron systems within group IIIA-IVA-VA elements and possible rare earth doped semiconductors for qubit operation.

**Coherent Single Photon Emission from Colloidal Lead Halide Perovskite Quantum Dots**

*Hendrik Uzat*, Weiwei Sun, Alex Kaplan, Franziska Krieg 1, Matthias Gintereder 1, Boris Spokony 1, Nathan Klein 1, Katherine Shulenberger 1, Colin Perkins 1, Maksum V. Kovalenko 3 and Moungi Bawendi 1; 1 Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Institute of Inorganic Chemistry, Department of Chemistry and Applied Bioscience, ETH Zurich, Zurich, Switzerland; 3Laboratory for Thin Films and Photovoltaics, Empa–Swiss Federal Laboratories for Materials Science and Technology, Duesseldorf, Switzerland.

Chemically prepared colloidal semiconductor quantum dots, most notably based on CdSe, have long been proposed as scalable and color-tunable single emitters for optical quantum information technologies. They have, however, suffered from prohibitively incoherent and unstable emission characterized by pronounced spectral diffusion and fluorescence intermittency at low temperatures.[1]

We now demonstrate that novel colloidal lead halide perovskite quantum dots (PQDs)[2,3] display a real utility as practical quantum emitters with unity emission efficiency and color-tunability over the entire visible spectral range. We show that a unique combination of long optical coherence times (T2 ~ 20 ps) and high oscillator strength (radiative lifetime T1 ~ 210 ps) at low temperatures, renders the emission of PQDs highly coherent. 1,4 Indeed, the degree of coherence (T2/T1) already approaches values of self-assembled III-V quantum dots – even without cavity integration. Using photon-correlation-Fourier spectroscopy we furthermore demonstrate that the spectral stability of PQDs is drastically improved compared to established quantum dots and is already comparable to some nitrogen-vacancy centers in diamond. We attribute this superior spectral stability to the absence of surface-trap states in lead halide perovskite semiconductors. Together with the observed high single photon emission purity (g2(0) < 0.04) and high fraction of coherently emitted photons (~0.85), our results suggest that PQDs – unlike any other chemically-made semiconductor quantum dot material – can be explored as sources of indistinguishable single photons and entangled photon pairs for quantum information technologies. We present our ongoing synthetic efforts to further increase the optical coherence and reduce the inhomogeneous broadening, which is already as small as for typical self-assembled III-V quantum dots.

Our results suggest that lead halide perovskites – with their high defect tolerance and bright lowest-lying exciton state [5] – are promising semiconductors for the scalable production of quantum emitters with highly coherent emission that can be processed onto virtually any substrate and that benefit from the integration with hybrid nano-photonic components that has been demonstrated for colloidal materials. Unlike defect centers in diamond, PQDs can be rationally optimized via the structure of the quantum dot, a research effort that will require input from the quantum photonics and colloidal chemistry community.

Realization of Hybrid Superconductor-Semiconductor Systems by Homoepitaxial Growth of Non-Equilibrium P-Doped Si(111) Mehdi Hatéfipour\textsuperscript{1}, Kasra Sardashi\textsuperscript{1,2}, Kaushini S. Wickramasinghe\textsuperscript{1}, Tri Nguyen\textsuperscript{1}, William Mayer\textsuperscript{1}, Joseph O. Yuan\textsuperscript{1} and Javad Shabani\textsuperscript{1}; 1Department of Physics, King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia; 2Department of Science and Math, Fashion Institute of Technology, New York, New York, United States; 3Center for Nanoscale Materials, Lemont, Illinois, United States; 4Department of Physics, King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia.

To fulfill the long-term vision of reliable quantum computation, the ideal hybrid platform allows quantum information to be processed, stored and transmitted on the same materials system [1]. Silicon can be a promising candidate for fault-tolerant hybrid quantum systems due to its multifunctionality and reliability as well as long coherence times [2]. Superconducting Si could provide a viable pathway for the realization of Si qubit circuits, by forming homogeneous Superconductor–Semiconductor–SC Josephson junctions. In this work, non-equilibrium p-doping of Si thin-films by homoeptaxial growth of Ga-rich Si on Si(111) is studied. MBE approaches to form this superconductor–semiconductor–SC junctions were fabricated and characterized. The p-doping levels and carrier concentrations were determined by temperature-dependent resistivity (\(\rho\)–T) measurements in 4-point van der Pauw and on Hall bars. Upon increase in Ga incorporation, \(\rho\)–T characteristics of the p-doped films transitioned from insulating to quasi-reentrant superconductivity with \(R_{\text{in}}/R_0\) of 0.82–0.89. Based on the known theories, primary growth mechanisms and strategies to go beyond the quasi-reentrant regime will be discussed.

Characterization of Er Defect Centers in Epitaxially Grown Er Doped Y2O3 Manish Kumar K. Singh\textsuperscript{1}, Khan Alam\textsuperscript{2,4}, Tijana Rajh\textsuperscript{2}, Tian Zhong\textsuperscript{1,2} and Supratik Guha\textsuperscript{1,2,1}; 1University of Chicago, Chicago, Illinois, United States; 2Argonne National Laboratory, Lemont, Illinois, United States; 3Center for Nanoscale Materials, Lemont, Illinois, United States; 4Department of Physics, King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia.

Erbium, with optical transition in the 1.5um band is one of the attractive REI candidates for optical quantum memory. Recent studies have, overcome unique challenges that erbium presents and have shown coherence times exceeding 1 second in \(^{166}\)Er. The coherence properties of REI are critically dependent on the host crystals, and methods of incorporating REI into the host structures play an important role as structural defects and impurities determine the local environment of the ions, which is an important factor contributing to linebroadening mechanisms.

Rare-earth oxides with low or no nuclear spin, such as CeO2 and Y2O3 are preferred host material for REI. The ability to tailor the properties of these systems on demand will be a powerful tool for quantum information applications. Molecular beam epitaxy (MBE) allows us to grow single crystal thin epitaxial films of certain RE oxides, and also enables precise control over the doping concentrations.

In this study Er-doped Y2O3 thin films were grown epitaxially on Si(111) using molecular beam epitaxy (MBE). Electron paramagnetic resonance (EPR) spectra of these samples show angular dependence of Er signal indicating crystalline quality of the host material. The site occupancy and crystalline environment of Er defect centers were studied by monitoring interpatter between carrier concentration, film thickness and angular dependence of Er signal. The samples were grown using an oxygen plasma source and the EPR linewidth indicates an inverse dependence on the oxygen pressure during growth. PLE measurements show that Er atoms are present in the C2 and C3 sites substituting for Y. Further, preliminary results for optical linewidth parallel the dependence seen in EPR linewidth. In addition, post-growth anneal in an oxygen atmosphere shows improvement in the EPR and PLE signal intensity and the linewidth.

Temporal quantum coherence and control is foundational to the science and engineering of quantum systems. Improving such coherent characteristics in quantum systems, a key to realizing extensible quantum computing schemes, may be accomplished in part by introducing new materials with superior properties.

Van der Waals (vdW) materials - a family of layered crystals including semi-metals, insulators, semiconductors, ferromagnetic materials, superconductors, and topological insulators - can be assembled in specific arrangements to create new electronic devices called vdW heterostructures. The extraordinary and versatile electronic properties of these heterostructures, in combination with their epitaxial precision, make vdW-based devices a promising alternative for constructing key elements of novel solid-state quantum computing platforms.

We demonstrate quantum coherent control of a superconducting circuit incorporating graphene-based vdW heterostructures. We show that this device can be operated as a voltage-tunable transmon qubit, whose spectrum reflects the unique electronic properties of massless Dirac fermions traveling ballistically. In addition to the potential for advancing extensible quantum computing technology, our results represent a new approach to studying vdW materials using microwave photons in coherent quantum circuits. A Density-Functional Theory Study on Al/AlO\textsubscript{x}/Al Tunneling Junction Chang-Fun Kim, Keith G. Ray and Vincenzo Lordi; Lawrence Livermore National Laboratory, West Lafayette, Indiana, United States.

The aluminum oxide tunnel junction is one of the key components in most superconducting qubit devices. We use density functional theory to investigate the microscopic details of the junction. By using ab-initio molecular dynamics and rigorous static ground state calculations, we accurately model the details of the discrete transition of electronic structure.
across the tunneling interface. Significantly, the aluminum-oxygen coordination is found to vary across the junction, creating irregular potential field that is not well described by the conventional and popular models such as the Landauer–Büttiker method in a constant potential approximation. We aim to provide the atomistic, electronic details of this unique interface as described by the first-principles density functional theory to explore its non-idealities and potential sources of dissipation and loss. The ab-initio result provides a correction to a previous study on the atomic coordinations based on the reverse Monte Carlo method. The calculated work function of the oxide film of the junction was 6.2 eV compared to 4.0 eV for the aluminum metal. The atomic dipole moments are calculated using the Bader’s atoms-in-molecules method, describing the dielectric property of the junction in a microscopic detail. The defect formation energies in the vicinity of the junction interface are calculated by the nudged elastic band method. The ab-initio calculations present further research opportunities to incorporate atomistic details into the device scale simulations of the superconducting qubits. Prepared by LLNL under Contract DE-AC52-07NA27344.)

Superconductive Rhenium Thin Films Electrodeposited from Water-in-Salt Electrolytes Qiang Huang1, Yang Hu2, William Sides2, David Pappas1 and Tyler Lyons1; 1National Institute of Standards and Technology, Boulder, Colorado, United States; 2Chemical and Biological Engineering, The University of Alabama, Tuscaloosa, Alabama, United States.

Electrodeposition has been used widely in the fabrication of microdevice and circuits because of the low cost, fast deposition rate, and, more importantly, the ease of scale-up. Electrodeposited superconductive films are of interest for cryogenic quantum devices as it avoids thermal perturbation resulted from the electrical heat. Such films are particularly of interest if the critical temperature (Tc) is above 4.2 K, which can be easily achieved with liquid helium. Recently, electrodeposited rhenium was demonstrated to show a critical temperature of about 6 K, representing a significant increase from its intrinsic 1.7 K[1]. However, electrodeposition of rhenium requires an acidic electrolyte, where significant hydrogen evolution is inevitable and causes inclusion of hydrogen and highly stressed or even cracked films. On the other hand, a so-called hydration layer forms during the dissolution of salts in water. Such hydration process requires and “consumes” water molecules. When an electrolyte contains a superhigh concentration of supporting salts, for example, alkali metal salts, the hydration of such salts can deplete the free water molecules in the aqueous electrolyte and significantly mitigates the evolution of hydrogen[2,3]. This paper presents a new electrodeposition method to synthesize superconductive rhenium films using water-in-LiCl electrolyte. A limiting current density emerged upon the addition of 5 M LiCl into an acidic Re electrolyte. This lowered hydrogen evolution reaction not only limited the voltage drop due to the high current and solution resistance, but also enabled electrochemical treatments at more negative potentials. An improved film morphology was observed with a suppressed hydrogen evolution currents when the water-in-salt electrolyte was used. A critical temperature of 6 K for as-deposited rhenium film was achieved and a decrease of Tc was observed for the films upon annealing at beyond 150 C. The details of chemical uniformity, grain structures, and Tc of such Re films will be presented. In addition, attempts to electrodeposited Re alloys with this water-in-LiCl electrolyte will be discussed as well.

Reducing Two-Level State Defects in Superconducting Resonators and Qubits Matteo Mariantoni, Jérémie H. Béjanin, Carolyn T. Earnest and Evan A. Peters; University of Waterloo, Waterloo, Ontario, Canada.

Practical quantum computers are closer to reality than ever before. Superconducting qubits, for example, have already been integrated in arrays of ~50 qubits and can be further integrated. However, dissipation phenomena due to imperfect materials largely limit the time a qubit can store quantum information. Qubit dissipation or decoherence is mainly due to quasiparticles, flux noise, and two-level state (TLS) defects. The last are material imperfections hosted in oxidized films in proximity of on-chip superconducting devices. In this talk, we focus on TLS loss and investigate different strategies to reduce their impact on the quality of superconducting resonators and qubits. First, we fabricate and characterize coplanar waveguide resonators made from aluminum thin films deposited on silicon substrates. We perform three different substrate surface treatments prior to aluminum deposition: One chemical treatment based on a hydrofluoric acid clean; one physical treatment consisting of a thermal annealing at 880 °C in high vacuum; one combined treatment comprising both the chemical and the physical treatments. We characterize the fabricated samples through cross-sectional tunneling electron microscopy, acquiring electron energy loss spectroscopy maps of the samples’ cross sections. We analyze the effects of the various substrate treatments on the roughness of the silicon surface by means of atomic force microscopy surface morphology mapping. We study the quality of the resonators by means of microwave measurements in the quantum regime and find that both surface treatments independently improve the resonator’s intrinsic quality factor and that the highest quality factor is obtained for the combined treatment, Q∼0.8 million.

We then employ similar fabrication methods as for resonators to implement superconducting Xmon transmon qubits. We characterize qubit decoherence finding energy relaxation times on the order of ~15 μs for fully flux tunable Xmons. We study the qubits by implementing one-qubit gates, while biasing the qubits using our three-dimensional wiring method, the quantum socket. Lastly, we present the blueprints of a new type of superconducting qubit, the “pocketmon” transmon qubit. This type of qubit is a variant of the Xmon, where the qubit capacitor is realized as an almost ideal parallel-plate capacitor with vacuum as dielectric. To implement the pocketmon qubit we develop a thermocompression bonding technology, which makes it possible to fabricate multi-chip devices. The qubit is comprised of two silicon chips: The base and the cap chip. A meandered aluminum inductor and the bottom square aluminum plate of a capacitor are patterned on the base chip; the inductor is connected to a common aluminum ground plane on one end and to the capacitor through an aluminum lead on the other end. The cap chip is etched to form vacuum pockets in correspondence to the inductor, capacitor, and lead, with an aluminum square plate and a common ground plane matching those on the base chip; the top capacitor plate is connected to ground by way of an aluminum lead. The common ground plane is coated with an indium film used to bond the base and cap chip. The distance between the two capacitor plates is set to be ~10 μm. The aluminum films used to realize the capacitor plates are characterized by an atomic dipole moments are calculated using the Bader’s atoms-in-molecules method, describing the dielectric property of the junction in a microscopic detail. The diffusion property across the junction interface are assessed by the nudged elastic band method. The ab-initio calculations present further research opportunities to incorporate atomistic details into the device scale simulations of the superconducting qubits. Prepared by LLNL under Contract DE-AC52-07NA27344.)

MBE Grown Nitride Heterostructures for Superconducting Quantum Circuits Christopher Richardson1, Ashish Alexander1 and Chris Weddle2; 1University of Maryland, College Park, Maryland, United States; 2Laboratory for Physical Sciences, College Park, Maryland, United States.

Low microwave loss superconducting circuit components are a necessity of fabricating high-fidelity superconducting qubits. Accordingly, significant research has focused on making high-quality planar resonators from elemental and nitride superconductors. Josephson junctions are the nonlinear component of superconducting qubits, that also need to be high performance. Interestingly, superconducting qubits all use Josephson junctions fabricated from aluminum and aluminum oxide using the double angle evaporation process. Details of this alternative design will be presented.

Plasma assisted Molecular beam epitaxy (PAMBE) is used to grow binary and ternary niobium titanium nitride alloys (Nb,Ti,N) and wide bandgap nitride (AIN) superconductors. This combination of nitride materials provides sufficient degrees of freedom that synthesis of an epitaxial Josephson junction may be possible. Using a structure first approach to design optimization, the structural, surface topology, chemical characteristics, and superconducting critical temperature of these films are used for optimization of the growth conditions before resonators are fabricated and tested. Initial growth results of nitride superconductors exhibit significant atomic interaction of the deposited adatoms and silicon substrates. Both amorphous interfacial layers, and significant diffusion of silicon during the formation of silicides are observed. Interpretation of the observed structures and impact on the superconducting properties will be assessed.
The outstanding progress in experimental quantum computing with superconducting Josephson-junction based qubits over the past few decades has pushed coherence times many orders of magnitude above that of the first measured. We are also in the midst of scaling towards complex architectures of multi-qubit processors where maintaining very low gate error rates at the limits supported by coherence times is extremely important. Here we will review some of the critical materials and device challenges for superconducting qubits from the perspective of improved coherence and improved error rates. Furthermore, we will discuss traditional validation and verification techniques, while also discussing alternatives to benchmark the performance of small quantum processors for near-term applications.

Superconducting quantum computing architectures rely on resonators and qubits with coherence lifetimes that are limited by two-level systems (TLS) present in bulk and interfacial dielectrics. Understanding this source of loss is critical to improving performance in superconducting circuits. However, few techniques exist for characterizing material issues associated with loss in the single photon regime by simply removing interfaces near qubits. I will introduce the mechanism of energy loss due to two-level system and share results of error rates at the limits supported by coherence times is extremely important. Here we will review some of the critical materials and device challenges for superconducting qubits from the perspective of improved coherence and improved error rates. Furthermore, we will discuss traditional validation and verification techniques, while also discussing alternatives to benchmark the performance of small quantum processors for near-term applications.

Two-level state (TLS) loss in dielectric materials and interfaces remains at the forefront of materials research in quantum information science. Due to a lack of defects and decreased disorder, crystalline films grown epitaxially in an ultrahigh vacuum environment are thought to have a reduced TLS concentration and thus lower loss at millikelvin temperatures and single photon powers [1]. In this work, we demonstrate a method of sensitive and accurate TLS loss measurement by measuring a lumped element resonator fabricated from a superconductor-dielectric-superconductor trilayer. The deposition of the trilayer prior to fabrication increases control over the metal-dielectric interfaces, and the generalized fabrication process allows straightforward comparison of dielectrics that are of interest to quantum computing. We extract the dielectric loss by comparing to coplanar waveguide resonators and lumped element resonators with interdigitated capacitors. This method is designed to compare dielectric loss in both epitaxial and non-epitaxial trilayers.

Superconducting quantum computing architectures rely on resonators and qubits with coherence lifetimes that are limited by two-level systems (TLS) present in bulk and interfacial dielectrics. Understanding this source of loss is critical to improving performance in superconducting circuits. However, few techniques exist for characterizing material losses under conditions relevant to superconducting quantum circuit operation. In this work, we present a method for quantifying the TLS losses of different bulk and interfacial dielectrics present in superconducting coplanar waveguide (CPW) resonators. By combining statistical characterization of sets of specifically designed CPW resonators on isotropically etched silicon substrates with detailed electromagnetic modeling, we determine the separate loss contributions from individual material interfaces and bulk dielectrics. Additionally, we report on progress towards applying this technique to characterize and improve qubit losses. In general, this technique provides an effective method for assessing superconducting qubit materials in order to guide targeted improvements to qubits, resonators, and their superconducting fabrication processes.

This material is based upon work supported in part by the Intelligence Advanced Research Projects Activity (IARPA) and in part by the Department of Defense under Air Force Contract No. FA8721-05-C-0002 and/or FA8702-15-D-0001. Searching for the Origins of Loss in Superconducting Qubits

Two-level state (TLS) loss in dielectric materials and interfaces remains at the forefront of materials research in quantum information science. Due to a lack of defects and decreased disorder, crystalline films grown epitaxially in an ultrahigh vacuum environment are thought to have a reduced TLS concentration and thus lower loss at millikelvin temperatures and single photon powers [1]. In this work, we demonstrate a method of sensitive and accurate TLS loss measurement by measuring a lumped element resonator fabricated from a superconductor-dielectric-superconductor trilayer. The deposition of the trilayer prior to fabrication increases control over the metal-dielectric interfaces, and the generalized fabrication process allows straightforward comparison of dielectrics that are of interest to quantum computing. We extract the dielectric loss by comparing to coplanar waveguide resonators and lumped element resonators with interdigitated capacitors. This method is designed to compare dielectric loss in both epitaxial and non-epitaxial trilayers.

participation model, the measured quality factor of the resonators can be related to the loss tangent (\(\tan(\delta)\)) associated with TLSs by \(\sum p_i \tan(\delta) = Q_{TLS}^\text{i} \) where \(p_i\) is the participation ratio of the electric field which is the fraction of the total electric energy stored at each interface.

In this study, the role of different chemical species at various interfaces of the coplanar waveguide resonators are investigated. Quarter-wavelength coplanar waveguide resonators are fabricated from MBE grown aluminum (Al) on silicon (Si (111)) wafers. Resonators are wet-etching to ensure that the devices are as identical as possible. Devices are packaged and measured consistently to reduce any other sources of variation in the measured quality factor. Variations in the surfaces are introduced by distinct treatments on Si and Al surfaces that allow comparison of interfaces with different incorporation values of oxygen and nitrogen. These surface treatments also modify the structural properties of the overgrown Al showing polycrystalline, twinned single crystal, and pure single crystal Al films.

These treatments of the Si and Al surfaces impact the measured quality factor. The low loss devices have single photon internal quality factor near 800k. The measured data along with the simulated participation ratio is used to calculate the relative loss tangent across the tested interfaces. The relation between the calculated loss tangent and the various chemical species present at interfaces will also be explored.

4:00 PM QN06.06.06

A continuous taper can be engineered between two transmission lines of different characteristic impedance to reduce reflection of the signal that propagates from one line to the other. There are a number of taper designs presented in the literature that achieve this goal. [1,2] These designs assume impedance mismatch of the two lines is sufficiently small that voltage reflections within the taper also can be considered small. Here we extend the theory of the optimal lossless impedance taper of [2], allowing for impedance mismatch and voltage reflection of arbitrary magnitude. We apply our extended theory to the optimal design of taper for the two use cases of (i) an unavoidably large impedance mismatch between transmission lines and (ii) a narrow notch filter corresponding to a specific range of frequencies of bandpass. We also apply our theory to a proposed design of on-chip Purcell filter, which can be used in the fast readout of superconducting transmon and Xmon qubits, for example.

The Role of Fields, 2D Stacking and Long-Range Order in the Search of Majorana Fermions in a Honeycomb Kitaev Candidate Arnab Banerjee1, Christian Balz1, Paula Kelley2, Craig Bridges1, Jiaqi Yang1, Yaohua Liu1, David Mandrus1 and Stephen Nagler1; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Material Science and Engineering, The University of Tennessee, Knoxville, Knoxville, Tennessee, United States.

The 2D Kitaev model on a honeycomb lattice predicts a special quantum spin liquid (QSL) ground state with excitations resembling Majorana Fermions and gauge flux excitations. These emergent features are exciting prospects to both basic physics and applications towards technologies for topologically protected quantum qubits. Our past range of experiments on the 2D magnetic Mott insulator alpha-RuCl3, which has honeycomb layers held together with weak van-der-Waals interactions, have revealed a continuum of fractionalized excitations resembling predictions from Majorana Fermions. In a 8 T magnetic field, the long-range order vanishes and the continuum becomes gapless, supporting a state where direct evidence of non-Abelian excitations can be measured. Interestingly, within this 8 T phase, recent thermal Hall effect measurements have revealed 1/2-quantized chiral edge states reminiscent of free Majorana Fermions stable to 5 K, producing a lot of excitement in the community. In this talk, I will describe our recent neutron experiments on the role of the 3D magnetic long-range order and the nature of the 2D stacking, which is critical to understand this material and its phases. Our result point to the hierarchy of the 2D (within a 2D layer) and 3D interactions (between the 2D layers) in the Hamiltonian which is responsible for the physics observed. I will describe the present and future endeavors to complete the understanding of the phase diagram of this material, as well as on how to stabilize the phase where these excitations are observed.

Electrical Transport Measurements of Quantum Structures with Atomically Precise Probes Markus K. Maier and Brandon Giles, Scienta Omicron GmbH, Denver, Colorado, United States.

A major challenge in the development of novel devices in molecular and atomic scale electronics and specifically in QBits for Quantum Information Processing (QIP) is their interconnection with larger scaled electrical circuits. Local electrical probing by multiple probes with atomic precision can significantly improve efficiency in analyzing electrical properties of individual structures without the need of a full electrical integration. The LT NANOPROBE merges a SEM navigated 4-probe electrical transport measurement system with four individual high stability SPM’s with precision in the pm range. This exact stability allows for atomic resolution in STM and nc-AFM (QPlus) and expands applications towards the creation of atomically precise structures and their direct analysis by electrical transport measurements and SPM based spectroscopy methods.

The system - including simultaneous SEM probe navigation - is operated near thermal equilibrium at T< 5K and has been developed towards an extremely low thermal drift, which is the most important ingredient to allow for enough measurement time on atomic structures, a precision regime that is virtually inaccessible at room temperature. We will present the technical concept and measurements that prove the performance level of the instrument, specifically low thermal drift and pm stability. As an exciting application, we will refer to atomic scale lateral transport measurements on dangling bond dimer rows created on hydrogenated Ge(001), in which probes are as close together as 30nm and positioned for transport measurements from atom to atom.

We will also show the newest technology improvements, such as high frequency capabilities and optical access for pumped probe experiments. Future technology challenges as well as applications and scientific drivers for this type of scientific instrumentation will be discussed.

8:45 AM *QN06.07.02

First Principles Atomistic Modeling of Decoherence Sources in Qubit Devices Vincenzo Lordi; Lawrence Livermore National Laboratory, Livermore, California, United States.

Understanding the detailed materials origins of decoherence in qubit devices will enable rational design of improved devices and fabrication processes for practical quantum information processing. We utilize first principles materials simulations to study a range of possible coherence-limiting defects and materials properties at the atomic scale. Examples will be presented for superconducting qubits, ion trap qubits, and silicon/silicon-germanium quantum dot qubits.

Specifically, we will review our recent work in the computational search for sources of flux and dielectric noise in superconducting qubits, including paramagnetic surface impurities, grain boundary effects, the atomic structure of Josephson junction dielectric layers, and the dielectric response of interface features. Many of these atomic features are associated with spurious two-level fluctuators that couple to the qubit and cause decoherence. For ion traps, possible sources of anomalous heating associated with electrode materials and surface impurities are studied with atomistic simulations. The phenomenon of anomalous motional heating of the trapped ion is a major limiting factor of the coherence time for surface ion trap devices. Various levels of detail are used to model the surfaces and impurities realistically. Finally, we will describe studies of dangling bond defects in insulating layers of silicon and silicon-germanium quantum dot devices as a possible source of charge noise in those devices. Prepared by LLNL under Contract DE-AC52-07NA27344.
Cooled samples to cryogenic temperatures is common for quantum materials and quantum information devices. Effective cooling requires adequate thermal conduction pathways between the cooling stage and the sample. A three-tiered structure of CTE mismatch (sample/mounting material/stage) is studied. Silicon wafers are good standard reference samples widely used across thin film research, are flat and mirror-like surfaces that will reflect a laser signal. The curvature of a Si wafer sample is measured in real time as a function of temperature. A projected pattern of laser spots is reflected from a piece of Si wafer that is mounted to a stage in a cryostat. Monitoring changes in the spot spacing is a result of the sample’s change in curvature and indicates an applied bending moment. Mounting techniques tested include using common cryogenic adhesives such as Apiezon N grease, GE varnish and Stycast epoxy as well as attaching samples in place on a copper cooling stage with copper wire and Teflon tape. Finally, the Cu sample stage is replaced with a Si sample stage in order to match the CTEs of the stage and the sample, leaving only the mismatch of a thin bonding layer. These techniques are compared and analyzed using a balanced force model and linear elastic/plastic theory to determine the degree to which each method stresses the sample.

Correlating Material Structure to Properties with High Spatial Resolution Using In situ and High Precision Electron Microscopy

Eva Olsson; Chalmers University of Technology, Gothenburg, Sweden.

In situ electron microscopy can be used to reveal the correlation between local atomic structure and properties. This talk will address in situ electron microscopy using local sample manipulation combined with the ability to measure the local electrical transport properties and effects induced by electric fields, light and mechanical strain. This is achieved by using a scanning tunnelling microscope in scanning electron microscopes and transmission electron microscopes [1-4] and by specially designed stages for uniaxial mechanical strain [5]. The electron microscopes provide both imaging capabilities and spectroscopy methods for the determination of local material and electronic structure. The use of scanning electron and transmission electron microscopes enables the in situ studies to be carried out on different length scales spanning from the subatomic dimension to micrometer. The position of individual atoms and atom columns can be determined with picometer precision [6]. The direct correlation on the small scale involving individual interfaces, defects and atoms provides access to new information about which microstructural constituents that are active in determining the material properties on the different length scales. It is possible to study both bulk and surface effects and understand how the properties can be tuned and the performance tailored for each specific application.

Influence of Cryogenic Mounting on Thermal Stress Measurements

Margaret H. Samuels1,2 and Christopher Richardson1; 1Laboratory for Physical Sciences, College Park, Maryland, United States; 2Materials Science, University of Rochester, Rochester, New York, United States.

Cooling samples to cryogenic temperatures is common for quantum materials and quantum information devices. Effective cooling requires adequate thermal conduction pathways between the cooling stage and the sample; however, many mounting techniques introduce materials with mismatched coefficient of thermal expansion. The mismatch may result in a bending moment or stress in the sample. Both can deform the sample while measurements occur, may cause plastic deformation, and potentially couple to the physical quantity of interest.

In this study, various mounting techniques are employed to create thermal conduction pathways between the cooling stage and the sample. A three-tiered structure of CTE mismatch (sample/mounting material/stage) is studied. Silicon wafers are good standard reference samples widely used across thin film research, are flat and mirror-like surfaces that will reflect a laser signal. The curvature of a Si wafer sample is measured in real time as a function of temperature. A projected pattern of laser spots is reflected from a piece of Si wafer that is mounted to a stage in a cryostat. Monitoring changes in the spot spacing is a result of the sample’s change in curvature and indicates an applied bending moment. Mounting techniques tested include using common cryogenic adhesives such as Apiezon N grease, GE varnish and Stycast epoxy as well as attaching samples in place on a copper cooling stage with copper wire and Teflon tape. Finally, the Cu sample stage is replaced with a Si sample stage in order to match the CTEs of the stage and the sample, leaving only the mismatch of a thin bonding layer. These techniques are compared and analyzed using a balanced force model and linear elastic/plastic theory to determine the degree to which each method stresses the sample.
grown on Si or Ge substrates; rather it must be grown on a relaxed Si$_{0.2}$Ge$_{0.8}$ virtual substrate. Demonstrations using RP-CVD have used a thick Ge layer grown directly on Si (001) that is combined with a reverse composition grading to Si$_{0.2}$Ge$_{0.8}$. These virtual substrates usually possess a rough surface and crosshatch morphology that needs chemical mechanical polishing before QW growth. This experimental study focuses on the growth and characterization of abrupt metamorphic Si$_{0.2}$Ge$_{0.8}$ buffer layers grown on Si (001) substrates by means of MBE. The Si and Ge fluxes are created with electron beam evaporation solid sources that are controlled by electron impact emission spectroscopy. In this proposed design, a fully relaxed Si$_{0.2}$Ge$_{0.8}$ layer is directly grown on Si (001) at a lower substrate temperature than what can be accomplished with RP-CVD. A strain balanced Ge/Si$_{0.2}$Ge$_{0.8}$ supper lattice is grown to filter threading dislocations followed by a relaxed Si$_{0.2}$Ge$_{0.8}$ spacer that also serves as the bottom barrier for the Ge QW. The 10 nm-thick Ge QW is grown with a Si$_{0.2}$Ge$_{0.8}$ top barrier layer and a 1-nm Si cap. Growth details and structural characterization of the materials using a variety of techniques will be described.

Quantum phenomena is at the heart of current condensed matter physics and materials science. Quantum oxide materials are one of promising candidates to study the quantum phenomena, owing to the strong coupling between various degrees of freedom. With more recent attention being paid to the topological state of matter, it is important to understand how this state influences different physical properties of oxides and how it is coupled to the conventional degrees of freedom in oxides.

In this tutorial we will cover various aspects of quantum behavior of oxides. The tutorial will focus on the transport properties and electronic structures of quantum oxide materials, and novel imaging techniques and theoretical approaches for characterization of the materials.

8:30 AM
Electrical and Thermal Transport Properties of Quantum Materials (From Basics to Dirac and Oxide Systems) Benoît Fauqué, ESPCI

In this tutorial I will give an introduction to the electrical and thermoelectric transport in solids. After an introduction on their experimental implementation I will show how these properties can be used to characterize the electronic ground states of the matter. I will particularly focus on the effect of a magnetic field on semi-metals which allows you to determine the Fermi surfaces (by the study of quantum oscillations) and can even generate new electronic state of the matter.

10:30 AM
Electronic Structure of Quantum Oxides (Angle and Spin-Resolved Photoemission) Phil King; University of St Andrews

Angle-resolved photoemission spectroscopy (ARPES) is arguably one of the most direct momentum-resolved probes of the electronic structure of solids and their surfaces. The spectral function measured by ARPES encodes information on the many-body interactions of importance to determining a material’s properties, and, with recent developments in spin-resolved detection, can now additionally yield key insights on the momentum-resolved spin-polarisation of electronic states. As such, ARPES has proved a powerful probe of the quantum many-body states and phases of oxide quantum materials. In this tutorial, we will cover the basics of ARPES and its operation, and review some recent key results from surface and interface studies of oxide crystals and thin films.

characteristics for such applications. Mechanisms such as spin-polarized current injection, the spin Hall effect, and precessional spin pumping have been used to generate spin currents, while spin current may be detected by the inverse spin Hall effect or via spin transfer torque exerted upon a ferrimagnet.

We have recently demonstrated that X-ray detected ferromagnetic resonance (XFMR) provides unique capabilities to probe the generation and propagation of spin currents in multilayered spintronics structures directly [1]. Taking advantage of magnetic contrast and element specificity of X-ray magnetic circular dichroism (XMCD), we showed that in a Ni$_8$Fe$_{12}$/Cu$_{20}$/Mn$_{80}$/Cu$_{20}$/Co$_{20}$ multilayer, spin current excited in the Ni$_8$Fe$_{12}$ layer propagates across the Cu spacer layer and excites a precession in the Co layer.

In magnetic thin films, the amplitude of the magnetization precession is typically not isotropic, i.e. the magnetization vector does not precess on a symmetrical cone but rather on an elliptical trajectory with an amplitude of the precession varying along different directions perpendicular to the static applied field. The asymmetry reflects the magnetic anisotropy of the system. Making use of the fact that XMCD probes the magnetization component collinear with the direction of the incoming X-ray beam, we are able to measure the precession amplitude along orthogonal directions by choosing suitable experimental geometries. This allows us to determine the exact shape of the precession cone with element-selectivity, valence state specificity and sensitivity to the symmetry of the absorber site in complex oxides such as Ni$_{1-x}$Zn$_{1-x}$Al$_x$Fe$_2$O$_4$ (NZAFO) [2].

Moreover, utilizing the sensitivity of X-ray magnetic linear dichroism (XMLD) to antiferromagnetic order, allows for expanding the capabilities of X-ray detected magnetic resonance to antiferromagnetic systems. We will present our current efforts to probe the propagation of spin currents in ferrimagnetic materials as well as ferromagnetic/antiferromagnetic multilayer structures.

A Theoretical Outlook on the Properties of Spin Ice and Other Magnetic Pyrochlore Thin Films
Michel Gingras; Department of Physics and Astronomy, University of Waterloo, Waterloo, Ontario, Canada.

Frustrated magnetic materials and strongly correlated electron systems are a forefront of research in modern condensed matter physics and materials science. Despite almost three decades of investigations, the theoretical understanding of these fascinating systems remains incomplete. The most prominent theoretical frameworks used to tackle these systems take the form of an emergent gauge theory akin to the gauge theory that describes conventional electromagnetism.

Spin ice is an unusual substance in which the magnetic moments of individual atoms behave very similarly to the protons in conventional water ice — hence the name spin ice — failing to align even at very low temperatures and displaying the same residual entropy that Linus Pauling calculated for water ice and which is measured experimentally. Spin ices, which belong to the broad class of compounds called magnetic pyrochlores, actually have something in common in common with electromagnetic fields; both can be described by a gauge theory. Many aspects of conventional electromagnetism are sensitive to constraints from enclosure boundaries, such as total internal reflection used in communication with optical fibers. It is then reasonable to wonder if spin ices have similar sensitivities to boundary effects and confinement. Motivated by the recent experimental realizations of spin ice and other magnetic pyrochlore thin films, I will discuss in this talk some of the exotic physical phenomena that arise when considering spin ice thin films such as, for example, a novel magnetic charge crystallization on the film surface while the bulk remains thermally disordered [1]. From a broader context, magnetic pyrochlore thin films offer a natural platform to study the confinement of emergent gauge fields describing strongly correlated systems and the evolution of nontrivial magnetic correlations as one moves from three to two dimensional spin textures [2]. Finally, I will discuss the consequences of open surfaces on the mechanisms of order by disorder in thin films of the XY pyrochlore antiferromagnet. We find that a complex competition between multiple orders take place, as a function of temperature and film thickness. A gradient of ordering spreads over long length scale inside the film while the nature of the phase transitions is blurred between two and three dimensional critical phenomena [3].

Beyond the physics of films, this work also pertains to near-surface effects in single crystals of rare-earth pyrochlore oxides.

Interacting and Spin-Orbit Coupled Electronic States of Delafossite Oxide Natural Superlattices
Phil King; School of Physics and Astronomy, University of St Andrews, St Andrews, United Kingdom.

The ABO$_2$ family of delafossite oxide metals can be considered as natural superlattice structures comprising high-conductivity metal layers separated by insulating transition-metal oxide building blocks. I will present our angle-resolved photoemission (ARPES) measurements from several members of this series. In PdCrO$_2$, the oxide layer is an antiferromagnetically-ordered Mott insulator, where we find that a coupling between the metallic and insulating subsystems renders photoemission sensitive to the spin susceptibility of the Mott layer [1]. In PdCoO$_2$ and PtCoO$_2$, the oxide layer is a band insulator, but this becomes hole-doped at the surface due to electronic reconstruction driven by a polar surface charge. We demonstrate how the resulting Co$_2$O$_4$ surface supports metallic states which host a surprisingly-large Rashba-like spin-orbit splitting, resulting from a structural configuration which ensures a large energy scale associated with inversion symmetry breaking at this surface [2]. For the Pd-terminated surface, we find how an electron self-doping, again driven by the surface polarity, mediates a Stoner transition to itinerant ferromagnetism [3], in contrast to the non-magnetic nearly-free-electron-like character of the Pd-derived states in the bulk [4]. Together, these results indicate the wide range of materials properties that can be stabilized in delafossites, as well as at their surfaces and interfaces.

Key collaborators on this work include Veronika Sunko (St Andrews and Max-Planck Institute for Chemical Physics of Solids, Dresden), Federico Mazzola (SIAM), Helge Rosner, Seunghyun Kim, Pallavi Kushwaha, and Andy Mackenzie (MPF-CFSS), Sota Kitamura and Takashi Oka (MPF-PKS), and Leonid Pourovskii and Antoine Georges (Collège de France).

SESSION QN07.02: Low-Dimensional Behavior

1:30 PM QN07.02.01
Freestanding Crystalline Oxide Membranes and Heterostructures
Harold Hwang$^{1,2}$; $^1$Stanford University, Stanford, California, United States; $^2$SLAC National Accelerator Laboratory, Menlo Park, California, United States.

The ability to create and manipulate materials in two-dimensional (2D) form has repeatedly had transformative impact on science and technology. In parallel with the exfoliation and stacking of intrinsically layered crystals, the atomic-scale thin film growth of complex materials has enabled the creation of artificial 2D heterostructures with novel
functionality and emergent phenomena, as seen in perovskite oxides. We present a general method to create freestanding complex oxide membranes and heterostructures with millimeter-scale lateral dimensions and nanometer-scale thickness. This facilitates many new opportunities we are beginning to explore, including the topological melting transition of 2D crystalline order, the application of extreme strain states, and integration with other materials families.

2:00 PM QN07.02.02
Novel Epitaxial Strain Effects on the Hybrid Improper Ferroelectrics from First-Principles Xuezeng Lu and James Rondinelli; Northwestern University, Evanston, Illinois, United States.

Epitaxial strain is a powerful tool to generate ferroelectricity owing to polarization-strain coupling. Local lattice degrees-of-freedom such as rotations of metal-oxygen octahedral also couple to strain, and can be used to tune a material’s oxygen rotational-related properties such as metal-insulator transitions and magnetic reconstruction by strain. Here, we first use electronic structure calculations to investigate the strain effects on (001) thin films of the hybrid-improper ferroelectric (HIF) A$_2$B$_2$O$_2$ compounds. Surprisingly, other than the bulk polar Cmcm phase, we find a new nonpolar phase becomes the ground state under both experimentally accessible biaxial compressive and tensile strains, which is beyond the people’s believe about the role of the polarization-strain coupling. Furthermore, the generality of the polar-to-nonpolar (N-NP) transition in HIFs (not only in A$_2$B$_2$O$_2$ compounds) leads us to find a novel route to tune the physical properties that are classified as mechanical, optical and magnetic responses, which we also propose could be electric-field-tunable, near the P-NP phase transition boundary. Our results may offer a route to search for new functionalities in hybrid-improper ferroelectrics.

2:15 PM QN07.02.03
Realization of Room-Temperature Ferroelectric Ferromagnet via 1D Tetragonal Network Kyung Tae Kang, Chang Jae Roh, Jinyoung Lim, Taewon Min, Jun Han Lee, Kyoungjin Lee, Tae Yoon Lee, Seunghun Kang, Daehye Seol, Jiwooong Kim, Hojim Chi, Ahn Mihye, Seung Chul Chae, Yoon Seok Oh, Jaekwang Lee, Jaegun Yu, Jong Seok Lee and Woo Seok Choi; 1Sungkyunkwan University, Suwon-si, Korea (the Republic of); 2Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of); 3Seoul National University, Seoul, Korea (the Republic of); 4Pusan National University, Busan, Korea (the Republic of); 5Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of); 6Hokkaido University, Hokkaido, Korea (the Republic of).

Distortive modulation of the transition metal-oxygen (MoO$_3$) polyhedra provides an efficient strategy for designing the functional metal oxides. Ferroelectricity occurs as the collective distortion of the Mo$_6$ polyhedral network breaks a spatial inversion symmetry. For conventional perovskite oxides, ferroelectricity occurs owing to the ionic displacements within a 3D network of MoO$_6$ octahedra. Meanwhile, the polyhedral tilting and rotation within some 2D networks of Mo$_6$ (x = 5 or 6) polyhedra can also lead to centrosymmetry breaking through the trilinear coupling with the spontaneous polarization. This gives rise to the geometric ferroelectricity even in the oxides including magnetic ions, i.e., multiferroic.

Considering the fundamentally different principle of 2D network for ferroelectricity from that of 3D network, one can further suggest the 1D chain network to explore unprecedented nature of ferro-ordrings. Here we exhibit the combined partial distortion (CPD) induced ferroelectricity and coupled ferromagnetism in 1D chain network by investigating the brownmillerite SrFeO$_3$$_2$, epitaxial thin film of FeO$_2$ tetrahedra. The constrained distortion of low symmetry of FeO$_2$ tetrahedra leads to the simultaneous displacement of ions and rotation of the tetrahedra. The CPD further play a role in inducing cant ferromagnetism coupled with electric polarization via Dzialoshinskii-Moriya interaction. Our result provides a new paradigm for designing 1D MO$_6$ networks, expected to benific the emergent ferro-ordering materials including room-temperature ferroelectric ferromagnets.

2:30 PM QN07.02.04
Artificial 1D Quantum Stripes of Complex Oxides Ambrose Seo; Department of Physics and Astronomy, University of Kentucky, Lexington, Kentucky, United States.

Tuning the dimensionality of a system offers a useful tool for realizing new quantum phenomena associated with critical phase transitions and topological properties. However, only a few naturally occurring complex oxides with tunable, intrinsic 1D and 2D structures are available for experimental studies. In this talk, I will present a new approach of synthesizing 1D – 2D quantum stripe systems by creating dimensionally-confined superlattices from in-plane oriented layered materials. For example, we have demonstrated this method to synthesize 1D – 2D IrO$_2$ stripes using c-axis oriented superlattices of SrIrO$_3$ and insulating (La,Sr)IrO$_3$, both are of the K$_3$NiF$_4$ symmetry [1]. The dimensional confinement of the superlattices has been confirmed by structural characterizations. Optical spectroscopy shows clear anisotropic characteristics and dimensional electronic confinement of the spin-orbit coupled $J_{eff} = 1/2$ band. Spin and orbital excitations observed in resonant inelastic x-ray scattering spectra suggest larger exchange interactions and more confined orbital excitations in the 1D IrO$_2$ stripes as compared to its 2D counterpart. The observed electronic confinement and localized spin-structure are quite consistent with density functional theory calculations. This method of tuning the dimensionality between 1D and 2D via stripe-superlattices is a viable technique for obtaining dimensionality-induced quantum phase transitions, in which exotic excitations such as the fractional quantizations of quasi particles can emerge.

3:30 PM QN07.03.01
Strain-Induced Magnetic Transitions in Sr$_2$Mn$_5$O$_8$ Structure Yongjin Shin and James Rondinelli; Northwestern University, Evanston, Illinois, United States.

Sr$_2$Mn$_5$O$_8$ (SMO) in the C$_2$hMn$_5$O$_8$-type structure is one structure among A$_2$B$_2$O$_2$ compounds derived from ABO$_3$ perovskites with ordered oxygen vacancies (OOVs). The ordered arrangements of vacancies enable unique functional properties in such compounds, because the ligand-field modified orbital structure reconstructs as the octahedral BO$_6$ units are transformed into different BO$_5$, polyhedral arising from the OOVs. The magnetic order of transition metal oxides is governed by interaction of these orbitals and occupancy of electrons. For example, SMO exhibits a unique E-type antiferromagnetic (AFM-E) ordering because of the d$^4$ electronic configuration of Mn$^{3+}$ in the square pyramidal network. Hydrostatic pressure and biaxial strain provide additional routes to tune the magnetic properties of materials through lattice strain-induced changes to the orbital structure. Here, we investigate the relative stabilities of different magnetic orders realized through hydrostatic pressure and strain induced non-equilibrium local structures using density functional theory. We show that SMO hosts multiple magnetic transitions from AFM-C, AFM-E*, AFM-E, AFM-E*, and FM upon application of biaxial strain from compressive to tensile strain in (001) thin film geometries. In contrast, the AFM-E state is robust under hydrostatic pressure. As epitaxial strain produces anisotropic stresses, we observe different magnetic transitions depending on the relative orientation of the vacancy order with respect to the biaxial epitaxial strain. We conclude by summarizing the different changes in local structures and its impact on magnetic orders.

3:45 PM QN07.03.02
Engineering and Monitoring Spin Orientation in Anti-Ferromagnetic Oxide Multilayers Using X-Ray Spectroscopy Alpha T. N'Diaye, 1Mengmeng Yang, 2Qian Li, Elke Arendsholz, 1Zi Q. Qiu; 1Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2University of California, Berkeley, California, United States.

The majority of digital information is stored magnetically today. Nanoscale magnetic domains encode “1’s” and “0’s” on common commercial hard drives and newer magnetic data storage concepts rely on domain walls or parallel and antiparallel magnetization in magnetic multilayers. To develop novel materials and concepts for data storage applications, we
employ X-ray spectroscopy as well as X-ray magnetic dichroism to determine spin-states in a diverse range of materials. With the same tools, we are exploring new materials for data processing, as indications increase the the potential for further miniaturization of Silicon chips is soon to be exhausted.

The control of ferro- and antiferromagnetic spin orientation is a crucial element of today’s and tomorrow’s information technology applications, for instance needed for hard drive read heads or magnetic random access memory (MRAM). Novel device concepts using antiferromagnetic spintronics or antiferromagnetic skyrmions promise revolutionary innovations in information science. A detailed understanding of the mechanism which antiferromagnetic spin orientation is the prerequisite for pursuing these ideas.

With soft x-ray linear dichroism we follow the thickness dependent spin re-orientation in a NiO/CoO bilayer with varying CoO and NiO layer thicknesses. The oxide-oxide interface in this simple oxide system can be regarded as a model for the a supercell of complex oxide superlattices which have been used to demonstrate a host of new and exciting properties, such as interfacial ferromagnetism or novel electronic states.

In this simple system with negligible charge transfer or structural distortions we first investigate how the purely thickness dependent coupling between CoO and NiO forces the system from an antiferromagnetic in-plane spin orientation for larger CoO layer thickness to an out-of-plane spin orientation for thicker NiO. To this end we use a double wedge sample geometry which we locally probe with x-ray spectroscopy to access different thickness combinations ranging from 0-2.5nm for CoO and 0-14nm for NiO. We find the spin reorientation to be a consequence of the balance between interfacial coupling and bulk anisotropies of NiO and CoO.

Furthermore, we augment this system with a ferromagnetic Permalloy (Py) layer and show how an in-plane antiferromagnetic NiO spin configuration enhances the coercivity of the ferromagnetic permalloy layer substantially to ca. 400Oe while in the in-plane configuration the coercivity remains comparable to the coercivity of pristine Py.[1]

4:00 PM QN07.03.03
Spatially Resolving Spin Textures in Epitaxial Oxide Ferromagnet-Antiferromagnet Heterostructures Rajesh V. Chopdekar1, Yue Jiu1, Michael Lee2 and Yayoi Takamura2; 1Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Materials Science and Engineering, University of California, Davis, Davis, California, United States.

Recent interest in antiferromagnetic (AFM) spintronics has surged due to the possibility of obtaining ultrafast magnetization dynamics with no stray field, and complex oxide AFMs offer possibilities to engineer AFM spin textures via their many degrees of freedom and sensitivity to epitaxial strain. However, this lack of stray field makes imaging of the AFM domain structure difficult though conventional magnetic imaging techniques. This talk will discuss the use of x-ray photoemission electron microscopy (X-PEEM) with both x-ray linear and circular dichroism to spatially resolve the ferroic order in the AFM and ferromagnetic (FM) layers of a model system of alternating FM La0.7Sr0.3MnO3 and G-type AFM La0.7Sr2FeO4 (x=0 or 0.3). In the limit of few unit-cell thick layers for (001)-oriented samples, the AFM spin axis lies in the plane of the film in contrast to thicker layers where the spin axis cants out of plane. In contrast, (111)-oriented superlattices show markedly different behavior with two populations of spin orientations, a subset with spin axes canted along low-index <110> directions and which exhibit spin flop coupling to the FM layer, and a subset whose spin axis lies within the (111) plane. The coupling at the AFM/FM interface for both orientations allows for control of the AFM domain structure through magnetization rotation of the FM layer, and recent work has shown shape anisotropy offers an additional degree of freedom to control complex oxide AFM domain orientation. X-PEEM with variable temperature and x-ray polarization offers a powerful tool to determine the AFM spin axis on the scale of single AFM domains, and such a local probe is necessary for a full understanding of how the similar energy scales of shape anisotropy and interfacial exchange can be tailored in order to design spin textures in these oxide heterostructures.

4:15 PM QN07.03.04
Partial Magnetic Order in FePO4: Colin Sarkis1, Michael Tame1, James Neilson1, Hubro Cao2 and Kate Ross1; 1Colorado State University, Fort Collins, Colorado, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Competing antiferromagnetic interactions in triangular motifs of magnetic Fe3+ in the noncentrosymmetric compound FePO4 (spacegroup R3m) give rise to magnetic frustration. This leads to an unusual helical magnetic state below Ts=163K, in which needle-like domains exhibit long range antiferromagnetic order along the c axis, but have a correlation length restricted to ζ=7nm in the ab plane. Through single crystal neutron diffraction, we report a degenerate manifold of ordering wavevectors in the ab plane, which smear the incommensurate Bragg peaks into a continuous ring. We show this result to be consistent with the competition between J1 (nearest neighbor) and J2 (next nearest neighbor) interactions in a Heisenberg model, which produces a quasi-degenerate manifold of ordering wavevectors. When doped with non-magnetic Ga3+, polycrystalline samples show helical winding length and correlation length in the ab-plane to be equal. The restriction to short range order in the ab plane, along with the intimate connection of helical winding length and correlation length, imply the presence of a high density of non-trivial topological defects which are tied to the magnetic structure.

4:30 PM *QN07.03.05
Complex Magnetic Domain Structures in Oxides—Physical Origin and Device Application Jian Shen; Fudan University, Shanghai, China.

Physics of magnetic domains of conventional magnetic materials can be well described by minimization Landau-Lifshitz free energy. However, for magnetic oxides, competition between various types of exchange interactions has often led to complex magnetic domain structures that are far from being understood. One of the most typical example is the domain structure in colossal magnetoresistive manganites, which is featured by spatial coexistence of ferromagnetic, antiferromagnetic and even spin glass domains. These domains are not only different in magnetic states, but are also in different conducting states. By studying the effect of spatial ordering of the chemical dopants, we conclude that the dopants-induced disorder is the key reason for the formation of the complex domain structures in magnetic oxides. Based on the understanding of the physical origin of the complex magnetic domains in oxides, we have developed various methods to control the domain patterns in oxides and fabricated multi-bit memory device that can also carry out logic operations.
antireflection layer to greatly improve the absorption of near-infrared light, thereby overcoming the absorption limitation of near-infrared light. Instead of the conventional p-n junction and p-intrinsic-n junction, we introduce a ~15 nm thick alumina insulator layer introduced between a p-type Si substrate and n-type ZnO nanowire (NW) arrays, which are found that the charge carriers separation and collection efficiency have significantly enhanced. The photo-sensing responsivity and sensitivity are found to be nearly one order of magnitude higher than that of a reference device of p-Si/n-ZnO NW arrays, significantly higher than the commercial silicon photodiodes as well. The light-induced charge carriers flow across the appropriate thickness of insulator layer via the quantum mechanical Fowler-Nordheim tunneling mechanism. By virtue of the piezo-photoelectronic effect, the charge density at the interfaces can be tuned to alter the energy bands and the potential barrier distance for tunneling. Additionally, along with the use of incident light of different wavelengths, the influence of the insulator layer on the transport of electrons and holes separately is further investigated. The demonstrated concepts and study would lead to sensitivity improvement, quality enhancement of data transfer, decrease of power consumption and cost-reduction of silicon photonics.

**Performance Improvement REBCO Multilayers by Means of Surface/Interface Quantum Modulation**

Linfei Liu, Shunfan Liu, Tong Zheng, Wei Wang and Yijie Li

Shanghai Jiao Tong University, Shanghai, China.

REBa2Cu3O7-x (REBCO, RE=rare earth) coated conductors (CCs) have the huge market potential for large scale of commercial applications due to their excellent superconducting properties. Up to now, the high cost is still a bottleneck for practical applications. The most effective way to reduce the cost is to increase critical current density $J_c$ of thick REBCO films. However, $J_c$ of REBCO films will decrease as the increasing of REBCO film thickness. In this work, we report the enhancement of $T_c$ and $J_c$ of REBCO films achieved through the surface/interface quantum modulation. REBCO multilayers were fabricated on CeO2/IBAD-MgO buffered metal tapes by pulsed laser deposition (PLD). At first, $Y_{1-x}Gd_xBa_2Cu_3O_y$ (YGBCO) films were grown on CeO2/IBAD-MgO buffered metal tapes. Then, metal nanoparticles such as Ag and In were grown on YGBCO films. Comparing with the pristine REBCO films, higher $T_c$ and $I_c$ were observed from the YGBCO films with metal nanoparticles. The $T_c$ and $I_c$ values were increased by 1K and 40A, respectively. Furthermore, the YGBCO/In doped CeO2 (CeO2:In) YGBCO hetero-structures were fabricated. It was found that the $I_c$ value of the YGBCO/ CeO2:In/YGBCO trilayers was almost doubled. Interaction at the interface comprises a variety of effects, such as epitaxial strain, interface defects, elemental inter-diffusion, interface charge layers, electrical charge transfer between layers, and others, which can improve the superconducting properties of REBCO films. The results provide the important insights into the superconducting property engineering of REBCO CCs by artificial microstructure control.

**YBa2Cu3O6+-δ Nano-SQUIDs Based on Tunnel Nano-Junctions Fabricated by Focused Helium Ion Beam Direct Writing**

Hao Li1, Han Cai1, Ethan Cho1 and Shane Cybart1,2

1Mechanical Engineering, University of California, Riverside, Riverside, California, United States; 2Material Science Engineering, University of California, Riverside, Riverside, California, United States.

Focus helium ion beam (FHIB) materials modification is an emerging technique with the capability to make high-quality thin-film YBa2Cu3O6+-δ (YBCO) superconducting Josephson junctions [1]. In this method, ion irradiation converts the film from a superconductor to an insulator by disordering the crystalline lattice. No material is removed or etched, as a result nanoscale insulating features are obtainable for both Josephson junctions[2] and superconducting electrodes for devices such as superconducting quantum interference devices (SQUIDs) [3].

We investigate YBCO nano-SQUIDs to push the scaling limits. YBCO SQUIDs with loop dimension from 1.2 μm down to 10 nm have been fabricated. Current-voltage characteristics revealed high-quality of Josephson tunnel junctions with insulating barriers. Voltage modulation as a function of magnetic field was measured for the nano-SQUIDs by both an on-chip control line and external coil in a wide temperature range from 4.2 K up to ~50 K. The highest modulation voltage was ~0.8 mV for a single nano-SQUID, and the smallest magnetic flux effective area achievable was ~0.25 μm2. The flux noise characteristics was measured open loop using a small signal method, which showed a white noise of ~0.6 μΦ0/Hz1/2 for the Nano-SQUID with loop dimension 400 nm.

**Electronic Structure and Transport Properties in Bi2-xCaFeO3-y with Control of Oxygen Vacancy Content**

Ji S. Lim1,2, Jin Hong Lee1,2, Atsushi Ikeda-Ohno1, Tokito Ohkohchi1, Ki-Seok Kim1, Jan Seidel3 and Chan-Ho Yang1,2,3,4

1Department of Physics, KAIST, Daejeon, Korea (the Republic of); 2Center for Lattice Defectronics, Daejeon, Korea (the Republic of); 3Institute for Materials Research, Tohoku University, Sendai, Japan; 4School of Materials Science and Engineering, The University of New South Wales, Sydney, New South Wales, Australia.

Oxygen vacancies are ubiquitous in oxide systems, which can play important roles to cause interesting physical phenomena such as metal-insulator transition, magnetic and ferroelectric orders, and high-$T_c$ superconductivity. Oxygen vacancy concentration has been a key control parameter to modulate physical properties [1]. In this work, we study the electronic structure and transport properties of Ca-substituted BiFeO3 (BCFO) thin films with controlling the oxygen vacancy concentration [2]. BCFO films can spontaneously produce oxygen vacancies owing to the stable oxygen number of Fe3+ ions. The as-grown state can be transformed into an electrically-formed state through electro-migration of oxygen vacancies, thereby creating a spatially uniform stoichiometric hole doping region [3]. We measure conduction band and valence band spectra by using X-ray photoemission spectroscopy and find that a non-rigid polaronic band emerges in the hole doping system. In addition, we investigate temperature dependence of electronic transport leading to a disorder-driven formation of a Coulomb-gap state.

**Temperature Dependent Exchange Bias in EuO$_x$,Si**

Syed Qamar Abbas Shah1, Gaurab Rima1, Jian Wang1, Guanhua Hao1, Simeon Gilbert1, Andrew J. Yost1 and Jinke Tang1,2

1University of Nebraska-Lincoln, Lincoln, Nebraska, United States; 2Physics, Rutgers University, Rutgers, New Jersey, United States; 3Canadian Light Source, Saskatoon, Saskatchewan, Canada; 4Department of Physics and Astronomy, University of Wyoming, Laramie, Wyoming, United States.

EuO$_x$ combines several interesting properties: large magneto-optical effects, colossal magneto-resistance, and enhanced Curie temperature due to bound magnetic polarons. EuO$_x$ is also one of a very few ferromagnetic insulators and, as an ultra thin film, very sensitive to interface effects. Utilizing pulsed laser deposition, we deposited a film of EuO$_x$, onto a Si substrate in order to create a ferromagnetic (FM)/anti-ferromagnetic (AFM)/Semiconducting (SC) interface,$\text{EuO}_x$/Si,$\text{EuSi}_3$/Si, for applications in spintronics (spin filters). X-ray diffraction indicates the film crystallize into a preferred EuO(111) orientation, it also indicates a clear presence of EuSi2 which suggests Si diffuses across MgO buffer layer into the EuO$_x$. Density functional theory calculations are employed to model the conduction and valence bands from Eu and O and compared to x-ray absorption spectroscopy data. A magnetic signature, revealed by x-ray magnetic circular dichroism measurements, suggests the presence of a magnetic order above the Curie temperature. Strong, temperature dependent exchange bias coupling, due to the AFM/FM interface of $\text{EuO}_x$/Si, is observed in magneto optical Kerr effect spectroscopy hysteresis loops. Additionally the temperature dependent oscillatory nature of the exchange bias suggests the AFM layer undergoes a magnetic moment flip. This study demonstrates the realization of a ferromagnetic/antiferromagnetic/semiconductor interface and will be beneficial to future spintronic applications.
Various forms of titanium dioxide (TiO₂) have been applied in several fields - including electronics, energy, as well as environmental engineering - all which capitalize on the semiconductor behavior of this inexpensive, abundant and chemically stable material. Both common crystal structures of TiO₂, rutile and anatase, have large band gap (3.0 and 3.2 eV, respectively) limiting the principal optical absorption to the short wavelength UV photons only. To further enhance the photocatalytic activity, and thus make TiO₂ suitable for solar applications, a number of strategies have been worked out in the last decade. While anatase is known to have much higher photocatalytic activity than that of rutile, their mixed-phases have been known to have superior activity and have been utilized as commercial catalyst for decades. The band alignment between anatase and rutile mixed phases plays the decisive role in carrier separation after photogeneration. Electrochemical impedance analysis has confirmed that the flat band potential of anatase is about 0.2 eV lower than that of rutile. At the interface of the two phases, the photoexcited electrons tend to transfer from the anatase to the rutile, which has been corroborated by many researchers. Therefore, engineering the junction between two phases is crucial to properly address photocatalytic behavior in anatase-rutile systems. In this study, two types of core-shell heterojunction TiO₂ NFs were synthesized by sequential hydrothermal, calcination, and impregnation processes. Rutile TiO₂ NFs core with anatase TiO₂ NFs shell is denoted as R@A TiO₂ NFs, and the reverse structure is denoted as A@R TiO₂ NFs. In our study, the photodegradation of organic dyes and Kelvin Probe Force Microscopy (KPFM) analysis were applied to shed light on the mechanism of the excited electron-hole pair separation. The results of photodegradation showed that the A@R TiO₂ NFs had the highest activity under UV-B and UV-A irradiation, being nearly 3-fold higher as compared to AEROXIDE® TiO₂ P25. The results in conjunction with KPFM measurements indicated that in the heterojunction structure, electron-hole pairs were efficiently separated and the excited electrons stayed in the anatase phase, and holes were injected to rutile phase. When the A@R TiO₂ NFs heterostructures are decorated with Pt nanoparticles, the nanocomposite is particularly active in photocatalytic hydrogen evolution from ethanol-water mixtures with a production rate of ~8,500 μmol/h·g. Our study not only explains the role of anatase-rutile junctions in photocarrier separation, but also projects the development of other efficient photocatalytic heterostructures for green energy production and conversion.

Two-dimensional electron gases (2DEGs) at oxide interfaces provide unique playgrounds for the exploration for emergent phenomena which motivate not only new concepts but also applied research. The perovskite SrTiO₃ is composed of 3d electrons, and well established, oxygen vacancies and the magnetic proximity effect can be utilized to introduce magnetic moments (Δsp per T cantor) [1], generating well spin-polarized 2DEGs [2]. This offers us valuable opportunities to build up magnetic 2DEGs, which is centrally important for spintronics. While most of the previous works focused on the 2DEGs at LaAlO₃/SrTiO₃ interfaces, here we report on three new kinds of 2DEGs systems: anatase TiO₂-based 2DEGs induced by low-energy argon ion irradiation and the 2DEGs formed between a magnetic insulator EuO and a high-k perovskite KTaO₃.

BaTiO₃ (BTO) is an intensively studied ferroelectric material with several ground-state polar structures: tetragonal, orthorhombic and rhombohedral varying from room temperature to low temperatures.[1] BTO is known that tetragonal phase of which polarization is [001]-direction is the most stable at room temperature. BTO films were grown epitaxially on (111)-oriented SrTiO₃ substrates with an intermediate SrRuO₃ electrode by pulsed laser deposition in order to see the results of the competition between six stable polarization each at another room temperature. Here, we use spherical aberration-corrected scanning transmission electron microscope (STEM) to identify domain structures and phases. We demonstrate that the ferroelectric polarization domains of (111)-BTO at room temperature contain both tetragonal and orthorhombic phases, by measuring pm-scale atomic displacements of Ti-cations directly from the images. Furthermore, the domain sizes range down to a few nanometers. Such a peculiar domain configuration is in good agreement with our phase field simulation, which shows that the orthorhombic domain is bridging different 90° tetragonal domains as a way to relieve the elastic strain of domain walls. We believe that the phase coexistence along with miniaturized domains have given rise to relaxor-like behaviors in the (111)-BTO film as we observed. We have deposited SrTiO₃ thin-films on SrTiO₃ buffer layer, and the reverse structure is denoted as R@A TiO₂ NFs. In our study, the photodegradation of organic dyes and Kelvin Probe Force Microscopy (KPFM) analysis were applied to shed light on the mechanism of the excited electron-hole pair separation. The results of photodegradation showed that the A@R TiO₂ NFs had the highest activity under UV-B and UV-A irradiation, being nearly 3-fold higher as compared to AEROXIDE® TiO₂ P25. The results in conjunction with KPFM measurements indicated that in the heterojunction structure, electron-hole pairs were efficiently separated and the excited electrons stayed in the anatase phase, and holes were injected to rutile phase. When the A@R TiO₂ NFs heterostructures are decorated with Pt nanoparticles, the nanocomposite is particularly active in photocatalytic hydrogen evolution from ethanol-water mixtures with a production rate of ~8,500 μmol/h·g. Our study not only explains the role of anatase-rutile junctions in photocarrier separation, but also projects the development of other efficient photocatalytic heterostructures for green energy production and conversion. **Reference**

**Synthesis and Characterization of Freestanding SrIrO₃ Epitaxial Thin-Films**

Sujan Shrestha, Maryam Souri, John Connell, Matthew Coile, Eric Tiegel, Joseph Brill and Ambrose Sieo, Department of Physics and Astronomy, University of Kentucky, Lexington, Kentucky, United States.

Mott insulating states formed in layered iridates, such as SrIrO₃, have recently attracted substantial interest due to their unexpected novel properties caused by the coexistence of strong spin-orbit interactions and electron correlations. Recent studies on SrIrO₃ have revealed the possibilities of novel phases such as potential high-Tc superconductivity with d-wave gap.1 However, even though much experimental work using different tuning parameters, such as lattice strain, pressure and chemical doping, has been done, superconductivity has yet to be observed in this material. Moreover, it is also puzzling that electron-doped SrIrO₃ bulk crystals are metallic while SrIrO₃ thin films with as much as 15% electron-doping are insulating.2 This discrepancy may be due to strain-induced defects which are common for thin-film systems.

We have deposited SrIrO₃ thin-films on SrTiO₃ substrates using SrAl₂O₃ buffer layer.4 The water soluble SrAl₂O₃ has been shown to generate strain-free thin-films.4 High quality samples were obtained by depositing SrIrO₃/SrAl₂O₃ heterostructures on SrTiO₃(100) substrates using pulsed laser deposition. X-Ray diffraction and reciprocal space mapping shows that the SrAl₂O₃ buffer layer is relaxed and the SrIrO₃ is partially relaxed with respect to the SrTiO₃ substrate. The optical transmission spectra show that the peak energies (both a and b) are blue shifted in the SrIrO₃/SrAl₂O₃ heterostructure as compared to the SrIrO₃ thin-film on SrTiO₃. Our results demonstrate that the structural and optical properties of SrIrO₃ thin-films can be tailored using SrAl₂O₃ buffer layers and we will further discuss the electronic properties of freestanding SrIrO₃ thin-films in comparison to SrIrO₃ single crystal and SrIrO₃ thin-films on different substrates.

Magnetoresistance of Semi-Metals and Lightly Doped Semi-Conductors

Although SrTiO$_3$ was the first oxide superconductor to be discovered, the nature of its superconducting state has been a longstanding subject of debate in the literature, reflecting in many ways the elusiveness of other families of superconductors, such as the cuprates. A striking feature is that superconductivity already appears at very low carrier densities, when the Fermi temperature is lower than the Debye temperature, which is at odds with BCS theory. Bulk, undoped SrTiO$_3$ is an incipient ferroelectric for which quantum fluctuations suppress a low-temperature transition to a ferroelectric ground state. Several recent proposals have suggested that there could be a connection between ferroelectricity and superconductivity of SrTiO$_3$. In this presentation, we will report on experiments that tune the superconducting states of SrTiO$_3$ thin films grown by molecular beam epitaxy. We will discuss the effects of proximity to ferroelectricity as well as other ground states on the superconducting transition temperature and critical fields.

Large unsaturated magnetoresistance has been recently reported in numerous semi-metals [1]. Many of them have a topologically non-trivial band dispersion, such as Weyl nodes or lines. In the first part of my presentation I will show that elemental antimony displays the largest high-field magnetoresistance among all known semi-metals. I will present a detailed study of the angle-dependent magnetoresistance and use a semi-classical framework involving an anisotropic mobility tensor to fit the data [2]. A slight deviation from perfect compensation and a modest variation with magnetic field of the components of the mobility tensor are required to attain perfect fits at arbitrary strength and orientation of magnetic field in the entire temperature window of study. In the second part I will discuss the case of lightly doped SrTiO$_3$–x [3]. At low temperature we find that SrTiO$_3$–x displays a large transverse ($j$⊥$B$) but also longitudinal ($j$//B) magnetoresistance which can be captured, like in the case of the semi-metals, by a semi-classical framework including a field dependent mobility carriers.

Our results demonstrate that large orbital magnetoresistance is an unavoidable consequence of low carrier concentration and the sub-quadratic magnetoresistance seen in many semi-metals and doped semi-conductors can be attributed to field-dependent mobility, expected whenever the disorder length-scale exceeds the Fermi wavelength [4].

Quantum Phenomena in Interfacial 3d-5d Oxide Heterostructures

The non-trivial spin topology protects the spin texture against disorder and fluctuations, leading to substantial potential to miniaturize, store, and transport information with excellent stability and efficiency. Significant efforts have been focused on harnessing the Dzyaloshinskii-Moriya (DM) interaction, which results from strong spin-orbit coupling combined with broken inversion symmetry to generate magnetization rotations with fixed chirality and is a highly effective mechanism to generate skyrmions. To date, the most promising results have been achieved in multi-layer systems, which benefit from cooperative DM interactions from multiple interfaces and possible additional stabilization from inter-layer magnetic coupling of skyrmion columns. Furthermore, recent studies have identified the important roles of interfacial oxygen, hybridization, and charge transfer in determining the sign and strength of DM interactions. Transition metal oxides, in particular those containing heavy 5d elements, also possess the requisite materials parameters necessary for skyrmion formation. However, the majority of the studies focused on non-oxide-based systems. In this talk, we will present our observations on charge transfer induced magnetism, anomalous Hall effect, topological Hall effect in interface engineered 3d-5d transition metal oxide heterostructures. The critical role of the DMI and its interfacial control will be discussed together with the potential of 5d transition metal oxides for developing novel quantum materials.

Ferromagnetic Order Above 1000 K in a Double Perovskite Osmate Synthesized by Molecular Beam Epitaxy

In the magnetic insulating oxides, it is known that the cubic crystal symmetry is favorable for higher Curie temperatures ($T_C$) [1], since the network morphology hosting the mechanisms of exchange interactions is subject to the crystal symmetry. So far, these oxides are typically 3d transition metal oxides where spin-orbit coupling (SOC) is tiny. An enhancement of the SOC in 5d systems is a promising way to boost the long range ferri/ferromagnetic (FM) order. For example, it was shown for a pyrochlore osmate (Ca$_2$OsO$_6$) that the SOC is responsible for its long range order [2]. Here we show that a highly B-site ordered cubic double-perovskite Sr$_3$OsO$_6$, which satisfies above criteria, surpasses the
long standing $T_c$; (943 K for spinel ferrite $\text{LiFeO}_3$) [3] record in all insulators and oxides by more than 100 K. We synthesized the magnetic insulator Sr$\text{OsO}_6$, by molecular beam epitaxy (MBE) on (001) SrTiO$_3$ substrates (300-nm thick). Atomic-resolution scanning transmission electron microscopy (STEM) along with diffraction (TED) measurements have revealed the cubic structure and excellent Sr/Os ordering on the B'/B-site. For double perovskites, it is well known that the crystal symmetry is dominating the exchange interactions, e.g., SrFeMoO$_6$ ($T_c = 415$ K, cubic) [4] and SrFeWO$_6$ (antiferromagnetic, $T_N = 37$ K, monoclinic) [5]. Thus, the finding new property of Sr$\text{OsO}_6$ plays a crucial role for the emergence of high $T_c$, which is an electronically isostructural compound, Ca$_2$Os$_6$, having a monoclinic structure, exhibits $T_c = 50$ K. Owing to optical band gap of ~2.65 eV in Sr$\text{OsO}_6$, the electronic charge carriers move by hopping between localized electronic states, and this is supported by the temperature dependence of resistivity ($\rho$); $\rho(T) \propto T^{1+\delta}$ (variable range hopping model), along with the high resistivity value ($\rho(300 \text{ K}) = 75 \text{ 2cm}$).

Using density functional theory calculations based on a Pariser-Parr-Pople (PPP) functional, we reproduced the ferromagnetic ground state of Sr$\text{OsO}_6$. We show that the large SO of the Os$^{5d}$ orbitals indeed drive the system toward an insulating state with $J_{\text{eff}} = 3/2$ [6]. Our calculations reveal that the $J_{\text{eff}}$ states are split into effective total angular momenta of $J_{\text{eff}} = 3/2$ (doublet) and $J_{\text{eff}} = 1/2$ (singlet) states. The $J_{\text{eff}} = 3/2$ states are fully occupied with two 5$d$ electrons per Os$^{5d}$, resulting in an insulating state. Our experimental results for Sr$\text{OsO}_6$ show that in $5d$ systems extraordinary high $T_c$ is possible in spite of the long distance (5.81 Å) between 5$d$ ions. The $J_{\text{eff}} = 3/2$ insulating state with $T_c$ above 1000 K is thus consequences of the cubic rock-salt type environment of Os$^{5d}$ ions and the enhanced SOC found in Sr$\text{OsO}_6$. Further investigations, e.g., XMCD, are required to analyze the hitherto unidentified exchange interactions.

**Discovery of a New Quantum Dimer Magnet on a Strongly Spin-Orbit Coupled Honeycomb Lattice—Yb$\text{Si}_2\text{O}_5$**

S. S. Erickson, G. Koster, and J. Ross

Colorado State University, Fort Collins, Colorado, United States.

A significantly strong Bose-Einstein condensate (BEC) of magnetic ions would be a milestone in the field of quantum magnets.

In this presentation we will report the observation of a giant inverse Edelstein effect in NiFe/LaAlO$3$/SrTiO$3$ heterostructures, with spin-to-charge conversion one order of magnitude more efficient than in previous systems [8]. Moreover the large dielectric constant of the STO substrate makes possible the use of a back-gate voltage $V_g$ to modulate the Rashba effect. This can be interpreted in terms of a crossover between the occupancy of one to several bands with different orbital characters and different spin–orbit textures. Our recent experiments suggest that oxide interfaces have a strong potential for spintronics, both for the generation or detection of spin currents through direct or inverse Edelstein effects, and for spin-based quantum computing. Spin currents, which are at the heart of spintronics, allows the electrical control of magnetic (and resistance) states in magnetic nanostructures. In this context, there is a huge interest in finding new techniques for the efficient generation and manipulation of spin currents, especially using the spin-orbit interactions in non-magnetic materials. This has been greatly facilitated by the discovery of the Rashba effect, a manifestation of spin-orbit interaction (SOI) in solids, where the spin degeneracy associated with the spatial inversion symmetry is lifted due to a symmetry-breaking electric field normal to the heterointerface [5].

The Rashba effect is a manifestation of spin-orbit interaction (SOI) in solids, where the spin degeneracy associated with the spatial inversion symmetry is lifted due to a symmetry-breaking electric field normal to the heterointerface [5].

Edelstein has realized that in a Rashba two-dimensional electron system, the flow of a charge current is accompanied by a non-zero spin accumulation [6] coming from uncompensated spin textured Fermi surfaces. The reverse effect, corresponding to a spin-to-charge conversion through SOI (inverse Edelstein effect), was first demonstrated at Ag/Bi(111) interfaces [7].

In this presentation we will report the observation of a giant inverse Edelstein effect in NiFe/LaAlO$3$/SrTiO$3$ heterostructures, with spin-to-charge conversion one order of magnitude more efficient than in previous systems [8]. Moreover the large dielectric constant of the STO substrate makes possible the use of a back-gate voltage $V_g$ to modulate the 2DES carrier density and electronic properties. By this way, we found that the amplitude of the converted current can be modulated over one order of magnitude, and even changes sign. This can be interpreted in terms of a crossover between the occupancy of one to several bands with different orbital characters and different spin–orbit textures. Our recent experiments suggest that oxide interfaces have a strong potential for spintronics, both for the generation or detection of spin currents through direct or inverse Edelstein effects, and for their electrical modulation. Moreover, our observation of a very large spin-to-charge conversion efficiency at an interface with a moderate Rashba splitting highlights the importance of a long scattering time, and for the design of novel Rashba enhancement of electrical insulation from metallic layers are carefully engineered. We will compare the conversion efficiency of STO/LAO interface with that of the Spin Hall effect of metals, other Rashba interfaces and surface of Topological Insulators. We will also show that this record value can even be much enhanced by tuning carefully the heterostructure.

First-Principles Study of the Origin of N-Type 2DEG in LaAlO$_3$/SrTiO$_3$ (111) Heterostructure

Jakekwan Lee$^1$, Taewon Min$^2$, Youngmin Kim$^3$ and Sangho Oh$^4$; $^1$Pusan National University, Busan, Korea (the Republic of); $^2$Sangkyunkwan University, Suwon, Korea (the Republic of).

The emergent discovery of two-dimensional electron gas (2DEG) in LaAlO$_3$/SrTiO$_3$ (LAO/STO) heterostructure has attracted considerable attention over the past decade. Recently, unlike strongly localized 2DEG in LAO/STO (001) heterostructure, a wide n-type 2DEG density distribution is reported in the LAO/STO (111) interface (K. Song et al., Nat. Nanotechnol. 13, 198 (2018)). According to the polar catastrophe scenario, the LAO/STO (111) interface consisting of [Ti]$^+2$ and [LaO$_3$]$^-$ layers is expected to exhibit the highly localized p-type characteristics. Despite these controversies, the origin of n-type 2DEG at the LAO/STO (111) interface has not been clearly revealed yet. Here, we carry out first-principles density functional theory calculations to reveal the origin of n-type 2DEG widely distributed through the the interface of LAO/STO (111) heterostructure. We find that the n-type 2DEG originates from extra electrons created by the oxygen vacancy at the [[LaO$_3$]$^-$] terminated LAO (111) surface, and these excess oxygen vacancies significantly modulate the relative displacements between La and oxygen atoms and octahedral rotations in LAO layers. The presence of oxygen vacancy, atomic displacement modulation and octahedral rotation in the vicinity of LAO (111) surface are confirmed by annular dark-field scanning transmission electron microscope image at the atomic scale.

Anomalous Exchange Bias Induced by Hidden Interface in Oxide Heterostructures

Aiping Chen; Center for Integrated Nanotechnologies, Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Advances in thin film synthesis enable unique opportunities to enhance and control the physical properties of interfaces by controlling the interactions in complex oxides. It is well known that interface layers provide opportunities to create or control functional properties of oxide heterostructures. However, the role of such an interfacial layer in controlling functionalities has not been fully explored. In this talk, the influence of buried interfaces in oxide heterostructures on their magnetic properties will be discussed. A shift of the magnetization hysteresis along the applied field axis was observed. We show the loop shift is an exchange bias (as opposed to the shift of a minor loop) and is present in single phase manganite thin films. Interestingly, the sign of exchange bias is controlled by the cooling field strength. When the cooling field is small, negative exchange bias is observed while positive exchange bias was observed for cooling fields exceeding a threshold. The origin of such an exchange coupling is related to the pinned interfacial layer, confirmed by polarized neutron reflectometry. Our results shed new light on using oxide interfaces to design functional devices.

Interface functionality in oxide heterostructures can be controlled by strain engineering, due to the nearly degenerate ground states of competing order in these systems. A central question is which role structural reconstructions can be used to establish and control new magnetic spin textures. In general probing antiferromagnetic spin structures are difficult, and we present data on the interplay between AF spin axis of LFO and the occurrence of magnetic reconstructions at the (111)-oriented LSMO/LFO interface. To probe the spin texture of the different layers, we rely on a combination of soft x-ray spectroscopy, x-ray photoemission electron microscopy and polarized neutron reflectometry. Our results shed new light on using oxide interfaces to design functional devices.
non-trivial electronic states. Recently, both AMR and AHE have also attracted significant attention in antiferromagnetic metals and semiconductors. For example, significant AHEs in non-collinear antiferromagnets have been discovered. Another phenomenon of recent interest is the potential coupling between the orientation of the Niel vector and the topology of the electronic states in antiferromagnets with symmetry-protected Dirac and/or Weyl. Both AHE and AMR can serve as signatures of such interactions. While an elegant theoretical framework exists for the intrinsic AHE and its connection to the Berry curvature of the electronic bands, AMR remains comparatively less well understood. The degenerately doped antiferromagnetic semiconductor EuTiO$_3$ is a unique testbed for these ideas for several reasons. Despite a small net magnetization, it exhibits an intrinsic AHE that changes sign as a function of the carrier density. We report on the symmetry of the anisotropic magnetoresistance (AMR) in doped EuTiO$_3$ films as a function of the applied magnetic field. Multiple transitions in the AMR symmetry are observed and are attributed to magnetic field induced changes in the band topology. In particular, at high fields a transition from positive to negative magnetoresistance is observed, which coincides with change from four-fold to two-fold symmetry in the AMR. This indicates a non-trivial phase transition in the electronic structure. We discuss the results in the context of Weyl points that form in the band structure of the EuTiO$_3$ as a function of magnetic fields.

4:15 PM *QN07.08.03 Quantum Transport in Magnetic Semiconductor EuTiO$_3$ Films Kei Takahashi$^{1,2}$, Kazuki Maruhashi$^3$, Tomoki Murata$^1$, Qing Y. Wang$^1$, Hiroaki Ishizuka$^1$, Mohammad S. Bahramy$^{1,1}$, Sunao Shimizu$^1$, Ryosuke Kurihara$^1$, Atsushi Miyake$^1$, Masashi Tokunaga$^1$, Naoto Nagaosa$^{4,1}$, Yoshinori Tokura$^{2,5}$ and Masashi Kawasaki$^{1,2}$. RIKEN, Wako, Japan; PRESTO, Japan Science and Technology Agency (JST), Tokyo, Japan; 3Institute of Physics, Chinese Academy of Sciences, Beijing, China; 4Institute for Solid State Physics, University of Tokyo, Kashiwa, Japan; 5Department of Applied Physics and Quantum Phase Electronics Center, The University of Tokyo, Tokyo, Japan.

Quantum properties in oxides have been well explored in correlated electron systems with rich interplay among charge-spin-orbital degrees of freedom in electrons, now extending the playground to a variety of topics such as spin-orbit, Weyl, and edge states. Research on quantum transport in high electron mobility oxides started from such conventional semiconductors as ZnO and SrTiO$_3$(STO). To extend the research further, EuTiO$_3$(ETO) is an ideal system by adding a knob of magnetic control (local 4$f^7$ moment on Eu$^{3+}$). We employ a metalorganic gas source molecular beam epitaxy (MOMBE) at very high substrate temperature that enabled us to observe quantum Hall effect in STO quantum well [1]. The mobility in ETO films has reached to 300 and 3,000 cm$^2$/Vs at 2 K, respectively, for strained and strain-free states. Those films show unique quantum properties due to crystal-field and Zeeman splittings, respectively.

In the case of strained films, we observed additional terms in the anomalous Hall effect during the magnetization process, which is not proportional to the magnetization, caused by the type II Weyl nodes in the conduction band [2]. For the strain-free films, Shubnikov–de Haas (SdH) oscillations turned out to be clearly observable at the ferromagnetic state. Our band calculation suggests that the oscillating bands, originally derived from Ti 3d orbitals, are fully spin polarized and modified by the f-d coupling between Eu 4f and Ti 3d orbitals. These new findings strongly suggest that the electron-doped ETO film with high mobility is an ideal magnetic semiconductor to explore novel magneto ‘quantum’ transport phenomena.

SESSION QN07.09: Ionic Movement in Oxide Quantum Materials
Session Chairs: Julia Mundy and Chan-Ho Yang
Thursday Morning, April 25, 2019
PCC North, 100 Level, Room 127 C

9:00 AM *QN07.09.01 Electric Field Control of Magnetism Through Proton Evolution Pu Yu. Tsinghua University, Beijing, China.

Ionic substitution during the growth forms an essential pathway to manipulate the carrier density, leading to a rich spectrum of electronic states in strongly correlated systems. To obtain a further control of the functional materials after the growth, the electrostatic charge modulation methods through dielectrics, ferroelectrics and ionic liquids have been widely employed, demonstrating great reversible tunability. However, an intrinsic limitation of these electrostatic approaches is that they are only effective for materials with thicknesses of a few nanometers, due to the short screening length of the charge carriers. Recently the electric-field induced ionic evolution demonstrates a great tunability of bulk compounds. Among the studies, the hydrogen ion (proton) attracts particular attention due to its comparatively small radius as well as easy accessibility. In this talk, we will demonstrate an efficient and reversible control of the carrier density in a series of strongly correlated oxide systems through the ionic liquid gating induced protonation. The insertion of protons electron-dopes the materials, leading to an exotic magnetic phase transition along with the increase of proton concentration. We envision that electric-field controlled protonation opens a new avenue systematically control the electric and magnetic field phase diagram in strongly correlated complex oxide systems.

9:30 AM QN07.09.02 Reversible Control of Oxygen Vacancy Ordering in 2D and 3D Lattices Using Active Strain and Voltage Pulses Lide Yao, Sampo J. Inkinen and Sebastiaan van Dijken; Aalto University, Espoo, Finland.

Oxygen defects can have a profound effect on the physical properties of transition metal oxides. In complex oxides where magnetic, ferroelectric and superconducting phases emerge from strong correlations between localized transition metal electrons, oxygen vacancies can radically alter a plurality of quantum phenomena via valance changes and structural phase transitions. The ability to control the concentration and profile of oxygen vacancies in oxide nanostructures would thus open up comprehensive prospects for new functional ionic devices.

Here, we use in situ transmission electron microscopy (TEM) to demonstrate reversible switching between uniform structural phases in epitaxial La$_2$Sr$_{1.5}$MnO$_5$ films. In our experiments, we employ a piezo-controlled probing holder to apply short voltage pulses and local strain. Simultaneous high-resolution imaging and resistance probing under zero strain reveals reproducible voltage-induced order transitions in a low-resistance perovskite phase, a high-resistance La$_2$Sr$_{1.5}$MnO$_5$ brownmillerite structure, and an intermediate-resistance perovskite-like phase [1]. Reversible horizontal migration of oxygen vacancies within the manganite film, driven by combined effects of Joule heating and bias voltage, predominantly triggers the structural and resistive phase transitions. Concurrent application of perpendicular strain and voltage pulses produces an entirely new structural phase whereby oxygen vacancies order in regular 3D rather than 2D patterns.

9:45 AM QN07.09.03 Tuning Electron Correlation in Low-Dimensional Vanadium Oxides—Implications for Multivalent-Ion Cathode Materials and Next-Generation Computing Materials Justin L. Andrews, Abhishek Parij and Sarbajit Banerjee; Texas A&M University, College Station, Texas, United States.

Charge ordering and the localization of electrons in periodic wells is an intrinsic property of extended solids. Synthetic approaches that allow for precise control over the property are greatly desirable; however, systematically modulating periodic electron localization with some measure of tunability of the electron migration barriers represents a difficult challenge. The wider energy dispersion of bands when directly compared to discrete molecular orbitals in single molecules typically favors far greater delocalization of electrons and the multiplicity of sites implies that dimensional confinement of carriers can be established only for low-dimensional crystallographic motifs. One promising approach to modifying carrier density is by varying the electronic coupling across adjacent metal sites, but such attempts often result in phase transitions to entirely different crystal structures. Given the complexity of the problem, the chosen chemical system should exhibit electronic behavior spanning extremes between highly correlated and itinerant. Vanadium oxides represent such a system due to availability of multiple accessible redox states and an unequalled variety of structural motifs that can accommodate the intercalation of ions spanning the breadth of periodic table to create a diverse set of ‘bronzes’ with the stoichiometry M$_x$V$_y$O$_z$. Finally, vanadium has narrow V 3d-bands and the resulting oxides tend to crystallize in low dimensional motifs which surprisingly have the ability to avoid collapse upon topochemical transformations. Successfully achieving precise control over the
strength of electron correlation in this system has significant implications for the design of materials in disparate fields. Two such examples include the design of multivalent ion cathode materials and the design of materials that exhibit controllable and reversible electronic instabilities.

As a first example, charge localization in battery cathode materials represents a significant obstacle. In fact, coupling of a highly localized electron to a phonon mode hinders diffusion of the donated electrons through the vanadium oxide framework and must be addressed through chemical modification of the cathode material. Although moving beyond Li\textsuperscript{+} to Mg\textsuperscript{2+} and other divergent species presents the holy grail of sustainable battery technology, charge localization for the doubly-polarizing divalent ions becomes a significant problem, with only a small number of materials capable of this difficult feat. An alternative approach to mitigate the self-trapping of polarons is to utilize metastable phase space to design vanadium oxide frameworks that mitigate charge localization in $\alpha$-V$_2$O$_3$. We have recently shown that metastable phases ($\gamma$-V$_2$O$_3$ and $\gamma'\text{-}V_2$O$_3$) introduce frustrated coordination environments which facilitate cation diffusion and mitigate charge localization, enabling the reversible intercalation of Mg\textsuperscript{2+} and Ca\textsuperscript{2+}, respectively.

As a second example, one solution to the breakdown in Dennard scaling between transistor size and power density is to replace the traditional metal-oxide-semiconductor field-effect transistors (MOSFET) with novel computing architectures that exploit complex two-dimensional superconducting systems. Highly correlated materials which exhibit superconductivity at the precursors of an electronic transition are of interest because they can switch internal resistance values (often from metallic to insulating) rapidly upon external perturbation of the system; however, tailoring the temperature or gate-voltage threshold of these electronic transitions is critical. Modulation of this threshold and its magnitude requires precise control over charge localization and electron diffusion barrier to promote electronic transitions. We have recently reported examples of method for tuning electron correlation in M$_x$V$_2$O$_5$ bronzes with electronic instabilities through dimension reduction, interlayer separation, and stoichiometry.

SESSION QN07.10: Exotic Superconductivity
Session Chairs: Manuel Bibes, Hiroshi Kohno and Jobu Matsuno
Thursday Morning, April 25, 2019
PCC North, 100 Level, Room 127 C

10:30 AM *QN07.10.01
Demystifying the Growth of Superconducting Sr$_2$RuO$_4$ Thin Films
Hari P. Nair; Cornell University, Ithaca, New York, United States.

Sr$_2$RuO$_4$ is an unconventional superconductor with potentially a spin-triplet, odd-parity superconducting ground state. There are many reports of high purity single crystals of Sr$_2$RuO$_4$ with $T_c$ up to 1.5 K. Furthermore, recent studies on Sr$_2$RuO$_4$ single crystals have shown that the $T_c$ can be further increased up to 3.5 K using uniaxial strain. To date, however, there are only three published reports of superconducting Sr$_2$RuO$_4$ thin films and the $T_c$s achieved are significantly below 1.5 K. This relative paucity of superconducting thin films is likely due to the extreme sensitivity of the odd-parity superconducting ground state in Sr$_2$RuO$_4$ to disorder. According to recent theoretical predictions, biaxially strained epitaxial thin films with isotropic in-plane strain can potentially maintain the topologically nontrivial $p_x \pm i p_y$ superconducting ground state while simultaneously enhancing $T_c$ by tuning the Fermi level towards a van Hove singularity. Thin films also provide a pathway for scalability, which is critical for potential practical applications of spin-triplet superconductors such as qubits for ground-state quantum computing. Here, we outline and demonstrate a thermodynamic growth window to achieve repeatable growth of superconducting Sr$_2$RuO$_4$ with higher $T_c$ than all prior thin films using molecular-beam epitaxy. We will also present some preliminary evidence of epitaxial strain-induced tuning of $T_c$.  

11:00 AM QN07.10.02
Metal-Insulator Transition in High Transition Temperature Superconductor Josephson Junction Barriers
Ethan Cho, Hao Li, Yan Ting Wang and Shane Cybart; University of California, Riverside, Riverside, California, United States.

We will present a study of Josephson junctions created with direct-write focused helium ion irradiation. Josephson devices were created by irradiating a narrow channel across a superconducting electrode with a focused helium ion beam. We studied how the irradiation dose affected the electrical transport properties such as critical current and voltage state resistance. For lower doses of irradiation, the critical current rapidly increased with decreasing temperature consistent with a metallic barrier junction. Whereas for higher doses the critical current approaches a maximum value like that seen in conventional insulating barrier Josephson junctions. Furthermore, we observed a continuous transition from metallic to an insulating behavior in the voltage state resistance with increasing dose. This transition can be modeled with a single parameter related to barrier strength which is directly proportional to the irradiation dose.

11:15 AM QN07.10.03
Synthesis and Electronic Configuration of Infinite-Layer Nickelate Thin Films
Danfeng Li\textsuperscript{1,2}, Matthias Hepping\textsuperscript{1,2}, Haiyu Lu\textsuperscript{3}, Xiao Feng\textsuperscript{3}, Yasuyuki Hikita\textsuperscript{4}, Chunjing Jia\textsuperscript{1,2}, Brian Moritz\textsuperscript{2}, Eugenio Paris\textsuperscript{5}, Yi Tieng\textsuperscript{1}, Zahid Hussain\textsuperscript{6}, Yi-De Chuang\textsuperscript{6}, Zhi-Xun Shen\textsuperscript{1,2}, Thorsten Schmitt\textsuperscript{1}, Thomas P. Devereaux\textsuperscript{1,2}, Wei-Sheng Lee\textsuperscript{6} and Harold Wang\textsuperscript{1,2}; Geballe Laboratory for Advanced Materials, Stanford University, Stanford, California, United States; Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory, Menlo Park, California, United States; Paul Scherrer Institut, Villigen, Switzerland; Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; SSRL, SLAC National Accelerator Laboratory, Menlo Park, California, United States.

In the quest for analogs to high-$T_c$ cuprates, nickelates stand out as a promising candidate and have received considerable research interest, due to their electronic structure potentially being in proximity to that of the cuprates. The strategy is therefore to engineer the electronic structure of nickelates to resemble the key ingredients of cuprates, such as a half-filled single band near the Fermi level, antiferromagnetic correlations in the undoped parent compound (S\textsuperscript{=})\textsuperscript{1/2}, and hybridization between $d_{x^2-y^2}$ and $e_g$ orbitals and oxygen ligands. Here, we present the synthesis of an infinite-layer nickelate (LaNiO$_2$) thin film, where the Ni ions have square planar coordination with O in quasi-2D NiO$_2$ planes [1], using a low temperature metal hydride reduction process [2]. We study its electronic structure, in comparison with that of an isostructural cuprate (SrCuO$_2$) thin film, by using x-ray absorption spectroscopy (XAS) and resonant inelastic x-ray scattering (RIXS) at the O K- and Ni L-edges.

11:30 AM QN07.10.04
Coexistence and Competition Between Ferromagnetism, Rashba Spin-Orbit Coupling and Superconductivity in Oxide 2DES
Daniele Storza\textsuperscript{1,2}, Benoit Jourault\textsuperscript{1,2}, Emiliano Di Gennaro\textsuperscript{1,2}, Roberto Di Capua\textsuperscript{1,2}, Alessia Sambri\textsuperscript{1,2}, Davide Massarotti\textsuperscript{1,2}, Maria D'Astuauno\textsuperscript{1}, Fabio Miletto Granozio\textsuperscript{1}, Francesco Tatone\textsuperscript{1,2} and Marco Salluzzo\textsuperscript{1}; University of Naples Federico II, Napoli, Italy; SPIN, CNR, Naples, Italy; Laboratoire Charles Coulomb, UMR 5221, CNRS, Université Montpellier 2, F-34095, Montpellier, France.

Two dimensional electron systems (2DES) formed at the interface between insulating transition metal oxides have demonstrated an extraordinary range of properties. The coexistence among these properties can be studied via electric field effect, making oxide 2DES an ideal test bench for the investigation of novel quantum phenomena. A notable example is the coexistence between superconductivity and Rashba spin-orbit coupling in the 2DES at the interface between LaAlO$_3$ and SrTiO$_3$ (LATO/STO). We will review the recent remarkable progress in understanding complex LAO/STO superconducting nanodevices [1], which can shed some light on the nature of superconductivity in LAO/STO, and focus on indications of the presence of an unconventional superconducting order parameter obtained in LAO/STO based Josephson junctions [2]. The large and electric field tunable Rashba spin-orbit coupling shown by the LAO/STO 2DES is also of interest for possible spintronic applications [3]. A viable route for electric field control of the spin transport in spintronic devices requires, however, the creation of a spin polarized current. We will present the transport properties of a spin polarized oxide 2DES realized using a thin layer of delta doping EuTiO$_3$ (ETO) intercalated between LAO and STO [4] and demonstrate how ferromagnetism and Rashba spin-orbit coupling in this heterostructure can be controlled via electric field effect and temperature [5].
Berry Phase Engineering at Oxide Interfaces  
Andrea Cavigliala  
Kavli Institute of Nanoscience, TU Delft, Delft, Netherlands.

Geometric phases in condensed matter play a central role in topological transport phenomena such as the quantum, spin and anomalous Hall effect (AHE). In contrast to the quantum Hall effect—which is characterized by a topological invariant and robust against perturbations—the AHE depends on the Berry curvature of occupied bands at the Fermi level and is therefore highly sensitive to subtle changes in the band structure. A unique platform for its manipulation is provided by transition metal oxide heterostructures, where engineering of emergent electrodynamics becomes possible at atomically sharp interfaces. We demonstrate that the Berry curvature and its corresponding vector potential can be manipulated by interface engineering of the correlated itinerant ferromagnet SrRuO3 (SRO). Measurements of the AHE reveal the presence of two interface-tunable spin-polarized conduction channels. Using theoretical calculations, we show that the tunability of the AHE at SRO interfaces arises from the competition between two topologically non-trivial bands. Our results demonstrate how reconstructions at oxide interfaces can be used to control emergent electrodynamics on a nanometer-scale, opening new routes towards spintronics and topological electronics.

2:15 PM  QN07.11.02  
Exotic Magnetic Interlayer Coupling in Atomically Designed SrRuO3/SrTiO3 Superlattices  
Seung Gyo Jeong1, Sungmin Woo1, Jiwon Kim1, Youngmin Kim1,2, Sungkyun Park1, Hu Young Jeong1 and Woo Seok Choi1; 1Department of Physics, Sungkyunkwan University, Suwon, Korea (the Republic of); 2Center for Integrated Nanostructure Physics, Institute for Basic Science, Suwon, Korea (the Republic of); 3Department of Physics, Pusan National University, Pusan, Korea (the Republic of); 4UNIST Central Research Facilities and School of Materials Science and Engineering, Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Magnetic properties of perovskite SrRuO3 (SRO, a ferromagnetic metal) epitaxial thin films are strongly affected by the Ru-O bonding geometry, electronic structure, and dimensionality. Therefore, atomically precise oxide superlattices composed of SRO and SrTiO3 (STO, a nonmagnetic insulator) is an attractive model system to modulate and study the complex magnetic interaction. Various magnetic phenomena such as interlayer exchange coupling, quantum confinement, and spin-lattice coupling near the oxide interfaces can be investigated. In this presentation, we precisely and systematically control the number of atomic unit cell layers of SRO and STO in atomically designed SRO/STO superlattices. By controlling both the thicknesses of SRO and STO layers using pulsed laser epitaxy, we first demonstrate the structure-dependent magnetization of the artificial crystal. A strong correlation between the lattice symmetry (or Ru-O bonding geometry) and ferromagnetic ordering could be realized. In addition, we observed exotic magnetic interlayer exchange coupling between the ferromagnetic SRO layers across the insulating STO layer. Possible mechanisms for the unprecedented magnetic ground state behavior are suggested and discussed.

2:30 PM  QN07.11.03  
Margaret Mc Cartner1, Sujit Das2, Yun-Lang Tang3, Christoph Klewe2, Padraic Shafer4, Elke Arenholz2, Javier Junquera1, Lane W. Martin2 and Ramamoorthy Ramesh1; 1Department of Physics, University of California, Berkeley, Berkeley, California, United States; 2Department of Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 3Materials Science Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 4Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 5Departmento de Ciencias de la Tierra y Fisica de la Materia Condensada, Universidad de Cantabria, Cantabria, Spain.

Emergent topologies in ferroelectric heterostructures—the polar analogs of magnetic vortices and skyrmions—have become a recent topic of interest for their potential to host exotic functionalities (e.g., emergent chirality and negative capacitance). These topologies can be stabilized in low-dimensional ferroelectrics. Superlattices of PbTiO3/SrTiO3 have proven to be particularly fruitful in this area; for example, the existence of polar vortex structures in such superlattices grown on DyScO3 substrates has been demonstrated. Furthermore, polar skyrmion structures have been observed in PbTiO3/SrTiO3 superlattices grown on SrTiO3 substrates using a combination of scanning transmission electron microscopy, X-ray diffraction, and second-principles calculations. Using resonant soft X-ray diffraction, we study the chirality of these polar skyrmions and show that the skyrmions have a preferred handedness. The origin of the circular dichroism is shown to be a chiral configuration of the titanium orbitals in the skyrmions.
Understanding and manipulating oxygen octahedral rotations have been subjects of much recent interest, and particular octahedral rotations are now parameters used in the design of new perovskite materials and heterostructures. As examples, modifications to the Ni-O-Ni bond angle in the nickelates have a profound effect on the temperature of metal–insulator transition, and changes to the octahedral rotation angles in the manganeseates promote different types of antiferromagnetic order. Although ferroelectricity is not conventionally related to oxygen octahedra, it has been predicted that geometrically modulated octahedral rotations can induce ferroelectric behavior, which is promising for the design of cross-coupled multiferroics. Control over the oxygen octahedral framework is widely recognized as key to the design of functional properties in perovskite oxide heterostructures. Although the oxygen octahedral framework can be manipulated during synthesis, the as-grown oxygen octahedra generally remain fixed, preventing the development of adaptive behavior in electronic and ionotonic systems. Theoretical calculations have shown that the coupling between oxygen octahedra and an external electric field is typically very weak if present at all, due to the geometrical centricity of octahedra. Therefore, it is considered extremely challenging to dynamically tune octahedral rotation by electric field.

In this talk, we will demonstrate that oxygen octahedral rotations can be dynamically and reversibly manipulated by an electric field when in the presence of defects, leading to significant changes in the electronic properties of a perovskite oxide during linear lattice distortion. Employing in situ synchrotron X-ray techniques to investigate heterostructures of the simple perovskite WO$_3$, we find that while application of a negative voltage leads to only subtle changes in structure and electronic properties, positive voltages have a dramatic effect on the oxygen octahedral rotation due to defect injection. The process is fully reversible, with the material returning to its original state after the gate voltage is removed. The results of density functional theory show that some octahedral rotation angles depend more strongly on the oxygen vacancy concentration than others and that both rotations and defects alter the electronic structure. Ionic liquid gating not only allows switchable defect structure and behavior by an electric field, but also provides a means of attaining the dynamic manipulation of octahedral rotations and the associated correlated properties. Such tunable properties can be used to establish nonequilibrium rotation patterns not available by static methods and facilitate the development of low-power electronics. Our results illustrate a highly effective approach for dynamically tuning the oxygen octahedral rotation in perovskite heterostructures for applications in oxide electronics and ionotronics.

3:45 PM QN07.12.03

Atomic Dynamics in VO$_2$: Across the Metal-Insulator Transition—Ultrafast Transition and Equilibrium Thermodynamics Olivier Delaire, Simon Wall, Shan Yang, Luciana Vidas, Matthieu Chollet, Michael Glownia, Michael Koziwa, Tetsuo Katayama, Thomas Henighan, Mason Jiang, Timothy Miller, David Reis, Lynn Boatner, and Mariano Trigo; 1Duke University, Durham, North Carolina, United States; 2ICFO–The Institute of Photonic Sciences, Barcelona, Spain; 3SLAC National Accelerator Laboratory, Menlo Park, California, United States; 4Japan Synchrotron Radiation Research Institute, Sayo-Gun, Japan; 5Stanford University, Palo Alto, California, United States; 6Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Vanadium dioxide (VO$_2$) can be switched from an insulating to a metallic state with either ultrafast laser pulses [1] or heating above $T_{MT}$=340K [2,3]. In both the photoexcited and thermal transitions, the insulator-to-metal transition (IMT) is accompanied by a structural change from a monoclinic (M1) to a rutile (R) structure, and numerous prior efforts have focused on elucidating the evolution of both the electronic and lattice degrees of freedom. The photoexcited transition occurs in a time scale of hundred femtoseconds, and while ultrafast X-ray diffraction has provided tremendous insight into the atomic dynamics during such ultrafast transformations, diffraction peaks alone probe only an average over multiple unit cells and are less sensitive to deviations from the average atomic path connecting the initial and final state. To overcome this limitation, we use femtosecond total x-ray scattering (diffuse and Bragg) from the LCLS x-ray free-electron laser to study the dynamics of the structural transition of bulk VO$_2$ at all length-scales [1]. We observe that the structural transition proceeds by uncorrelated disordering of the vanadium ions from their initial dimerized distribution [1], rather than the previously proposed synchronized motion along an optical phonon mode. After photoexcitation, the system explores a large volume of the available phase-space in a timescale comparable with a single phonon oscillation [1,2]. Our ab-initio molecular dynamics simulation quantitatively match our ultrafast x-ray scattering measurements, and show an unusual highly anharmonic, flat potential energy surface for the quasi-rutile structure in the photoexcited state, developing on femtosecond timescales and disrupting the vanadium dimers of the M1 phase by populating a continuum of modes. The rapid evolution after photoexcitation is enabled by the large phase space of phonon modes with low-frequency $\nu$-vibrations, which was also noted in [2] to yield a large phonon entropy gain stabilizing the rutile phase, and the strong damping of phonons in the rutile phase. Our current observations thus reveal an interesting parallel between the ultrafast and the thermal transitions. These results overture our current understanding of an archetypical ultrafast phase transition and provide new microscopic insights into rapid evolution toward equilibrium in photoexcited matter.

4:00 PM QN07.12.04

Ultrafast Control of Material Properties Through Non-linear Lattice Dynamics from First Principles Guru Khalsa and Nicole A. Benedek; Cornell University, Ithaca, New York, United States.

The development of intense ultrashort mid and far infrared laser sources has created an opportunity for functional materials based on the direct excitation of infrared active phonons. Strong excitation of infrared active phonons can produce sizable unidirectional distortions of crystal structure through non-linear coupling to other phonons. Complex oxide ceramics provide an important test-ground for this experimental approach due to their diversity, strong coupling to optical fields, and demonstrated connection between subtle structural changes and functional properties.

Our recent theoretical efforts in perovskite oxides explore selective control of functional properties that exploit nonlinear lattice dynamics induced by the excitation of infrared phonons. Using first-principles techniques we predict that ultrafast optical control of magnetism is experimentally accessible in rare-earth titanates and show that, when combined with strain, this optical technique exposes a magnetic phase inaccessible in the equilibrium phase diagram.

4:15 PM QN07.12.05

Field Induced Phases of the XY Pyrochlore Er$_3$Sn$_2$O$_7$: Danielle Yahnle, Ludovic Jaubert, Michel Gingras, Darren Pereira, Duminda Sanjeewa, Joseph Kolis and Kate Ross; 1Colorado State University, Fort Collins, Colorado, United States; 2University of Bordeaux, Bordeaux, France; 3University of Waterloo, Waterloo, Ontario, Canada; 4Clemson University, Clemson, South Carolina, United States; 5Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Er$_3$Sn$_2$O$_7$ has been proposed as an example of the dipolar XY antiferromagnetic (AFM) pyrochlore. This system is theorized to undergo a first order phase transition to an ordered phase known as the Palmer-Chalker (PC) phase. The behavior of Er$_3$Sn$_2$O$_7$ has been found to be somewhat enigmatic, however, with neutron scattering measurements revealing the emergence of the PC state at a lower temperature than predicted, via an apparently second order transition. In addition, slow dynamics have been observed throughout the low temperature regime, including within the PC state. These deviations from theoretical expectations have been attributed to quantum fluctuations resulting from a competition between classical ordered eigenstates. We report on field dependent specific heat measurements on Er$_3$Sn$_2$O$_7$. In zero field, we find a slightly higher phase transition temperature than previously reported. In finite field, we find a reentrant phase diagram that compares well quantitatively with classical Monte Carlo simulations only in the high field region of the phase diagram. This provides further evidence of strong quantum fluctuations in Er$_3$Sn$_2$O$_7$ in low fields, suggesting its proximity to a quantum disordered regime.
Colloidal Nanoparticles—From Synthesis to Applications

SESSION QN08.01: Nanoparticle Synthesis and Applications I
Session Chairs: Mei Cai and Hongyou Fan
Monday Morning, April 22, 2019
PCC North, 100 Level, Room 129 B

8:30 AM *QN08.01.01
Growth and Transformation of Colloidal Nanostructures in Confined Spaces Yadong Yin; University of California, Riverside, Riverside, California, United States.

Colloidal nanostructures have been studied quite extensively in the research area of heterogeneous catalysis long before the introduction of the concept of nanoscience and nanotechnology. The significant progress achieved in the past twenty years in chemical synthesis has enabled precise control over not only the size but also the shape of the metal nanostructures, and therefore attracted intense interest not only in catalysis but also optoelectronics due to the well-known effect of localized surface plasmon resonance. In this presentation, I will introduce our recent progress in the synthesis of colloidal metal nanostructures in confined spaces using various templating methods, their chemical transformation behavior, and further manipulation of their secondary structures. By combining the confinement of templates with the seed-mediated growth strategy, we demonstrate the significant advantages of this general method over the conventional ones in creating a large variety of nanomaterials with novel plasmonic properties.

9:00 AM *QN08.01.02
On the Prenucleation Stage of Colloidal Semiconductor Quantum Dots Kui Yu; Sichuan University, Chengdu, China.

A worldwide interest during the past thirty years has been witnessed in the development of colloidal semiconductor nanocrystals (NCs). With significant efforts on the control of the size and size distribution, NC synthesis has been performed as an empirical art, lacking of fundamental understanding of the pre-nucleation stage also called the induction period. Colloidal semiconductor quantum dots (QDs) and magic sized clusters (MSCs) have been observed to evolve in a reaction together, sometimes. In this presentation, I will present our systematic study on their formation pathways. Based on our experimental data, we propose that there are two individual pathways in the prenucleation stage of the formation of QDs. The LaMer model of the classical nucleation theory (CNT) describes one pathway and the self-assembly of the cation and anion precursors is the other pathway which results in the formation of MSCs. We believe that our exploration of the prenucleation stage moves one step forward towards mechanism-enabled design and synthesis of NCs.

9:30 AM *QN08.01.03
Ultrafast Photophysics Dynamics In Situ Quantum Dot Devices Jianbo Gao; Clemson University, Clemson, South Carolina, United States.

Quantum dot devices have wide applications in photovoltaics, optoelectronics, and sensors due to quantum dot unique quantum confinement effect, which can be tailored by size, shape, structure, and composition. Therefore, the ultrafast photophysics dynamics of charge carrier in situ devices (electrons, holes, or ions) including carrier transport, injection through optical or electrical, recombination, trapping, and transfer is one of the most fundamental questions.

We developed ultrafast photocurrent spectroscopy and ultrafast electroluminescence spectroscopy to address the ultrafast carrier dynamics in situ devices including solar cells, single-photon detectors, light emitting diodes, and photodetectors. In addition to that we understand ultrafast carrier transport and recombination dynamics, we discover novel photoconductivity phenomena, which cannot be addressed by other laser pump-probe spectroscopies.

10:00 AM BREAK

10:30 AM *QN08.01.04
Whole Cell Pathogen and Small Molecule Analytical Detection with Aptamer-Functionalized Particles Susana Diaz-Amaya1, Li-Kai Lin1, Amanda Deering2 and Lin Shang1; 1School of Materials Engineering, Neil Armstrong Hall of Engineering, Purdue University, West Lafayette, Indiana, United States; 2Department of Food Science, Philip E. Nelson Hall of Food Science, Purdue University, West Lafayette, Indiana, United States.

Infectious outbreaks caused by foodborne pathogens such as E. coli O157:H7 are still occurring worldwide and cause acute illnesses and significant industrial impact. As a chemical component of organic materials, bisphenol A (BPA) is used in the food and consumer products industries. Despite its benefits, low-dose exposure to BPA adversely affects human health because it is an endocrine disrupting chemical (EDC). We present on the feasibility of using aptameric DNA sequences, covalently conjugated to colloidal nanoparticles, for the sensitive and highly specific detection of whole cell pathogens and small molecule toxic molecules via surface enhanced Raman spectroscopy (SERS) analysis. Low concentrations of E. coli O157:H7 were detected (~10^4 CFU/mL) and quantified (~10^3 CFU/mL) within 20 minutes in both pure culture and ground beef samples. We also report on a new range-extended bisphenol A (BPA) detection method that includes high-SERS-performance gold nanoparticles, i.e., 40 nm gold nanostars (GNSs) and 4-aminothiophenol (4-ATP) as Raman reporters. The limit of detection for BPA was 0.073 ppb, which is 205 and 20 times more sensitive than those of visual intensity and color intensity quantifications, respectively.

11:00 AM QN08.01.05
Stoichiometric Preparations of Iron Oleate to Improve the Reproducibility of Iron Oxide Nanoparticle Syntheses Dale L. Huber1, Sergei A. Ivanov2, Erika Vreeland1 and John Watt1; 1Sandia National Laboratories, Albuquerque, New Mexico, United States; 2Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 3IR Dynamics, Albuquerque, New Mexico, United States.
Iron Oleate has long been one of the most popular precursors for the synthesis of high-quality iron oxide nanoparticles. This is true despite the fact that it is not commercially available and must be custom synthesized. There are a handful of related syntheses that are in common use, but reproducibility of the synthesis is a significant concern. Iron oleate does not readily form a simple complex with one iron atom bonded to three oleate ligands as one might imagine. Instead, iron oleate often exists as a complex mixture of species that includes a series of oligomeric species with iron atoms bonded to each other through oxo bridges as well as other structure. This non-stoichiometric mixture is not easily purified as iron oleate resists the most common purification approaches. Iron oleate can not be recrystallized, as it does not crystallize and instead forms an oil or glass depending upon its temperature. Washing approaches are difficult to reproduce as the oleate ligands can be very labile, and repeated washes will continue to remove oleate ligands until it finally forms an insoluble solid. This lack of control also makes it difficult to purify the compound through chromatography as the compound can decompose on the column. Unfortunately, differences in the precursor synthesis can lead to difficulty in reproducing nanoparticle syntheses. We will discuss two approaches that have been demonstrated to yield highly reproducible iron oleate precursors. In the first approach, we produce iron oleate through the decomposition of another organometallic species in an excess of oleic acid yielding a solution of known stoichiometry that can be used without purification. In the second approach, judicious selection of reagents, solvents, and reaction conditions can yield an isolated compound of pure iron oleate with an iron:oleate ratio of exactly 1:3. These compounds can then be used to enhance the reproducibility of iron oxide nanoparticle syntheses. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia LLC, a wholly owned subsidiary of Honeywell International Inc. for the DOE’s National Nuclear Security Administration under contract DE-NA0003525. This paper describes objective technical results and analysis. Any subjective views or opinions that might be expressed in the paper do not necessarily represent the views of the U.S. Department of Energy or the United States government.

11:15 AM QN08.01.06 Structural Transformations of Functional Nanoparticles Zewei Quan; Chemistry, Southern University of Science and Technology, Shenzhen, China.

Novel materials with new properties are often realized by modifying their structures of existing materials without altering their composition. One of the approaches is to apply a high pressure to a material. In this part, I will show how to take advantage of another scaling law - nanoparticles as single structural domains to investigate PbTe nanoparticles by high-pressure method. Reversal of Hall-Petch effect concerning the structural stability to particle size was first reported on PbTe nanoparticles. Based on this novel observation, the pressure-dependent amorphizations on 5 nm PbTe nanoparticles was further utilized to harvest the metastable amorphous PbTe nanoparticles of great technological applications. Then, I will also talk about how to use pressure to engineer the bandgap of photovoltaic perovskites. Finally, the phase engineering of metastable Au nanostructures is also delicately achieved and the atomic transition path is revealed.

11:30 AM QN08.01.07 High ON-Current Vertical Field-Effect Transistors Based on Environmentally-Benign Quantum Dots Jeongkyun Roh, Hyeong Jin Yun and Victor Klimov; Chemistry Division, Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Colloidal quantum dots (QDs) have gained considerable attention as a new class of nanomaterials that can potentially enable the next-generation solution-processible electronic and optoelectronic devices (Science 353, 85523, 2016). Owing to their superior optical properties, intense studies on QD-based color converters, light-emitting diodes (Nature 515, 96, 2014, Nat. Photon. 12, 159, 2018) and solar cells (Nat. Nanotechnol. 13, 456, 2018) have been underway leading to successful commercialization of the QD-display technology. The next frontier is exploration of electronically coupled QD solids in the context of prospective applications in solution-processible flexible electronics toward wearable electronic and sensing systems. One existing challenge in this area is low mobility of non-toxic QDs, which limits performance characteristics of non-toxic QD-based field-effect transistors (FETs) that represent basic building blocks of electronic circuits. Low mobilities lead to low ON-currents of typical QD-FETs. Increase in the current is possible by reducing the FET channel length, however, this would require the use of expensive and non-scalable patterning methods such as e-beam lithography. Here, we demonstrate high ON-current QD FETs based on environmentally-benign QDs by employing a vertical architecture, which is a vertical stack of a gate electrode, a gate insulator, a source electrode, semiconductor transport layer, and a drain electrode. Using this approach, we reduce a channel length down to sub-nanometer scale, and as a result, achieve an unprecedented ON-current of ~0.1 A/cm² in p-type QD FETs, which is three orders of magnitude higher than in standard lateral FETs. This notably high ON-current of vertical QD FETs is demonstrated using non-toxic Zn-doped CuInSe₂; QDs (J. Am. Chem. Soc. 138, 4201, 2016) and achieved despite their low hole mobility of ~0.001 cm²/Vs. A switchable behavior of a vertical FET is enabled by the porous structure of a source electrode, which allows for the gate-controlled electric field to penetrate into a vertical channel and modulate a charge carrier density. The pattern of the source electrode is defined by optical interferometric lithography, which is a simple, fast, scalable and mask-less patterning method. To improve switching properties of the FET, a charge-blocking layer was applied to the top surface of the patterned source electrodes. This allows us to steer the charge flow in a lateral direction along the gate oxide interface, which is the channel region well-modulated by gate bias. Furthermore, we demonstrate polarity control of QD vertical FETs by employing a simple complex with one iron atom bonded to three oleate ligands as one might imagine. Instead, iron oleate often exists as a complex mixture of species that includes a series of oligomeric species with iron atoms bonded to each other through oxo bridges as well as other structure. This non-stoichiometric mixture is not easily purified as iron oleate resists the most common purification approaches. Iron oleate can not be recrystallized, as it does not crystallize and instead forms an oil or glass depending upon its temperature. Washing approaches are difficult to reproduce as the oleate ligands can be very labile, and repeated washes will continue to remove oleate ligands until it finally forms an insoluble solid. This lack of control also makes it difficult to purify the compound through chromatography as the compound can decompose on the column. Unfortunately, differences in the precursor synthesis can lead to difficulty in reproducing nanoparticle syntheses. We will discuss two approaches that have been demonstrated to yield highly reproducible iron oleate precursors. In the first approach, we produce iron oleate through the decomposition of another organometallic species in an excess of oleic acid yielding a solution of known stoichiometry that can be used without purification. In the second approach, judicious selection of reagents, solvents, and reaction conditions can yield an isolated compound of pure iron oleate with an iron:oleate ratio of exactly 1:3. These compounds can then be used to enhance the reproducibility of iron oxide nanoparticle syntheses. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia LLC, a wholly owned subsidiary of Honeywell International Inc. for the DOE’s National Nuclear Security Administration under contract DE-NA0003525. This paper describes objective technical results and analysis. 11:45 AM QN08.01.08 The Importance of ‘Beneficial Impurities’ in Surfactant Assisted Synthesis of Colloidal Nanoparticles Yuval Golan; Department of Materials Engineering, Ben Gurion University of the Negev, Beer Sheva, Israel.

While surfactant assisted synthesis is probably the most common technique for the preparation of colloidal nanoparticles, workers in the field often encounter severe irreproducibility issues. In this talk, we will present several examples, from our work [1,2], as well as by others [3-5], for the role of ‘beneficial impurities’ in nanoparticle synthesis. Furthermore, a new binary phase of cubic nanocrystalline semiconductors has been discovered in recent years in the form of colloidal nanoparticles. The first materials to be discovered were π tin mono-sulfide [6,7] and π tin mono-selenide [8], yet density functional theory calculations predict the existence of additional potentially useful compound semiconductors in the π structure. [9] There is growing experimental evidence that phase control in the tin mono-chalcogenide system is likely to be governed by ‘beneficial impurities’ as well.

Fabrication of Arrays of Highly Complex Noble Metal Nanostructures Using Nanoimprint Lithography in Combination with Liquid-Phase Epitaxy

Svetlana Neretina, Robert Hughes, Spencer Golze, Arin Preston and Trevor Demille; University of Notre Dame, Notre Dame, Indiana, United States.

Current best-practice lithographic techniques are unable to meet the functional requirements needed to enable on-chip plasmonic devices capable of fully exploiting nanostructure properties reliant on a tailored nanostucture size, composition, architecture, crystallinity, and placement. As a consequence, numerous nanofabrication methods have emerged that address various weaknesses, but none have, as of yet, demonstrated a large-area processing route capable of defining organized surfaces of nanostructures with the architectural diversity and complexity that is routinely displayed in colloidal syntheses. Here, a hybrid fabrication strategy is demonstrated in which nanoimprint lithography is combined with templated dewetting and liquid-phase syntheses that is able to realize periodic arrays of complex noble metal nanostructures over square centimeter areas. The process is inexpensive, can be carried out on a benchtop, and requires modest levels of instrumentation. Demonstrated are three fabrication schemes yielding arrays of core–shell, core–void–shell, and core–void–nanoframe structures using liquid-phase syntheses involving heteroepitaxial deposition, galvanic replacement, and dealloying. With the field of nanotechnology being increasingly reliant on the engineering of desirable physicochemical responses through architectural control, the fabrication strategy provides a platform for advancing devices reliant on addressable arrays or the collective response from an ensemble of identical nanostructures.

2:00 PM *QN08.02.02 Si Microparticle Based Electrode for Effective Stress Relaxation and Stable Electrochemical Cycling Donghyuk Kim1, Minkyu Park1, Hyunghchoul Shin2, Seungmin Hyun3 and Seung Min Han1; 1Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Korea Institute of Machinery and Materials, Daejeon, Korea (the Republic of).

Si anode of a lithium ion battery undergoes extreme volume expansions during lithiation and delithiation cycles. Finite element analysis indicates that significant build-up of lithiation-induced stresses can develop that results in fracture of the Si anode material. In this study, we report two different designs for Si microparticle based composite anode that allows for relaxation of the diffusion induced stresses in the Si microparticles. Self-healing polymer and Si microparticle freestanding composites was proposed and analyzed for its cyclic stability that confirmed enhanced retention, with the freestanding composite demonstrating 91.8% capacity retention after 100 cycles at C/10 rate. Second design for the composite anode uses Si microparticles that are embedded in combustion reacted, nanoporous ZnO. The nanoporous ZnO was shown to in itself undergo conversion reaction that hence increased the capacity and was able to help the coalescence of SiMPs for enhanced electrochemical cycling, which yielded a binder-less design with an initial capacity of ~3,900 mAh/g at C/20 rate and a reversible capacity of ~1,500 mAh/g beyond 200 cycles at C/5 rate. In addition, the Li2O/ZnO matrix derived from conversion-reacted nanoporous ZnO acted as an effective buffer to lithiation-induced stresses from volume expansion and served as a binder-like matrix that contributed to the overall electrode capacity and stability.

2:30 PM *QN08.02.03 Hybrid Metal–Inorganic Nanoparticle—Core–Shell Dendrimers and Star Copolymers Rigoberto C. Advincula1; Case Western Reserve University, Cleveland, Ohio, United States.

The preparation of new nanomaterials requires hierarchical levels of ordering and structuring: from molecular to macroscopic. Much has been demonstrated in metal, metal oxide, inorganic nanoparticles by way of size, shape, and polydispersity control. The Plasmonic and emissive properties dependent on size, shape, and hot spots are well known. Dendrimers and other hyperbranched polymer systems are of interest for their functionality in catalysis, drug delivery, reactivity, etc. Of high interest are dendrimer functionality in electro-optical applications and nanomedicine. This includes dendrimers capable of hierarchical ordered and self-assembly. We highlight the convergence synthesis of a variety of hybrid nanoparticle dendrimers and their electropolymerizability. The synthesis of precise dendrons as modular building blocks for functional dendrimers and the use of star copolymers for various core-shell architectures are demonstrated. Our group has reported a number of these hybrid systems and have reported the step-by-step routes towards structure-property relationships. These has resulted in controlled charge -transfer and energy transfer properties not to mention the ability to provide greater stability for these nanoparticles. What is also important is the use of surface sensitive spectroscopic and microscopic analytical tools applied rationally to highlight evidence of order and function.

3:00 PM BREAK

3:30 PM *QN08.02.04 Design Nanostructured Si materials for Practical Anodes of Next Generation Li-Ion Batteries Xiaolin Li, Haiping Jia and Ji-Guang Zhang; Pacific Northwest National Laboratory, Richland, Washington, United States.

Nanostructured materials have been found to be critical in promoting the performance of energy storage and conversion devices, such as batteries. Here, several nanostructured Si materials have been designed for practical anodes of high energy Li-ion batteries (LIBs). In one effort, the large (~20 μm) mesoporous Si sponge have controlled porosity and pore size, which can limit the particle volume expansion at full lithiation to ~30% and prevent pulverization of bulk particles. The porous Si anodes deliver a specific capacity of up to ~750 mAh/g based on the total electrode weight and >80% capacity retention over 1,000 cycles. The electrodes with the loading of ~1.5 mAh/cm2 demonstrated ~92% capacity retention over 300 cycles. The composite electrodes of porous Si and graphite (~3 mAh/cm2 loading) with a specific capacity of ~650 mAh/g demonstrate ~82% capacity retention over 450 cycles. In another effort, hierarchical structured Si/CNT microspheres developed not only have good porous structure to accommodate the volume expansion and achieve ~30% apparent particle swell at full lithiation, but also demonstrate good mechanical integrity with the structure sustained up to ~200 MPa pressure. The anodes deliver a high specific capacity of ~1500 mAh/g and 85% capacity retention over 200 cycles at the areal loading of ~3 mAh/cm2.

4:00 PM QN08.02.05 Light Activated Synthesis of Periodic Arrays of Metallic Nanoplates Robert Hughes, Svetlana Neretina, Spencer Golze and Sergei Rouvimov; University of Notre Dame, Notre Dame, Indiana, United States.

Our laboratory has developed a new synthetic procedure for generating periodic arrays of metallic nanostructures shaped as hexagonal or triangular nanoplates using a room temperature light-activated growth mode. Such structures have the potential to act as interactive components for the detection of biological and chemical analytes using various sensing modalities (e.g., Surface Enhanced Raman Scattering (SERS)). The synthesis is reliant on the formation of Au seeds exhibiting planar defects – without such defects the growth mode is deactivated. Through the engineering of defects, which have been extensively studied using Titan TEM imaging and electron diffraction, such structures have now and achieve ~30% apparent particle swell at full lithiation, but also demonstrate good mechanical integrity with the structure sustained up to ~200 MPa pressure. The anodes with the loading of ~1.5 mAh/cm2 demonstrated ~92% capacity retention over 1,000 cycles. The electrodes with the loading of ~1.5 mAh/cm2 demonstrated ~92% capacity retention over 300 cycles. The composite electrodes of porous Si and graphite (~3 mAh/cm2 loading) with a specific capacity of ~650 mAh/g demonstrate ~82% capacity retention over 450 cycles. In another effort, hierarchical structured Si/CNT microspheres developed not only have good porous structure to accommodate the volume expansion and achieve ~30% apparent particle swell at full lithiation, but also demonstrate good mechanical integrity with the structure sustained up to ~200 MPa pressure. 4:15 PM QN08.02.06 Metal Amidinate Precursors for General Solution-Phase Synthesis of Intermetallic Nanocrystals Andrew J. McGrath1, Filip Ronning and Sergei A. Ivanov; Los Alamos National Laboratory, Albuquerque, New Mexico, United States.

Nanocrystalline intermetallic compounds show promise in several applications, however chemical methods giving phase purity and size control are lacking. Using metal precursors previously developed for atomic layer deposition but rarely explored for solution-phase materials synthesis, we demonstrate the synthesis of several phase-pure transition metal alloys including the full library of MSn; and MSb (M = Cr, Mn, Fe, Co, Ni) with control over phase and stoichiometry, several of which are reported for the first time in nanocrystalline form. For stannides, the synthesis of which occurs above the melting point of Sn, the alloys formation progresses via an intermediate stage of small Sn nanocrystals stabilized by the strongly-binding amidinate ligands with subsequent diffusion of transition metal atoms into tin. We find that for metals with higher melting temperatures than Sn (such as Sb), the reductant injection temperature determines the phase purity of the intermetallic product. Temperature-dependent magnetic properties of the intermetallic nanocrystals have been studied, and the effect of annealing the nanocrystals at high temperatures on crystallinity is also explored.

4:30 PM QN08.02.07 Colloidal Quantum Dot Lasing with Sub-Single-Exciton Thresholds Using Second-Order Distributed Feedback Resonators Young-Shin Park1,2, Jeongkyun Roh1, Oleg

Ziha1,2; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Korea Institute of Machinery and Materials, Daejeon, Korea (the Republic of).

Colloidal semiconductor quantum dots (QDs) are attractive materials for application as laser media because of their high photoluminescence (PL) quantum yields, size-tunable emission colors, and amenability to solution-based processing. Optical amplification in these materials is hampered by nonradiative Auger recombination of gain-active multicharacter states. Recently, we have demonstrated that this problem can be successively addressed by interface-engineering in hetero-structured, compositionally graded QDs. Using these novel structures, we were able to demonstrate both low-threshold lasing with pulsed optical excitation as well as optical gain with d.c. electrical pumping (Nat. Mater. 17, 42. 2018). The next step on the way to practically realizing a QD laser diode is incorporation of a proper feedback system into a high-current-density light-emitting diode (LED).

Towards this goal, we investigate optical properties of photonic structures comprised of a one-dimensional distributed feedback (DFB) resonator and the newest generation of the QD with strongly suppressed Auger decay. These QDs have a CdSe core (~ 2 nm radius) enclosed into a radially graded CdZnS,Se layer (~ 5 nm thickness), completed with a final protective thin (< 1 nm) shell of ZnSe. These structures show a high biexciton PL quantum yield of ~ 45%, which is a result of an exceptionally long biexciton Auger lifetime of > 2ns. QDs are spin-coated onto a DFB produced into the SiO2 substrate via laser interferometric lithography. The grating parameters (pitch, duty cycle, and depth) are selected so as to provide optimal conditions for surface-emitting lasing with the second-order in-plane optical feedback. Applying a Fourier-plane angle-resolved spectroscopy for the analysis of surface lasing produced by the first-order Bragg scattering, we observe that our QD-DFB structures are characterized by an X-shaped photonic mode dispersion. In particular, we detect a ca. 10 nm stop band in the direction normal to the DFB plane which indicates strong optical feedback between counter-propagating in-plane modes (coupling coefficient of ~20), a key to obtaining low-threshold lasing. The fabricated structures also exhibit a fairly high quality factor of ~ 600.

Using optical excitation with 400 nm, 100-fs laser pulses, we observe single-mode lasing at the lower-energy edge of the stop band of the TE mode, which corresponds to reduced losses via surface emission due to a destructive character of interference between in-plane counter-propagating waves. The measured thresholds are consistently below 10 μJ/cm², and the lowest value is ~ 5 μJ/cm². To further lower the lasing thresholds, we apply ideas of “zero-threshold gain” by photo-chemically doping the QDs, which suppresses losses due to ground-state absorption (Nat. Nanotechn. 12, 1140. 2017). Using this approach, we are able to reduce lasing thresholds to the unprecedented level of ~2 μJ/cm², which corresponds to excitation of only ~0.3 exciton per QD on average. This is a 3-fold reduction compared to the fundamental one-exciton-per-dot limit in the case of the undoped QDs. In our ongoing work, we investigate lasing properties of similar DFB resonators incorporated into state-of-the-art QD-LED stacks.

Surface Chemistry of Colloidal Cesium Lead Halides Nanocrystals
Maryna Bodnarchuk1, Simon Böhme2, Ivan Infante1 and Maksym V. Kovalenko1,2,3
1Empa-Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, Switzerland; 2ETH Zürich, Zürich, Switzerland; 3University of Amsterdam, Amsterdam, Netherlands.

Colloidal organic/inorganic lead halide perovskite nanocrystals (NCs) are intensely pursued as highly promising, low-cost light-emitting materials with wide color gamut. These NCs exhibit unprecedented luminescent properties – narrow-band emission with high quantum efficiency, covering the whole visible spectral range and extending into near-infrared, all obtained without epilayer overcoating of the NC surfaces for electronic passivation of the surface states [1]. Their processing and luminescent properties are challenged by the lability of their surfaces, i.e. the interface of the NC core and the ligand shell. Surface and sub-surface atoms are likely directly involved in all possible chemistry equilibria and transformations. Controlling NC surface structure is therefore paramount for mitigating these instabilities. On the example of CsPbBr3 NCs, we rationalize the typical observation of a degraded luminescence upon aging or the luminescence recovery upon post-synthesis surface treatments using a simple surface-structure model, supported by DFT calculations [2]. Healing of the surface trap states requires restoration of all damaged PbX octahedra and establishing a stable outer ligand shell. Such NCs are halogen-rich. Restoration of such a structure, seen as an increase in the luminescence quantum efficiency to 90-100% and improvement in the overall robustness of CsPbBr3 NCs, was attained using a facile post-synthetic treatment with a PbBr2+DDAB (didodecyldimethylammonium bromide) mixture. In practical terms, we demonstrate that such an approach is useful to obtain purified CsPbBr3 NCs samples, washed up to three times in several solvents, with near unity photoluminescence quantum yields and long-term colloidal stability.

11:00 AM *QN08.03.02
Shape and Surface Patchiness Directed Nanoparticle Superlattice Assembly Revealed by Liquid-Phase Transmission Electron Microscopy
Qian Chen; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

We utilize the combined toolset of low-dose liquid-phase transmission electron microscopy and automated single particle tracking to reveal the fundamental crystallization pathways in nanoparticle superlattice formation. We concern nanoparticle systems involving systematically-changing shapes and surface patchiness, which give rise to a rich diversity of crystallization behaviors, such as hierarchical crystallization, layer-by-layer growth, polymorph interconversion as well as corner-connected open lattice formation. Such behaviors hinge on the specific length scale and time scale of nanoparticle motions, which can be potentially generalizable to the phase behaviors of other nano-sized systems in solution.
Metal-oxide nanocrystals doped with alienvalent atoms can exhibit localized surface plasmon resonances (LSPRs) that are tunable across the infrared regions of the electromagnetic spectrum. Yet, the chemical identity and the maximum concentration of active dopants for any specific metal-oxide nanocrystal have remained limited, which is largely due to the difficulty in establishing reaction kinetics that favors dopant incorporation with the widely used co-thermolysis method. In this presentation, I will share our recently developed ion-exchange method for the incorporation of various cationic dopants into preformed metal-oxide nanocrystals while preserving their size, shape and crystal structure. We show that successful addition of p-type dopants into n-type metal-oxide nanocrystals, which may not be feasible using alternative synthetic methods, leads to programmable LSPR redshifts by virtue of dopant compensation. We further demonstrate that enhanced n-type doping can be realized via rationally designed sequential cation-exchange reactions, yielding metal-oxide nanocrystals with the ensemble LSPR energy surpassing that of beginning nanocrystals. Our work shows that ion-exchange transformations can add a new dimension to the chemical design of infrared plasmonic nanocrystals, allowing metal-oxide nanocrystals synthesized by existing methods to be used as templates to create compositionally tunable nanocrystals with well-defined LSPR characteristics.

Quantum confined semiconductor nanocrystals have been widely investigated as light harvesting and charge separation components in photovoltaic and photocatalytic devices. The efficiency of these semiconductor nanocrystal-based devices depends on many processes, including light harvesting, carrier relaxation, charge separation and charge recombination. The competition between these processes determines the overall solar energy conversion (solar to electricity or fuel) efficiency. Compared with single component quantum dots (QDs), semiconductor nanoheterostructures, combining two or more materials, offer additional opportunities to control their charge separation properties by tailoring their compositions and dimensions through relative alignment of conduction and valence bands. Further integration of catalysts (heterogeneous or homogeneous) to these materials form multifunctional nanoheterostructures. Using Pt tipped CdSe/CdS dot-in-nanorods(NRs) and CdS nanoplatelets as model systems for 1D and 2D heterostructures, we are examining the mechanism of long-lived charge separation and H₂ generation in the presence of sacrificial electron donor. The rates of carrier transport, interfacial charge (electron and hole) transfer, and charge recombination can be directly monitored by transient absorption and time-resolved fluorescence spectroscopy. In this talk, we will discuss how the rates of these elementary carrier transfer and transport processes depend on the dimension (size and length), morphology and band alignment in these materials, affect the overall H₂ generation efficiency and can be optimized through rational material design.
harvest high quality supercrystals with desired superlattices.

4:00 PM QN08.04.05
Electronic, Optical and Transport Properties of PbS Nanocrystal Superlattices Yun Liu, Nolan Peard and Jeffrey C. Grossman; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Optoelectronic devices made from colloidal quantum dots (CQDs) often take advantage of the combination of tunable quantum confined optical and electronic properties and carrier mobilities of strongly coupled systems. For lattices of connected CQDs, of interest is the interplay between confinement effects and band-like behavior. In this work, first-principles calculations are applied to investigate the electronic, optical and transport properties of PbS CQD superlattices. Our results show that even in the regime of strong necking and fusing between CQDs, quantum confinement can be generally preserved. In the bandlike regime, computed carrier mobilities for simple cubic and 2D square lattices fused along the [100] facets are 2-4 orders of magnitude larger than those of superlattices fused along other [110] and [111] facets. The relative magnitude of the electron and hole mobilities strongly depends on the crystal and electronic structures. We also find that the carrier mobilities of CQD solids increases as the size of the quantum dot increases due to the stronger coupling between neighboring nanocrystals. Our results illustrate the importance of understanding the effects of crystal structure and connectivity of CQD films.

4:15 PM QN08.04.06
Computational Design of Nanoparticles with Tunable Water-Mediated Interactions Reid Van Lehn; University of Wisconsin–Madison, Madison, Wisconsin, United States.

Functionalized, monolayer-protected nanoparticles (NPs) are versatile materials with surface properties that depend on monolayer composition. Ultrasmall gold NPs (<10 nm in diameter) are of particular interest for drug delivery applications because their small size enables unique interactions with serum proteins and the cell membrane. However, structure-property-interaction relationships correlating NP compositions with their biological interactions remain unclear and can be challenging to determine experimentally.

Here, we present molecular simulation approaches from our group that can guide the design of NP monolayer compositions for biomedical applications. Motivated by prior work that identified NP hydrophobicity as a key parameter driving cellular internalization and protein adsorption, we use atomistic molecular dynamics simulations to quantify NP hydrophobicity as a function of monolayer physical and chemical properties. These results demonstrate how the cooperative interactions of collections of surface-grafted molecules contribute to spatially varying hydrophobic interactions with homogeneous monolayers. We further show that hydrophobic interactions at uniformly nonpolar interfaces can vary in magnitude depending on the fluctuations of surface-grafted alkanethiol ligands, and that these same fluctuations depend on NP core size and shape. These results are further confirmed by atomic force microscopy experiments. Finally, we present a new deep learning methodology to rapidly screen the hydrophobicity of NPs as a function of monolayer composition using only minimal simulation input. This mechanistic insight and new computational tools can be leveraged to design NPs with desired surface properties.

4:30 PM QN08.04.07
In-situ Atomic-Scale Observation of Kinetic Pathways of Sublimation in Silver Nanoparticles Leonard D. Francis; Department of Advanced Electron Microscopy, Imaging and Spectroscopy, International Iberian Nanotechnology Laboratory, Braga, Portugal.

The process by which a crystal sublimes into a gas is a first-order phase transition of considerable fundamental and practical importance in condensed-matter physics, material science and climate change, yet a detailed understanding of its relevant kinetic pathways is still evolving even for the model systems whose equilibrium configuration is known in advance.1 Transmission electron microscopy (TEM) in principle, enables us to observe dynamic process directly, yet to date many of the TEM studies on sublimation dynamics have been implemented on nanostructures at the nanometer scale, such as nanowires, nanorods and colloidal nanocrystals.2 Observing sublimation at the atomic scale has been mostly performed recently on two dimensional layered materials owing to their suitable thickness as a TEM sample in order to exclude the projection issues in electron microscopy. In case of metals, silver (Ag) nanocrystals with a face-centred cubic (FCC) structure show a low sublimation temperature.3 As such, Ag represents an ideal model material to track heating induced sublimation procedure inside an electron microscope. Nevertheless, due to the limit of spatial resolution of a conventional TEM, many critical details such as structural evolution, dynamic processes, sublimation mechanisms and role of defects during sublimation remain unclear as well as not very well established at the atomic scale. With the development of aberration-corrected TEM (AC-TEM) and advanced heating stage, in-situ dynamic observations at atomic resolution can be achieved even at a low voltage, allowing us to directly resolve extremely small nanostructures that are not clearly visible by a conventional TEM.

Here, we report the in-situ atomic-scale observation of the sublimation dynamics of Ag nanoparticles with a size smaller than ~30 nm under heating conditions using an advanced heating holder within an AC-TEM. The Ag nanoparticles are fabricated directly on the TEM heating chips by plasma irradiation in vacuum system to avoid unwanted solvent effects, and both plan-view and cross-section view of the sublimation dynamics are implemented at the atomic scale. We find surprisingly that the sublimation and atomic rearrangement coexist in small Ag nanocrystals during heating and reveal that the sublimation-induced stable surfaces are the low-energy [111] and [100] planes for the Ag nanocrystal with a size smaller than ~30 nm. In addition to the size-dependent sublimation behaviors, we also demonstrate that surface energy and defects are also of relevance in determining the sublimation pathways, i.e. the Ag nanoparticles of a low surface energy show a uniform sublimation pathway, while those of a high energy or 5-fold twin grain nanocrystal with a size smaller than ~30 nm. In addition to the size-dependent sublimation behaviors, we also demonstrate that surfactant energy and defects are also of relevance in determining the structural evolution, dynamic processes, sublimation mechanisms and role of defects during sublimation remain unclear as well as not very well established at the atomic scale.

4:45 PM QN08.04.08
Superlattice Nucleation and Underlying Mechanism of Magnetcite Nanocube Assembly Xin Huang and Zhongwu Wang; Cornell University, Ithaca, New York, United States.

The self-assembly of colloidal nanoparticles into ordered superlattices provides significant expansions for the capability of functional materials design. As the new type of building blocks, the geometric shapes of nanocrystals, such as sphere, cube and octahedron, play critical roles in determining the structure of assembled supercrystal. In the nanocube system, the observed superlattices were dominated by the three phases of simple cubic (SC), rhombohedral (Rh), and face-centered cubic (FCC), but how they nucleate and grow and from one to another remain largely unknown. In this work, we applied highly monodisperse magnetite nanocubes with an average side length of 12.5 nm, and controlled various assembly environments, and revealed the formation and growth of three major phases (SC, Rh and FCC). Taking advantage of synchrotron-based SAXS techniques, we also explored the structural correlations between these superlattices phases. With additional simulations and computations, we further discussed the driving forces and constructed a reasonable superlattice phase diagram of nanocube-based assembly. Our results not only dramatically expand our understanding of the shape-dependent phase behaviors of nanocrystal, but also provide insights for design and fabrication of novel functional materials.

Molecular Control over the Composition of Solid/Solid Interfaces within Nanocrystal Solids Obtained from Colloidal Nanocrystals Santosh Shaw², Tiago F. Silva¹, Jonathan M. Bobbitt³, ⁴, Fabian Naab⁵, Cleber L. Rodrigues¹, Bin Yuan⁶, Julia J. Chang⁷, Xinchun Tian⁸, Emily A. Smith⁹ and Ludovico Cademartiri², ⁴, ⁸; ¹Instituto de Física da Universidade de São Paulo, São Paulo, Brazil; ²Materials Science & Engineering, Iowa State University of Science and Technology, Ames, Iowa, United States; ³Chemistry, Iowa
State University of Science and Technology, Ames, Iowa, United States; 2US Department of Energy, Ames Laboratory, Ames, Iowa, United States; 3Michigan Ion Beam Laboratory, University of Michigan, Ann Arbor, Michigan, United States; 4Chemical & Biological Engineering, Iowa State University of Science and Technology, Ames, Iowa, United States.

We will describe a bottom-up approach to the control of the composition of solid/solid interfaces in nanostructured materials obtained from colloidal nanocrystals. Leveraging the highly selective removal of organics by plasma processing we show that introducing inorganic elements in the ligands of the starting building blocks allows for controlling the interfacial composition of the final all-inorganic ligand-free nanostructured film. We compare the results from ZrO₂ colloidal nanocrystals capped with trioctylphosphine oxide (TOPO) or oleic acid (OA). The interfaces in the plasma processed all-inorganic colloidal nanocrystal assemblies (CNAs) are either nearly bare (for OA-capped nanocrystals) or are terminated with phosphate groups (for TOPO-capped nanocrystals) resulting from the reaction of phosphate oxide groups with plasma species. This modification of the composition of the interfaces has extensive effects on the properties of the material: (i) different growth kinetics indicate different rate limiting processes of growth (surface diffusion for the phosphate-terminated surfaces and dissolution for the “bare” surfaces); (ii) different activation energies of growth indicate three-fold change in interfacial energy; (iii) different phase transformation temperatures show that surface modifications can stabilize the tetragonal phase of ZrO₂ at 900°C without the need for doping.

QN08.05.02

Fluorescent Silver Nanoclusters for Rapid Detection of Pathogenic DNA Yuxiang Chen¹, Peter Goodwin¹ and Jennifer Martinez²; ¹Los Alamos National Laboratory, Los Alamos, New Mexico, United States; ²Department of Chemistry, Northern Arizona University, Flagstaff, Arizona, United States.

DNA-templated silver nanoclusters (Ag NCs) have recently attracted significant research attentions due to their intriguing fluorescent properties, especially in the arena of biosensing and bioimaging. Compared to other widely used fluorescent probes, such as organic dyes, quantum dots, and metal nanoparticles, fluorescent Ag NCs show unique advantages including high photo-stability, low toxicity, and high fluorescent quantum yield, etc. In this poster, we will present a new fluorescent assay platform for the rapid and selective detection of pathogenic DNA sequences using a common foodborne pathogen, i.e. *Listeria*, as the target. In addition, this potentially versatile NCB based platform can be extended to detect other pathogens and bacteria strains at a point-of-care setting.

QN08.05.03

Ink Formulation, Surface Tension Control, and Optimal Microscale Printing of CdSe Quantum Dot Dispersion for Efficient Light Emitting Diode Array Ji-hye Kim, Seok-Ho Hwang, Ohyoung Kim and Byung Do Chon; Dankook University, Yongin, Korea (the Republic of).

Quantum dot light-emitting diodes (QD-LEDs) is a next-generation display technology with narrow-band, highly efficient and widely tunable emission. For a large area compatible patterning of QD-LEDs, solution process such as inkjet printing is promising but relatively complicated parameters exist. For example, quantum dot nanoparticle dispersion in a common solvent produces a non-uniform dried surface as well as strong coffee-ring at edge boundaries. Therefore, uniform filling of a confined light emitting pixel geometry is difficult. Using the mixture of various solvents such as 1,2,4-trimethylbenzene, anisole, and cyclohexylbenzene, giant effectiveness of ink jetting can be achieved. However, the redox of coffee-ring effect at edge boundaries can sometimes accompanies poor surface morphology. We have controlled the solid contents of CdSe nanoparticles at the condition of proper mixture solvents; addition of small amount of high viscosity and high boiling point solvent was effective method. Evaluation of the printed patterns including a dot/line size variation as well as surface morphology were linked with resultant device efficiency (ITO/PEDOT:PPy-TOP/CdSe quantum dot/ZnO/LiF/Al) for different solid contents of CdSe in inks. Fine-line microscale patterned quantum dot LED (line patterns of 80/120 micrometer linewidth/subpixel pitch; 165dpi and more precise pattern) could be fabricated on the photoresist-processed bank test QD-LED cells.

QN08.05.04

Controlled Fragmentation of Quasi-Infinite Particle Chains into Oligomeric Subchains Under the Influence of External Strain Anja Maria Steiner¹, Martin Mayer¹, Maximilian Seuss¹, Tobias A. König¹,² and Andreas Ferti¹,²; ¹Institute of Physical Chemistry and Polymer Physics, Leibniz-Institut für Polymerforschung Dresden e.V., Dresden, Germany; ²Physical Chemistry of Polymeric Materials, TU Dresden, Dresden, Germany.

Among the different plasmonically active assemblies, linear chains of nanoparticles are of special interest. These plasmonic polymers can provide directional, plasmonic waveguiding properties, as well as polarization-dependent field enhancement. An essential parameter governing many optical effects is the number of particles (n) forming a chain. Above the so called infinite chain limit, n, the dependence of plasmonic properties is limited; however, shorter chains below n=1 (i.e., plasmonic oligomers) are highly responsive to variations in n. Therefore, controlling n below the infinite chain limit is an active topic in nanophotonics. We present a scalable approach towards the formation of oriented chains consisting of a few plasmonic nanoparticles, according to the described plasmonic oligomers. These plasmonic oligomers are formed by first assembling quasi-infinite chains above the infinite chain limit and subsequently fragmenting them using mechanical deformation of the underlying elastomeric substrate. Detailed studies of the fragmentation process from quasi-infinite chains are conducted by UV–-vis–NIR spectroscopy and in situ atomic force microscopy (AFM). [2] By evaluation of the strain dependent optical properties, we observed a reversible, non-linear shift of the dominant plasmonic resonance. Using electromagnetic simulations, the optical spectra were deconvoluted into the corresponding ensemble of oligomers that correspond to the oligomer length distribution and dispersity yielded from the AFM measurements. Based on the obtained experimental results and mechanical simulations computed by the lattice spring model, we proposed a formation mechanism that explained the observed decrease of chain polydispersity upon increasing strain and provided experimental guidelines in tailoring chain length distribution. Furthermore, we also demonstrated that the chain length can be tuned depending on the ratio of cohesion between the particles and adhesion of the colloids to the supporting elastomeric substrate. In this work, we demonstrate, that mechanical stress is a powerful tool for the scalable fabrication of oriented linear plasmonic oligomers and opens new avenues for strain-dependent optical devices and mechanophotonic applications. An example is surface-enhanced sensing, where the reversible switching of the nanostructure may be utilized to trap/infiltrate target molecules into uniform hot-spots

QN08.05.05

Non-Classical Crystallization Mechanisms During the Synthesis of PbS Colloidal Nanocrystals Bin Yuan¹ and Ludovico Cademartiri¹; ¹Materials Science and Engineering, Iowa State University of Science and Technology, Ames, Iowa, United States; ²Ames Laboratory, Ames, Iowa, United States; ³Chemical and Biological Engineering, Iowa State University of Science and Technology, Ames, Iowa, United States.

One of the two main classes of mechanisms generally used to explain the formation of nanocrystals is the non-classical aggregative growth (e.g. oriented attachment, step-growth crystallization). Better understanding of these mechanisms should enable better control over the size, shape, and monodispersity of the products. Even though great strides have been made in using the aggregative growth mechanism to synthesize novel nanostructures (e.g. nanorings, ultrathin nanowires) and in visualizing the process in real time with liquid TEM since the seminal work Penn and Banfield on oriented attachment, there is still a long way to go towards understanding this process mechanistically. Two major roadblocks are (i) establishing a model reaction system that only involves the aggregative growth (meaning that classical growth mechanisms are not happening or negligible) and (ii) collecting the kinetic data (i.e. size and concentration of each individual population vs time) quantitatively. We will show how we have overcome the two abovementioned roadblocks by using PbS nanocrystals synthesized by a highly reactive sulfur precursor. This system shows no detectable Ostwald ripening or classical supersaturation-induced growth, and allows for the optical characterization of the individual populations. We show that modeling the aggregative growth kinetics in this system require two separate mechanisms, one whose activation energy is proportional to the radius of the particles and one that is proportional to the volume of the particles. We will then describe how these two mechanisms can be explained within the framework of oriented attachment.
Ceria nanoparticles are used to polish silica due to their high oxide removal rate without the need for added chemicals. Since the early 20th century, ceria has been used to polish glass lenses, and more recently thermal oxides during semiconductor chip fabrication. This second application benefits not only from a high removal rate but also from a high selectivity relative to nitriles. Both of these features are a result of a reversible redox reaction at the surface of the particles allowing them to participate in polishing through both mechanical and chemical means. Ceria’s ability to undergo this reaction is governed by the ratio of Ce⁴⁺/Ce³⁺ on the surface of the particles. As this ratio increases, the interaction with the silica surface, resulting in an increased removal rate. This ratio can be affected by both physical factors such as particle size and synthesis conditions, and chemical factors such as interactions with other slurry components. In this study, glass and thermal oxides were polished on a benchtop polisher and the removal rates were determined using a profilometer and ellipsometer respectively. Model slurries with oxidation state ratios between 5% and 25% were prepared by varying the oxidizing agent and surfactant concentrations as well as the surfactant type. A ceria slurry currently being used in industrial thermal oxide polishing was obtained as a reference (oxidation state ratio of 4%) and a silica slurry was used as a pure mechanical removal control. All the ceria slurries tested had a greater removal rate than the silica slurry, even at low oxidation state ratio. The greatest removal rate was found for the model slurry with 24% Ce⁴⁺ on the particle surfaces, resulting in removal rates at least 1.5 times those of the commercial slurry and 3 times those of the silica slurry for both materials. We discuss these findings and their implications for the specific design of future slurries.

Sodium is necessary for regulating osmotic pressure and assisting the operation of nerve, heart, muscle and various physiological functions in the body. Sodium intake is mainly through food, especially salt. However, excessive sodium intake is harmful because it may lead to the high risk of heart attack, stroke and the development of cardiovascular disease. For the above-mentioned reasons, we worked on developing a rapid, reliable, and sensitive method to detect salt concentration which can be directly monitored by naked eyes. In this study, we utilize the gold nanoparticles (AuNPs) as the colorimetric sensor due to the remarkable characteristic of localized surface plasmon resonance (LSPR) at visible wavelength regions. Based on the concept of LSPR effect, the designed AuNP-based sensor can readily monitor the change of salt concentrations through the color change observed by naked eyes. This phenomenon can be attributed to the ion-induced aggregation of AuNPs, where the response time relative to the salt concentrations can be modulated with the proper control of related detection conditions. Furthermore, in order to improve their detection sensitivity, the organic compound was utilized to further modify the surfaces of AuNPs, and can efficiently reduce the reaction time for readily identifying the biological and chemical sensing applications.

Over the past few decades, the development of rare earth (RE) based light emitting diodes (LEDs) has revolutionized the solid-state lighting industry due to the unique optical and electronic properties of RE elements. The RE luminescence in LED phosphors is often amplified via co-doping with a sensitizer agent (Ce³⁺, Yb³⁺) and/or coating a shell layer for surface passivation. However, there has been a huge push to replace the RE elements in these materials due to their rarity and high demand. Therefore, to sustain energy efficient LED lighting, earth abundant transition metal (TM) elements are being proposed as replacements to RE sensitizers owing to their large absorption cross-sections. Despite their susceptible nature, there is motivation to use TM sensitizers to design tunable luminescent phosphors through the energy coupling of RE-TM ions. The current project demonstrates the ability to tune the optical properties of upconversion phosphors, allowing for controlled absorption and emission spectra in RE doped core-TM doped shell phosphors. In this work, hexagonal β-NaYF₃:Er³⁺/core nanoparticles (NPs) were synthesized with different wet chemistry techniques such as hydrothermal, colloidal synthesis, etc. with controlled sizes, and TiO₂:Ni²⁺ shell layer was deposited via sol-gel chemistry. Initial optoelectronic (UV-Vis, and XPS) and structural (XRD) characterizations were performed on TiO₂:Ni⁴⁺ NPs to identify the optical absorption spectra, oxidation states, and crystal structure. The surface of TiO₂:Ni⁴⁺ NPs was functionalized with para-substituted benzoic acid ligands to demonstrate controlled optoelectronic properties of the TM dopant (Ni³⁺) in a solid host (TiO₂) by modifying the surface dipole by up to 9.5 D. The local structural and electronic changes around Ni³⁺ with the ligand were investigated via time-of-flight neutron scattering (NS) and soft x-ray absorption spectroscopy (XAS), respectively. The atomic pair distribution function (PDF) analysis of the NS data and the intensity ratio of t₂g-eg peaks in N₁ L-edge XAS spectra indicate that the local geometry distortion is accompanied by a change in the electron density in the valence orbitals (3d) of Ni²⁺. These adaptive optoelectronic properties of Ni²⁺ with surface ligands was coupled with the steady emissions of Er³⁺ in NaYF₃:Er³⁺/TiO₂:Ni⁴⁺ core-shell NPs to systematically tune the luminescence of the core-shell phosphor. The ligand induced shifts in the optical absorption (~ 50 nm) and emission spectra of these phosphors were determined by UV-Vis and photoluminescence (PL) measurements. Additionally, the excited state energy transfer kinetics between the RE-TM ion couple were extracted from the life-time decay measurements, which will assist in the development of TM sensitized RE phosphors. These adaptive luminescent phosphors will positively influence the solid-state lighting applications by reducing the RE dependence in LEDs, anti-counterfeit technologies, bio-detection etc.

Colloidal quantum dots (QDs) that are partially fused together to form highly-carried, highly-ordered superlattices (SLs) are an exciting new class of materials for optoelectronics. These **epitaxially-fused** QD SLs promise to combine the band-like carrier transport of bulk semiconductors with the size-tunable photophysics and solution processability of QDs. However, the structure and formation mechanism of these QD SLs are poorly understood, which limits our ability to fabricate high-performance QD SLs with controlled electronic properties.

In this talk, I present a novel combination of X-ray scattering and correlated electron imaging and diffraction used to rigorously determine the superlattice unit cell of oleate-capped QDs (oleate-SLs) and QD slurry particles. This “dual space” method is a powerful and general way to unambiguously assign the structure of 3D colloidal SLs at the single grain level. We find that oleate-SLs fabricated through self-assembly on a liquid substrate adopt a trigonally-distorted body-centered cubic structure with two major out-of-plane SL orientations. I show that the QDs have full orientational as well as positional order in this structure and that both the lateral size of the SL grains and their degree of distortion from true bcc depend on ligand coverage. The two orientations of oleate-SL grains convert to two distinct orientations of the epi-SL with a very different appearance in the electron microscope. The phase transition occurs almost purely via the 3D QDs with minimal rotational motion, resulting in a trigonally-distorted simple cubic epi-SL with fusion along the PhSe₁₀₀ facets. This simple translational phase transition is made possible by the trigonal distortion of the initial oleate-SL and results in ~5 μm epi-SL grains free of linear or planar defects. The ligand content, elemental distribution, and impact of atomic layer deposition infilling on the structure of the epi-SLs will also be highlighted. The powerful correlated imaging and diffraction methodology presented here will help enable detailed understanding of complex nanomaterial superstructures. Furthermore, we show that small distortions in the oleate-SL structure have important ramifications on the epi-SL phase transition and the ability to make highly-perfect epitaxially-fused QD superlattices.
the dried NPs. This renders deposited ink non-conductive unless additionally treated after deposition. In order to ensure metal-metal contact and conductivity, ligands have to be removed by sintering that is incompatible with many substrates [1]. In order to avoid this, we developed hybrid NPs that combine gold metal cores and conjugated polymer shells that we will briefly introduce in this talk. Their synthesis is based on a ligand exchange reaction of cetyltrimethylammonium bromide (CTAB) capped gold nanorods (AuNRs) by conjugated polymers such as poly[(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PPS) and poly[2-(3-thienyl)-ethoxy]-4-butylylsulfonate] (PTESBS). The hybrid particle design allows good electron transport upon ink drying, rendering sintering unnecessary. After deposition, dry films of hybrid NP inks exhibit conductivity on the order of 1.0 x 10⁴ S/m. We used infrared (IR) and Raman spectroscopy to demonstrate the successful ligand exchange and to investigate how metal core interact with polymers and how different particles connect. These polymers serve as ligands and confer high colloidal stability to particles in water and other solvents, too, enabling advanced ink formulations. The resulting inks exhibited good stability of at least one year at high gold concentration of 200 mg/mL [1].

Here, we present an extension of the sinter-free hybrid ink concept to core materials and shapes beyond the gold nanorods mentioned above. First, we discuss the large-scale production at high concentrations of faceted gold NPs with diameters below 100 nm. In order to control the coalescence process and avoid the NPs aggregation, we used plant extracts and infusions to synthesize metal and metal oxide NPs. Due to the simplicity and eco-friendliness of these methods, metal and metal oxide NPs synthesis using plant extracts and infusions has been widely used. The most common methods are based on the reduction of metal ions with organic compounds such as plant extracts or infusions. These methods are easy to use, do not require complex equipment, and are sustainable. However, the size and morphology of the NPs are not always well controlled. To overcome this limitation, we use a combination of plant extracts and infusions with metal solutions. This approach allows us to control the size and shape of the NPs, as well as their composition, and to achieve a high degree of monodispersity. The use of plant extracts and infusions as reducing and stabilizing agents is a promising approach for the synthesis of metal and metal oxide NPs with specific properties. These NPs have potential applications in various fields, such as catalysis, sensors, and energy devices. In our research, we have focused on the synthesis of silver and copper NPs using organic molecules as reducing and passivating agents. These NPs have shown promising properties for applications in water purification, drug delivery, and photovoltaics. We have also investigated the use of these NPs in the development of hybrid inks for inkjet printing. Our hybrid inks exhibit high colloidal stability, good conductivity, and a wide range of optical properties. These inks have potential applications in printed electronics, where they can be used for the fabrication of devices with high performance and low cost.
Facile, Green Synthesis of Cerium/Vanadate Oxide Nanoparticles—Biomedical and Electrochemical Application

Craig J. Neal1, Taili Selvin1 and Sudipta Seal2; 1Materials Science & Engineering, Nanoscience Technology Center, AMPAC, University of Central Florida, Orlando, Florida, United States; 2Materials Science & Engineering, Nanoscience Technology Center, AMPAC, College of Medicine, University of Central Florida, Orlando, Florida, United States.

Nanoscale cerium oxide has shown high catalytic activity towards numerous substrates in applications relevant to the chemical and biomedical industries. The utility of this material derives from the Ce4+/Ce3+ redox couple and surface oxygen defects, with the material's broad applicability across industries arising from the ability to tune surface defect concentrations via synthesis approach. Despite ceria’s high catalytic activity and efficiency: the material’s cost/scarcity may limit its use in industry. The present work focuses on a facile, green synthesis incorporating vanadium into ceria nanoparticles as a means to reduce the cost of catalyst materials, without sacrificing efficiency, while increasing the potential application space. Ultra-small, stable (hydrodynamic radius: 22 nm; zeta potential: 28 mV) cerium/vanadium oxide nanoparticles are produced via hydrolysis through the mixing of cerium and vanadate (as an inorganic redox agent) pre-cursors in water. The particles were washed to remove residual reagents and used without further modifications. The particles were deposited on glassy carbon electrodes and tested using cyclic voltammetry, chronocoulometry, and linear sweep voltammetry to detect various bio-molecules and as a pseudocapacitive material. Further, synthesis parameters were optimized and tested for enzyme-mimetic activity against comparable cerium oxide nanomaterials in standard chemical assays. This material demonstrates high catalytic activity in biomedical and electrochemical applications through a simple green synthesis method while reducing synthesis cost by limiting cerium fraction.

QN08.05.15

Using Quantum Dots in a Sol-Gel Matrix to Enable Deep UV Imaging for Silicon Based Detectors

Alex Knowles1, Scott Williams1, Zoran Ninkov2 and Ross Robinson1; 1College of Science, Rochester Institute of Technology, Rochester, New York, United States; 2Center for Imaging Science, Rochester Institute of Technology, Rochester, New York, United States.

CdSe/ZnS quantum dot (QD) incorporation into a sol-gel matrix that forms a deep UUV transparent thin film window will be presented. Silicon-based CMOS and CCD detectors coated with a thick Lumogen layer is the current state of the art in detector high-energy sensitization. QDs, however, may provide enhanced advantages over Lumogen, such as tunable emission wavelength, lower production costs, and a greater range of solvent choices. We have demonstrated that CdSe/ZnS quantum dots synthesized with polar solvent dispersible ligands enables formulation of ink jet printable inks. To achieve the film thicknesses required for high quantum yield detector sensitization, we have introduced sol-gel chemistry into the ink formulation to produce highly transparent UUV transmissive thick film windows. Implementation of MgF2 will be reported. Performance characterization using scanning electron microscopy, vacuum-ultraviolet absorption spectroscopy, and quantum yield will be presented.

QN08.05.16

Effect of Zn Precursor Concentration on the Blinking Behavior of CuInS2/ZnS Quantum Dots and Characterization of Fast Blinking Particles for Super-Resolution Imaging

Anh Nguyen and Colin Heyes; Arkansas University, Fayetteville, Arkansas, United States.

Cadmium-free CuInS2/ZnS core/shell quantum dots are synthesized through a non-injection synthetic method for both the cores and shelling steps. The resulting CuInS2/ZnS quantum dots are small (~4–7 nm) and spherical with photoluminescence quantum yields (PLQY) in the range of 40–70%. The structure, chemical composition and optical properties of CuInS2/ZnS quantum dots at both ensemble and single-particle level are carefully investigated as functions of the synthesis conditions. The results show that overcoating CuInS2 cores using relatively low amounts (0.1 mmol) of Zn(S2)2 precursor during the shelling step leads to an extensive cation exchange process that forms an alloyed core, followed by a thin ZnS shell that significantly increases the quantum yield. Increasing the amount of Zn(S2)2 to 2-4 mmol during shelling leads to more extensive cation exchange/alloying as well as forming thicker shells. Using higher amounts of Zn reduces the QY compared to using lower amounts of Zn, but the fluorescence intermittency (blinking) is significantly reduced. Moreover, we use a single particle subpopulation analysis to gain a better comprehension of the ion exchange/alloying/shelling processes and their role on the blinking mechanism.

Even though fast blinking (short on time, long off time) is a limiting property in many applications, they have great potential in improving super-resolution imaging. Here, we present our preliminary FIONA (fluorescence imaging with one-nanometer accuracy) characterization using bright but fast-blinking CuInS2/ZnS quantum dots. The results show that the localization precision of CuInS2/ZnS quantum dots can reach ~1 nm, highlighting the excellent potential of these QDs for super-resolution imaging applications.

QN08.05.17

Band-Graded Light Absorber and Organic Interfacial Layer for Highly Efficient and Air-Stable PbS Quantum Dot Solar Cells

Yeong Jae Baik1 and Sohee Jeong2; 1Hankyong National University, Gyeonggi-do, Korea (the Republic of); 2Korean Institute of Machinery and Materials, Daejeon, Korea (the Republic of).

PbS quantum dot solar cell is an emerging photovoltaic technology, which is also a versatile platform in emerging memory research due to its well-developed synthesis enabling a wide range of variations in optical bandgap. Moreover, recent development in leading groups have produced power efficiency of 10%, which sheds lights in its future application areas.

In this presentation, based on the band gap engineering capability of PbS quantum dots, the development of the enhanced power conversion efficiency of band graded PbS solar cells will be presented. In addition, to further enhance the power output equipped with a good ambient stability, a systematic study on PbS quantum dot solar cells with organic hole transport layers will be presented.

Using above two elemental technologies, it is expected that the state-of-the-art technology of quantum dot solar cells would gain a further advancement.

Air Stable Nanoparticle Alloys—Synthesis and Characterization

Mary Saini Devadas1, Naveen Kadasala1, Stephen Blama2, Bryan Augustin2, Amanda Belunis1, Vera Smolyaninova2, Ellen Hondograssi1 and Maksym Zhukovskyi1; 1Department of Chemistry, Towson University, Towson, Maryland, United States; 2Department of Physics Astronomy and Geosciences, Towson University, Towson, Maryland, United States; 4Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, Indiana, United States.

Nano-crystalline materials, because of their size, exhibit a variety of properties, which are different and often considerably improved in comparison with those of conventional polycrystalline bulk material. Of particular interest are nanoparticles of iron-cobalt because of their unique physical and chemical properties and their industrial importance in preparing magnetic recording materials, pigments, catalysts and inks. The goal of the project is to obtain alloys with the highest possible magnetization value. The metals that we have used in this study are Fe and Co. By varying the composition of the alloy nanoparticles (Fe:Co, 1:1 and 3:1) via a high temperature reduction reaction, highly stable nanoparticles have been synthesized. Their physical parameters have been characterized using TEM, XRD and composition by ICP-MS and EDX. For measuring magnetization, a home-built vibrating sample magnetometer is used. These alloys are particularly air-stable and have magnetization values that surpass the values of commercial ferrofluids, and ferrite powders. The details of the synthesis and characterization will be presented.

We acknowledge funding from NSF MRI 1626326 and DARPA AMEBA.

The Effect of Trimesic Acid Addition on the Preparation of Colloidal Sulfide Nanoparticles

José Humberto Palomares Leiva1,2; Francisco Javier Carrillo Pesquera1,3, Hilda Espanzar Ponce1, Javier Hernandez-Paredes1,3, Paul Zavala River1,2 and Ofelia Hernandez Negrete1,2; 1Universidad de Sonora, Hermosillo, Mexico; 2Departamento de Ingeniería Química y Metalurgia, Universidad de Sonora, Hermosillo, Mexico; 3Departamento de Física, Universidad de Sonora, Hermosillo, Mexico; 4Física de Materiales, Centro de Investigación en Materiales Avanzados, Chihuahua, Mexico.

There are numerous studies focused on the preparation of silica (SiO2) spheres. Most of these works have the goal to produce colloids of spherical monodisperse silica nanoparticles (NPs). However, it has been proposed that non-spherical silica NPs may have some advantages for engineering lower symmetry networks to fabricate photonic crystals. In the search for a way to prepare non-spherical silica NPs we have used different concentrations of trimesic acid (TA) during the Stöber reaction while keeping the ratio water-ethanol-TEOS-ammonia fixed. The samples were characterized by Scanning Electron Microscopy (SEM), Dynamic Light Scattering (DLS) and thermal analysis (DSC-TGA). The results showed that there is an increase in the size of the silica NPs as the TA concentration increases. However, at higher concentrations of TA, not only polydispersity was
present, but also a considerable population of smaller silica spheres. There was also irregular population in the range of microns produced for disordered aggregation. Moreover, TA encourages shape anisotropy through dimer formation of silica NPs. The amount of the dimers increases with TA concentration and for the higher concentrations, aggregates of three or more silica particles were formed. These findings suggested that this route of synthesis represents an alternative method of producing anisotropic silica NPs and motivate us to continue exploring other concentrations of TA and the use of other carboxylic acid derivatives.

QN08.05.20
A Facile Synthesis of Metal-Organic Frameworks (MOFs) and MOF/Active Metal Nanoparticles Composites via Laser Ablation Synthesis in Solution Erick L. Ribeiro1, 2, 3, Barnim Khomami1, 2 and Dibyendu Mukherjee1, 4; University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 2Sustainable Energy Education & Research Center (SEERC), Knoxville, Tennessee, United States; 3Nano-BioMaterials Laboratory for Energy, Energetics & Environment, Knoxville, Tennessee, United States.

The synthesis of Metal-Organic Frameworks (MOFs) has gained tremendous attention within the past decade owing to the extreme versatility of these functional materials. Although many reports on the generation of a broad variety of the MOF structures have been reported, the design of new facile, rapid and environmentally friendly fabrication strategy allowing a precise morphological and structural control of the frameworks, is still necessary. Herein, we report for the first time a methodology of laser-induced MOF formation using laser ablation synthesis in solution (LASiS) for the synthesis of zeolitic imidazolate framework-67 (ZIF-67). We have demonstrated the ability to rationally tailor the formation of the frameworks by adjusting solution-phase parameters (reagents concentration and temperature) along with laser variables (ablation time).

Secondly, we present our most recent findings in using LASiS in tandem with galvanic replacement reaction (LASiS-GRR) as a strategy and pathway for the synthesis of active metal nanoparticles (NPs) engaged in MOF structures that can exhibit unique functionalities even under extreme environments. Such encapsulation strategies can be of paramount importance in active and harsh environments where NPs need to be stabilized within the MOF structures to minimize their aggregations while conserving their properties. To this end, results for the Pt/MOF and Ag/MOF composites have shown, respectively, promising catalytic activity and plasmonic enhancement. The objective of this study is to present a complete description of the phenomena involved in this synthesis technique, allowing LASiS-GRR to be used for the fabrication of a wide range of NPs confined within MOFs crystals that go onto exhibit active catalytic, magnetic and optical properties.

QN08.05.21
A Fully Quantitative Model for Determining Growth Kinetics of Colloidal Nanoparticles Sinyu Wu and Yugang Sun; Temple University, Philadelphia, Pennsylvania, United States.

Colloidal nanoparticle synthesis has reached a level of empirical maturity with a consensus that growing well-defined colloidal nanoparticles depends on “kinetics control”. However, quantitative study of growth kinetics of colloidal nanoparticles is still missing and virtually unexplored. Rational control over growth kinetics for synthesizing colloidal nanoparticles with desirable properties on demand remains challenging. In this presentation, a strategy has been developed for analyzing growth kinetics of colloidal metal nanoparticle quantitatively by focusing both the very early and the very late growth stages, at which the size of growing nanoparticles and the reaction time follow linear functions. Applying this extreme-condition model to a microwave-assistant synthesis of colloidal silver nanoparticles, for the first time, results in the determination of intrinsic kinetics parameters involving in the growth of the silver nanoparticles. The diffusion coefficient (D) of the precursor species containing Ag+ is 4.9×10⁻¹⁴ m²/s and the surface reaction rate constant (k) of the precursor species on the surface of the growing silver nanoparticles is 8.7×10²⁵ m/s in an ethylene glycol solution containing 0.15 M polyvinylpyrrolidone at 140 °C. The extreme-condition model is ready to deconvolute the intrinsic kinetics parameters of growing colloidal nanoparticles once the enlargement rate of the nanoparticles can be experimentally measured in real time and with high temporal resolution. Availability of the high-fidelity values of k and D will provide the crucial information to guide the design and synthesis of colloidal metal nanoparticles with the desirable properties.

QN08.05.22
Milk Haptoglobin Detection Based on Enhanced Chemiluminescence of Gold Nanoparticles Giorgio Shitenberg; ARO Volcani Center, Bet Dagan, Israel.

The suggested research specifically addresses the major source of economic loss of the dairy industry, the bovine mastitis (BM), an inflammatory disease of mammary gland caused by bacterial intramammary infection. During earlier inflammation, the concentrations of acute phase proteins (APP) in both plasma and milk are escalated, which can be distinctively utilized as predicting diagnostic biomarkers of cattle’s BM clinical status. Herein, we demonstrate a liquid-phase luminol chemiluminescence (CL) system for sensitive detection of haptoglobin (Hp), a predictive APP of BM, by utilizing the binding capacity of hemoglobin (Hb). The CL intensity is linearly proportional to Hb-Hp complex formation, resulting in peroxidase-like activity inhibition of luminol-H₂O₂-Hb CL system. Enhanced CL, at least 10-fold effect within real samples, is attained by the addition of catalytically active cross-linked gold nanoparticles (GNPs) onto the luminol-H₂O₂ solution. Moreover, the influence of different somatic cell counts (representing subclinical and clinical BM status) and pathogen types (i.e., CNS and Streptococcus dysgalactiae) on the secreted milk Hp levels obtained from Holstein cows are established. The analyzed Hp concentrations are in agreement with a commercial enzyme-linked immunosorbent assay kit. The proposed CL sensing concept offers cost-effective, simple, label-free and reliable systematic analysis of Hp biomarker for BM, potentially initiating a positive effect on animals’ health and overall economy of the dairy farms.

QN08.05.23
Noble Metal/Organic Nanoparticles as a CT Contrast Agent Seong Ik Jeon and Cheol-Hee Ahn; Seoul National University, Seoul, Korea (the Republic of).

Molecular Imaging based on noble metal nanostuctures have gained interests in the field of medical applications for the past decades. Gold nanoparticles (AuNPs), also called gold colloids, are considered to be very stable and biocompatible metal nanoparticles. Previously, it was demonstrated that AuNPs modified with glycol chitosan (GC) polymers (GC-AuNPs) have excellent stability without aggregation in serum protein solution and tumor-targeting ability due to the enhanced permeability and retention effect.

Optical / PET and CT / MRI imaging are complementary visualization techniques, the former providing functional and molecular information and the latter providing anatomical details. Nanoparticles, especially metallic/inorganic nanoparticle, based imaging probes have been extensively developed to evaluate precise information about disease, utilizing their characteristic properties, such as surface plasmon resonance of gold nanoparticles and superparamagnetism of iron oxide. These characteristics provide both anatomic and functional information including the location, size and genetic details of disease by combining with NIRF imaging or PET. In spite of superb nature of these nanoparticles, they have a limitation to employ in vivo diagnosis because of their in vivo stability. Appropriate surface modification method was widely researched.

Here, we introduce several fabrication methods of nanoparticle based imaging probes and their biomedical applications. Gold nanoparticles were decorated with fluorophore labeled peptides for enzyme specific NIRF imaging and demonstrated the potential in vivo imaging probe. Gold nanoparticles, stabilized with biocompatible polymer, were prepared for in vivo NIRF/CT imaging and successfully visualized the liver and cancer. The distinguished properties of these probes showed promising potential of the activatable dual imaging probe system as a novel molecular imaging probe.

QN08.05.24
Revealing Driving Forces in Quantum Dot Supercrystal Formation Emanuele Marino1, 3, Thomas E. Kodger2, Gerard H. Wegdam1 and Peter Schall1; 1Institute of Physics, University of Amsterdam, Amsterdam, Netherlands; 2Physical Chemistry and Soft Matter, Wageningen University and Research, Wageningen, Netherlands; 3Department of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

The assembly of semiconductor nanoparticles, quantum dots (QD), into dense crystalline nanostructures holds great promise for future optoelectronic devices. However, knowledge of the sub-nanometer scale driving forces underlying the kinetic processes of nucleation, growth and final densification during QD assembly remains poor. Emulsion-templated assembly has recently been shown to provide good control over the bulk assembly of QDs by condensation into highly ordered three-dimensional supercrystals. Here, we combine emulsion-templated assembly with in situ small-angle X-ray scattering to obtain direct insight into the nanoscale interactions underlying the nucleation, growth and densification of quantum dot supercrystals. We show that at the point of supercrystal nucleation, nanoparticles undergo a hard-sphere like crystallization into a hexagonally close-
packed lattice slowly transforming into a face-centered cubic lattice. The ligands play a crucial role in balancing steric repulsion against attractive van der Waals forces to mediate the initial equilibrium assembly, but cause the QDs to be progressively destabilized upon densification. The rich detail of our kinetic study elucidates the assembly and thermodynamic properties that define QD supercrystal fabrication approaching single-crystal quality, paving the way towards their use in optoelectronic devices.

8:30 AM *QN08.06.01
Reversibly Reconfigurable Plasmonic Nanoparticle Materials David S. Ginger; University of Washington, Seattle, Washington, United States.

An exquisite sensitivity to the local environment combined with their ability to dramatically concentrate electromagnetic fields makes plasmon resonant nanoparticles ideal candidates for use in stimulus-responsive materials with potential applications ranging from biosensing to smart optics. In this talk, we explore the synthesis and characterization of reconfigurable plasmonic metallochromophores that change their structural organization, and hence their collective optical properties, in response to external stimuli such as light. We explore a variety of approaches to reversibly modulate interparticle plasmonic couplings in response to external triggers, ranging from discrete dimers functionalized with photoswitch modified DNA, to nanoparticle/polymer hybrids that enable temperature-, and photo-responsive behaviors on multiple timescales. These materials offer tunable optical responses across both the visible and near-IR. We discuss strategies for incorporating multiple stimulus-response functions, and for obtaining self-amplifying and self-limiting feedback behaviors with these materials.

9:00 AM *QN08.06.02
Autocatalytic Surface Reduction for Shape-Controlled Synthesis of Metal Nanocrystals Yousan Xia; Georgia Institute of Technology, Atlanta, Georgia, United States.

The formation of colloidal metal nanocrystals typically involves an autocatalytic process, in which the salt precursor adsorbs onto the surface of a growing nanocrystal, followed by chemical reduction to atoms for their incorporation into the nanocrystal. Despite its universal role in the synthesis of colloidal nanocrystals, it is still poorly understood and controlled in terms of kinetics. Through the use of well-defined nanocrystals as seeds, including those with different types of facets, sizes, and internal twin structure, we have quantitatively analyze the kinetics of autocatalytic surface reduction in an effort to control the evolution of nanocrystals into predictable shapes. Our kinetic measurements demonstrate that the activation energy barrier to autocatalytic surface reduction is highly dependent on both the type of facet and the presence of twin boundary, corresponding to distinctive growth patterns and products. Interestingly, the autocatalytic process is effective not only in eliminating homogeneous nucleation but also in activating and sustaining the growth of octahedral nanocrystals. This work represents a major step forward toward achieving a quantitative understanding and control of the autocatalytic process involved in the synthesis of colloidal metal nanocrystals.

9:30 AM *QN08.06.03
Impact of Surface Chemistry in Multimetallic Nanoparticle Synthesis and Performance Jill Millstone; University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

Metal-ligand chemistry impacts nearly every aspect of nanoparticle formation, physical properties, and utility. We develop methods to study and leverage these interactions to produce highly tailored multimetallic nanoparticles with dimensions spanning the nanoscale (1-100 nm). Here, we discuss how metal-ligand interactions may be used to mediate the incorporation and distribution of metals in and on discrete, colloidal nanoparticle substrates, as well as their optoelectronic properties once formed. In particular, we demonstrate that nanoparticle ligand chemistry may be used to access previously unobserved mixtures of metals such as continuously tunable Au-Co composition ratios, unique and Michael J. Janik

Chromophore-Gold Superratom Clusters— Optical and Electrochemical Properties Mary Saiini Devadas1, Nicole Hondriagniess1, Angela Meola1, Brianna Hutson1, Keith Reber1 and Maxym Zhukovsky2; 1Department of Chemistry, Towson University, Towson, Maryland, United States; 2Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, Indiana, United States.

Structure and reactivity of super atom gold clusters depends on the electronic interaction between core gold atoms and the ligand. The super atom clusters of the dimension 1.1 nm containing 25 atoms of gold and 18 ligands, can be of two shapes - spherical (icosahedral); comprised of core and shell gold; made of thiol (SR) ligands; Au@4 and rod shaped (bi-icosahedral); comprised of core and bridging gold atoms; made of SR and triphenylphosphine (PPh3) ligands; Au@4-5). Both clusters are photoluminescent (PL) but Au@4-5 has higher quantum yield. In this project we push the loading of chromophores on the nanoparticle surface and compare the changes in PL as a function of geometry. Ground state electron transfer is monitored via voltammetry to investigate the direction of electron flow. The influence of the chromophore (modified coumarin and anthracene) will be investigated and quantitatively analyzed to control the evolution of nanocrystals into predictable shapes. The activation energy barrier to autocatalytic surface reduction is highly dependent on both the type of facet and the presence of twin boundary, corresponding to distinctive growth patterns and products. Interestingly, the autocatalytic process is effective not only in eliminating homogeneous nucleation but also in activating and sustaining the growth of octahedral nanocrystals. This work represents a major step forward toward achieving a quantitative understanding and control of the autocatalytic process involved in the synthesis of colloidal metal nanocrystals.

10:45 AM QN08.06.05
Doping as Strategy to Tune Color of 2D Colloidal Nanoplatelets Marion Defour1, Eva Izquierdo1, Clément Livache1,2, Bertille Martinez1,2, Thomas Pons1, Emmanuel Lhuillier2, Christophe Delerue1 and Sandrine Ihurria; 1ESPCI Paris, Paris, France; 2INS, Sorbonne Université, Paris, France; 3Université de Lille, Lille, France.

Among nanocrystals, 2D nanoplatelets appear as a special class of emitters with the best defined (ie the narrowest) photoluminescence signal. The tunability of their color is commonly obtained thanks to quantum confinement. However only discrete values for thickness can be achieved which prevent continuous tuning of the spectrum. Here we demonstrate that doping is an alternative to tune the spectrum of these II-VI semiconductor 2D nanoplatelets from green to red. We develop a synthetic method to achieve silver doping of CdSe nanoplatelets and demonstrate the potential of the material for the design of wide gamut display. Silver doing was already reported on spherical quantum dots, but several questions relative to these materials were left without firm conclusion. Here we investigate the electronic properties of the silver doped CdSe NPL using a combination of optical spectroscopy, photoemission, transport and simulation. We are finally able to build a consistent picture of the electronic level associated to the growth of octahedral nanocrystals. This work represents a major step forward toward achieving a quantitative understanding and control of the autocatalytic process involved in the synthesis of colloidal metal nanocrystals.

11:00 AM QN08.06.06
Generalized Mechanism of Foreign Metal Assisted Shape Controlled Synthesis of Silver Octahedron via Seed Mediated Growth Supriya Jharmunni1, Robert M. Rioux2, Zhifeng Chen1, Yawei Li1 and Michael J. Janik2; 1Department of Chemistry, The Pennsylvania State University, University Park, Pennsylvania, United States; 2Department of Chemical Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States.
The formation of Ag octahedron nanoparticles (NPs) from Ag nanocube seeds using a foreign metal ion, Cu$^{2+}$ reported in literature has been attributed to the selective deposition of Ag on Ag(100) over Ag(111) facets, based solely upon observation of the final shape. The driving force for selective deposition of Ag on Ag(100) facets in the presence of the foreign metal ions still remains unknown. We performed a comprehensive study of the seed-mediated synthesis of Ag octahedron in presence of foreign metal ions ($M^{n+} = Ni^{2+}, Co^{2+}, Cu^{2+}, Pd^{2+},$ and Au$^{3+}$) with the objective of investigating the detailed pathway of transformation from Ag nanocube seeds to octahedron. We demonstrate a generalized mechanism based on experimental observations, periodic table trends, and theoretical calculations using density functional theory (DFT). We propose, the foreign metal ions deposit on the Ag(100) facets through either underpotential deposition (UDP) ($Cu^{+}, Ni^{2+}$ and $Co^{2+}$) or a galvanic exchange reaction (GRR) ($Pd^{2+}$ and $Au^{3+}$) depending on the $M^{n+}$ reduction potential with respect to Ag. The deposited metal induces a faster growth rate on Ag(100) facets through GRR, in the case of Cu, Ni, and Co, and through UDP in the case of Pd and Au, leading to the disappearance of Ag(100) facets and retention of Ag(111) facets. A faster growth rate on Ag(100) facets is experimentally confirmed from observation of intermediate high-index facets formed on the Ag(100) surface at higher injection rates of Ag$^{+}$. The formation of octahedron is also sensitive to the concentration of foreign metal ions added and the shape of the starting Ag seed template. This work provides a fundamental understanding of the role of foreign metal ions in seed-mediated shape-controlled synthesis of Ag octahedron, which can be extended to other more complex systems. It also offers a scope for a wide selection of foreign metal ions for shape-controlled synthesis of noble metal NPs, many of which are not explored yet, simply based on standard reduction potential values. Regardless of deposition mechanism, shape transformation from Ag(100)-bound to Ag(111)-bound structures is possible with the simultaneous addition (flux) of new Ag$^{+}$ ions.

11:15 AM QN08.06.07
Employing Colloidal Nanochemistry to Engineer Granular Magnetoresistance Materials Ben Zhou$^1$ and Jeffrey D. Rinehart$^{2, 3}$; $^1$Materials Science, University of California, San Diego, La Jolla, California, United States; $^2$Chemistry and Biochemistry, University of California, San Diego, La Jolla, California, United States.

The discovery of giant magnetoresistance in 1988 enabled the explosion of hard disk drive storage capacity, and continues to impact various sensing applications today. Granular magnetoresistance, discovered shortly after giant magnetoresistance, offers similar properties in a cheaper package, but has been limited by an inability to prepare well-characterized, uniform, nanoscale magnetic domains. Employing colloidal nanochemistry to design granular magnetoresistance materials allows for explicit control of grain structure and expedient testing of different materials. We have investigated the effects of nanoparticle size on magnetoresistance and explored more complex magnetoresistive phenomena in multi-component materials.

1:30 PM QN08.07.01
In Situ Atomic-Level Tracking of Heterogeneous Nucleation in Nanocrystal Growth with an Isocyanide Molecular Probe Dong Qin and Yiren Wu; Georgia Institute of Technology, Atlanta, Georgia, United States.

We report the use of 2,6-dimethylphenyl isocyanide (2,6-DMPI) as a spectroscopic probe to study the heterogeneous nucleation and deposition of Pd on Ag nanocubes under different conditions by surface-enhanced Raman scattering (SERS). As a competitive advantage, the spectroscopic analysis can be performed in situ and in real time with the nanoparticles still suspended in the reaction solution. The success of this method relies on the distinctive stretching frequencies ($n_{NC}$) of the isocyanide group in 2,6-DMPI when it binds to Ag and Pd atoms through $\pi$ donation and $\pi$-back donation, respectively. Significantly, we discovered that $n_{NC}$ was sensitive to the arrangement of Pd adatoms on the Ag surface. For example, when the isocyanide group bound to one, two, and three Pd atoms, we would observe the atop, bridge, and hollow configurations, respectively, at different $n_{NC}$ frequencies. As such, the $n_{NC}$ band could serve as a characteristic reporter for the Pd adatoms being deposited onto different types of facets on Ag nanocubes with atomic-level sensitivity. When 2,6-DMPI molecules were introduced into the reaction solution, we further demonstrated in situ tracking of heterogeneous nucleation and early-stage deposition of Pd on Ag nanocubes by monitoring the evolution of $n_{NC}$ bands for both Ag and Pd surface atoms as a function of reaction time. This in situ technique opens up the opportunity to investigate the roles played by reaction temperature and the type of Pd(II) precursor in influencing the heterogeneous nucleation and growth of bimetallic nanocrystals. The sensitivity of isocyanide group to Pd atoms helps elucidate some of the details on the reduction, deposition, and diffusion processes involved in heterogeneous nucleation.

2:00 PM QN08.07.02
Evaporative Self-Assembly as a Powerful Tool for Creating Functional Superstructures Eugene Zubarev; Rice University, Houston, Texas, United States.

Spontaneous assembly of colloidal nanostructures is often viewed as a bottom-up alternative to lithographic techniques when it comes to creating materials with novel collective properties. The intensive research in the past 10-15 years has brought numerous examples of functional superlattices, 3D colloidal crystals, and designed patterns of nanostructures. However, the majority of self-assembly methods suffer from poor reproducibility and limited scale, which often precludes the formation of macroscopically large structures and functional devices. This presentation will focus on the evaporative self-assembly of anisotropic gold nanocrystals and the underlying mechanisms of their colloidal crystallization. In addition, template-assisted evaporative assembly of nanowires, polymers, and collagen fibers into macroscopically-large hexagonal patterns will be discussed.

2:30 PM BREAK

3:30 PM QN08.07.03
Amphiphilic Nanoparticles—Characterization and Applications Francesco Stellacci; Institute of Materials, EPFL, Lausanne, Switzerland.

In this talk the characterization of gold nanoparticles coated with an amphiphilic mixture of ligand molecules will be illustrated. In particular advances in the characterization approach via small angle neutron scattering and mass spectroscopy will be illustrated. A review of the properties will these particles will be presented. Particular attention will be devoted in illustrating the antiviral properties and the ability of these particles to effectively label amyloid fibers.

4:00 PM QN08.07.04
Mechano-Responsive Tuning of Giant Circular Dichroism in Self-Assembled Crossed Particle Chains Patrick T. Prehod$^1$, Vaibhav Gupta$^1$, Martin Mayer$^2$, Anja Maria Steiner$^1$, Günter Auenhammer$^1$, Tobias A. König$^1$, and Jeffrey D. Rinehart$^{2, 3}$; $^1$Materials Science, University of California, San Diego, La Jolla, California, United States; $^2$Chemistry and Biochemistry, University of California, San Diego, La Jolla, California, United States; $^3$Chemistry, University of California, San Diego, La Jolla, California, United States.

Tailorable chiroptical effects in chiral plasmonic nanostructures render them promising candidates as high-efficiency broadband circular polarizers and enable enhanced direct asymmetric synthesis of chiral target molecules. Concerning flexibility in design and efficiency (circular dichroism (CD) > 10 deg), fabrication techniques like electron beam lithography and direct laser writing are usually superior to colloidal self-assembly methods (10-100 mdeg). However, using chiral templates (chiral nematic phases, DNA) or ligand-induced clustering of colloidal particles proved to be inevitable for low-cost production on large scales.

Here, we present a facile bottom-up approach to produce a crossed-chains bilayer on centimeter square area that, for the first time, is competitive ($CD = 11$ deg) to top-down methods. More interestingly, we prove significant spectral tunability (100 nm blue-shift) by mechanical deformation, which remains difficult to achieve in a post-fabrication fashion for other systems known in literature.

Two achiral nanoparticle chain arrays on compliant substrates are placed on top of each other to produce a chiral 3D arrangement of rotated chains. To this end, convective approach via small angle neutron scattering and mass spectroscopy will be illustrated. A review of the properties will these particles will be presented. Particular attention will be devoted in illustrating the antiviral properties and the ability of these particles to effectively label amyloid fibers.
Internalized Polysaccharide Nanoparticles Enhanced Production of the Natural Antimicrobial Peptide in Probiotics

Chong-Su Cho1, Whee-Soo Kim1, Liang Hong1, Sang-Kee Kang1, In-Kyu Park2 and Yun-Jiaie Choi1; 1Seoul National University, Seoul, Korea (the Republic of); 2Chonnam National University Medical School, Gwangju, Korea (the Republic of).

Antibiotics have been used in many parts of the world such as medicine, food preserving, and livestock. Abuse of antibiotics had led to an increase in inanitbiotic resistancebacterial infections in modern society. For probiotics to replace antibiotics, enhancing antimicrobial ability against pathogens is one of the key technologies on probiotics. Probiotics are not digested by human enzymes although they produce various benefictfeects to host. Polymeric nanoparticles (NPs) have been used for biomedical application because of their interesting characteristics, which enables them to overcome various biological barriers. In this study, we prepared three types of probiotics NPs usingpolysaccharides. Three type of polysaccharidessuch as inulin as a polyfructose, dextran as a polyglucoseand pullulan as a polymaltose were used. Therepriotic nanoparticles (NPs) were prepared by conjugating hydrophobic groups such as phthalylic acid, acetic anhydride, and propionic anhydride to polysaccharides. 

The anisotropic nanoparticle arrangement investigated via scanning electron microscopy (SEM) manifests in optical effects on macroscopic areas easily visible by the bare eye with the help of polarized illumination. The circular dichroism quantified by spectroscopic ellipsometry (SE) is shown to be tuned by post-fabrication change of inter-layer rotation and mechanical deformation. Possible morphological changes upon deformation are discussed to explain the reversible spectral shift, as verified by finite-difference time-domain (FDTD) simulations.

As demonstrated, simple designs cost-effectively fabricated via bottom-up techniques even stand the comparison with e-beam structures for nanoplasmonic devices. Additional tunability of the strong optical effects by external stimuli facilitates broad-band applications and opens the door for sensing applications.

4:15 PM QN08.07.05
Controlling Size, Shape and Surface Functionality of Tailored Iron Oxide Nanocrystals for Biomedical Applications

Isabel Gessner and Sanjay Mathur; University of Cologne, Cologne, Germany.

The exceptional properties of materials at the nano-scale have aroused a huge increase in their demand for a broad variety of applications. During particle engineering, precise control over physicochemical properties of the material plays a key role, allowing for a reproducible fabrication of optimized and highly efficient vectors. Although significant advances have already been made in this area, much optimization is still needed to understand the often very complex interplay between reaction parameters and obtained material characteristics.

Herein, the employment of specific surface ligands as well as controlled variation of reaction parameters during thermal decompositions, coprecipitations and solvothermal reactions enabled the synthesis of iron oxide nanoparticles (IONPs) with highly homogeneous particle morphology (spherical-, cube-, ellipsoid-shaped), size (5-200 nm) and phase (Fe3O4, Fe2O3, α-Fe2O3). The stoichiometric ratio of the precursor as well as reaction conditions also determined the formation of complex Fe3O4@Fe2O3 core-shell structures that were proven by X-ray diffraction analyses and Rieffel refinements. A subsequent functionalization with chemical linkers and biomolecules could be monitored using X-ray photoelectron spectroscopy, infrared spectroscopy as well as UV-vis spectroscopy. This step-by-step approach allowed for a very application-oriented synthesis of highly efficient MRI contrast agents as well as cancer targeting vectors.

4:30 PM QN08.07.06
Auger-Limited Carrier Recombination and Relaxation in CdSe Colloidal Quantum Wells

Matthew Pelton1, Yana Wang2, Jordan Andrews3, Igor Fedin4, Dmitri Talapin4, Haixu Long1 and Stephen K. O'Leary4; 1Physics, University of Maryland, Baltimore, Maryland, United States; 2School of Engineering, The University of British Columbia, Kelowna, British Columbia, Canada; 3Center for Nanoscale Materials, Argonne National Laboratory, Argonne, Illinois, United States; 4Physics, University of Chicago, Chicago, Illinois, United States.

Using time-resolved photoluminescence microscopy, we show that two-exciton Auger recombination dominates carrier recombination and cooling dynamics in CdSe nanodotlest, or colloidal quantum wells. The electron−hole recombination rate depends only on the number of electron−hole pairs present in each nanodot, and is consistent with a two-exciton recombination process over a wide range of exciton densities. The carrier relaxation rate within the conduction and valence bands also depends only on the number of electron−hole pairs present, apart from an initial rapid decay, and is consistent with the cooling rate being limited by reheating due to Auger recombination processes. These Auger-limited recombination and relaxation dynamics are qualitatively different from the carrier dynamics in either colloidal quantum dots or epitaxial quantum wells. The results are determined as a function of the shell thickness. We find that the results exhibit a non-monotonic dependence on the shell thickness, initially decreasing, reaching a minimum for shells with thickness of 2–4 monolayers, and then increasing with further increases in the shell thickness.

4:45 PM QN08.07.07
Control of Ultraviolet Luminescence in Upconversion Nanoparticles

Peter Dawson, Vina Nguyen and Marek Romanowski; University of Arizona, Tucson, Arizona, United States.

Upconversion nanoparticles have matured significantly over the past decade. Preparative and post-preparative techniques have been developed to control migration, tunability, and transfer of energy. These recent advances show promise in the world of photochemical and photovoltaic systems. We demonstrate the ability to improve yield, spectrally tune, and to extinguish the UV luminescence by means of preparative controls. UV luminescence can be extinguished by means of energy migration through excess ytterbium or phonon-assisted energy transfer through secondary activator. We also demonstrate the ability to control the UV luminescence post-preparation by means of pulse-width modulation of excitation. 

Control of Ultraviolet Luminescence in Upconversion Nanoparticles

These Auger-limited recombination and relaxation dynamics are qualitatively different from the carrier dynamics in either colloidal quantum dots or epitaxial quantum wells. The results are determined as a function of the shell thickness. We find that the results exhibit a non-monotonic dependence on the shell thickness, initially decreasing, reaching a minimum for shells with thickness of 2–4 monolayers, and then increasing with further increases in the shell thickness.

SESSION QN08.08: Poster Session II: Colloidal Nanoparticle

PCC North, 300 Level, Exhibit Hall C-E

QN08.08.01
Internalized Polysaccharide Nanoparticles Enhanced Production of the Natural Antimicrobial Peptide in Probiotics

Chong-Su Cho1, Whee-Soo Kim1, Liang Hong1, Sang-Kee Kang1, In-Kyu Park2 and Yun-Jiaie Choi1; 1Seoul National University, Seoul, Korea (the Republic of); 2Chonnam National University Medical School, Gwangju, Korea (the Republic of).

Antibiotics have been used in many parts of the world such as medicine, food preserving, and livestock. Abuse of antibiotics had led to an increase in inanitbiotic resistancebacterial infections in modern society. For probiotics to replace antibiotics, enhancing antimicrobial ability against pathogens is one of the key technologies on probiotics. Probiotics are not digested by human enzymes although they produce various benefictfeects to host. Polymeric nanoparticles (NPs) have been used for biomedical application because of their interesting characteristics, which enables them to overcome various biological barriers. In this study, we prepared three types of probiotics NPs usingpolysaccharides. Three type of polysaccharidessuch as inulin as a polyfructose, dextran as a polyglucoseand pullulan as a polymaltose were used. Therepriotic nanoparticles (NPs) were prepared by conjugating hydrophobic groups such as phthalylic acid, acetic anhydride, and propionic anhydride to polysaccharides. 

The effects of phthalylinulin NPs (PINPs), phthalyldextran NPs (PDNPs), and phthalylpullulanNPs (PPNPs) on cellular and antimicrobial activities of probiotics using Pediococcus acidilactici(PA) and Lactobacillus plantarum(LP) will be mainly reported.

Firstly, PINPs were prepared by varying the molar ratio of phthalylic anhydride as a hydrophobic group to inulin, and then dialysis. We found that the internalization of PINPs into PA was size-, glucose transporter- and energy-dependent. Interestingly, PINPs-treated probiotics enhanced the production of antimicrobial peptide (pediocin) which is effective against both Gram-positive and Gram-negative pathogens. Particularly, the antimicrobial activity of PINPs-internalized probiotics was about 9-fold higher than that of untreated probiotics. Gene transcriptional analysis demonstrated the rise in pediocinactivity in PA internalized with PINPs was accompanied with the enhanced expression of genes related to
stress response and pediocinbiosynthesis genes.

To confirm the previous concept with a different type of polysaccharides, PDNPs were prepared. We observed the internalization of PDNPs into PA varied upon the transporters in probiotics and influenced higher antimicrobial activities against pathogens. The mechanism of enhancing antimicrobial property of PA was same as PA internalized with PNPs. Moreover, in PDNPs, the antimicrobial activity of PA internalized with PDNPs was also proved via animal experiments. PA internalized with PDNPs was able to suppress pathogenic infections in the gut by decreasing pathogens and increasing beneficial bacterial species which are related with prebiotics. Moreover, the composition of gut microbiota altered in PA internalized with PDNPs toward other groups. Therefore, we can conclude that higher pediocinproduction may suppress the pathogenic gut infection by altering the composition of gut microbiota.

Also, we used LP to confirm whether prebiotic NPs enhance the antibacterial ability of lactic acid bacteria as a common phenomenon because the LP is also capable of producing natural anti-microbial substances, plantaricin. When PPNNPs were added into LP, the PPNNPs were internalized into LP through energy-dependent and galactose transporter mechanism. Furthermore, more plantaricin the natural anti-bacterial peptide was secreted from the PPNNPs-internalized LP which was a similar mechanism as PNPs and PDNPs.

To the best of our knowledge, this is the first report of the concept of prebiotic NPs using polysaccharides to improve the antimicrobial activity of probiotics against pathogens. The results suggest that prebiotic NPs are new type of intracellular stimulator of probiotics to produce antimicrobial peptides, and can be used as a potential treatment of many gut disease associated with pathogens.

QN08.08.02 Oscillatory Plasmonic-Excitonic Nanomaterials Matthew S. Kirschner1, Wendu Ding1, Yuxiu Li2, Xiao-Min Lin3, Lin Chen1,3, George Schatz1 and Richard D. Schaller1,2; Northwestern University, Evanston, Illinois, United States; 3College of Chemistry and Molecular Sciences, Wuhan University of Technology, Wuhan, China; 4Argonne National Laboratory, Lemont, Illinois, United States.

We have designed nanomaterials that utilize vibrational modes to manipulate electronic interactions. Gold bipyramids with systematically varied localized surface plasmon resonance energies were functionalized with a J-aggregated thiacarbocyanine dye molecule. The resulting systems exhibit two hybridized states with clear anticrossing behavior that have a Rabi splitting energy of 120 meV. Gold bipyramids respond to photoexcitation with the generation of coherent acoustic phonons that cause oscillations in the plasmon resonance energy. In the coupled system, these photoinduced oscillations alter the metal nanoparticle’s energetic contribution to the hybridized system and, as a result, change the plasmon-exciton coupling. These modulations in the hybridization are present across a wide range of bipyramid ensembles. We discuss new analysis methods we have developed to better model this complex behavior. Such oscillatory plasmonic-excitonic nanomaterials offer a route to manipulate and dynamically tune the interactions of plasmonic/excitonic systems and unlock a range of potential applications.

QN08.08.03 Monodisperse, Phase-Pure MgFe2O4 Nanoparticles in Aqueous and Nonaqueous Media and Their Photocatalytic Behavior Roland Marshall; University of Bayreuth, Bayreuth, Germany.

We have developed a straightforward and fast non-aqueous microwave synthesis protocol using acetylacetone and acetate precursors to produce nanocrystals of the earth-abundant cubic spinel ferrite MgFe2O4[1], which is a promising material for both photoelectrochemical and photocatalytic water splitting under visible light irradiation due to its narrow band gap (~2.0 eV) and matching band positions. Highly-crystalline single phase nanoparticles with specific surface areas of around 200 m²/g and good colloidal stability in non-polar solvents were achieved, and the crystallite size can be tailored by postsynthetic heat treatment. Colloidal stabilization of the nanocrystals in nonaqueous media was realized either in-situ during synthesis or postsynthetically by surface capping with oleylamine and oleic acid. Phase transfer to aqueous media was performed employing citric acid and betaine hydrochloride, resulting in agglomerate-free and stable dispersions of citrate- and betaine-functionalized MgFe2O4 nanocrystals. Furthermore, a one-step synthesis of highly stable, water-dispersible colloids of MgFe2O4 was achieved using polyvinylpyrrolidone as stabilizer. Photocatalytic reactions will be presented evaluating the use of such highly stable ferrite colloids for solar energy conversion.

QN08.08.04 Rapid Detection of Inorganic Arsenic—A Real-Time Screening Method Based on De-Aggregation of Gold Nanoparticles Mike Bismuth1 and Giorgi Shitenberg2; 1Nanotechnology, Bar Ilan University, Ramat Gan, Israel; 2Agricultural Engineering, Volcani Center, Rishon Lezion, Israel.

The proposed research is designed as a response to the important challenge of monitoring inorganic arsenic (iAs+3) pollutants in the environment. Arsenic is one of the most serious environmental pollution problems of our time, specifically in developing countries, owing to its widespread in nature and high toxicity to living organisms. Long-term exposure causes serious physiological implications i.e., heart disease, stillbirth and cancer, requiring frequent determination in water, soil, agricultural and food samples. Traditional methods of detection, together with the advanced rapid techniques, possess major on-site limitation revealing their inadequacy for real-time analysis. Thus, an early and rapid detection of iAs+3 followed by corrective and/or prevention actions can lead to reduction of overall polluting impact to safeguard public health. The main goal of this project is to develop a generic integrated biosensing platform for the detection and quantification of iAs+3 pollutants in aqueous solutions at low-level concentrations. Gold nanoparticles (GNPs) play a key role in the development of smart sensors and detection agents. Their high surface to volume ratio and unique optical properties facilitate the development of highly sensitive analytical tools for biosensing applications accompanied with the advantages of on-site applicability. Addition of real water to the GNPs induces aggregation, attributed to the water’s high salinity content by screening the negative charges that stabilize them. Herein, our sensing approach is based on nanoparticles de-aggregation mechanism. Furthermore, more plantaricin the natural anti-bacterial peptide was secreted from the PPNNPs-internalized LP which was a similar mechanism as PNPs and PDNPs.

QN08.08.05 Cost Effective Bandgap Tunability Through Ordered Doped Zinc Oxide Nanostructure Films Clinton Davis and Hemali Rathnayake; Nanoscience, University of North Carolina at Greensboro, Greensboro, North Carolina, United States.

Zinc oxide (ZnO) has gained popularity over the years for being an inexpensive semiconductor while having a wide bandgap of 3.37 eV, making it a possible candidate for replacing other materials that have a higher cost. Furthermore, by adding dopant materials and/or nanostructures the bandgap can be precisely tuned for specific applications. While other doping options exist, cation exchange gives the advantage that the structure is already formed and is simply adding an extra step to the synthesis process. The doped-ZnO structures were analyzed with SEM and TEM to confirm homogeneity and the presence of the dopant material. The results show that through facile synthesis via cation exchange, shifts in the bandgap up to 0.1 eV were achieved consistently in dilute concentrations ranging from 1-5%. XRD was used to confirm the dopants were part of the crystalline lattice by the shift of the wurtzite peaks.

QN08.08.06 Matrix-Free Stabilization of DNA-Engineered Colloidal Crystals with Silver Ions Taegon Oh, Sarah S. Park and Chad A. Mirkin; Northwestern University, Evanston, Illinois, United States.

A post-synthetic method for stabilizing colloidal crystals programmed from DNA has been developed. The method relies on Ag+ ions to stabilize the particle-connecting DNA duplexes within the crystal lattice, essentially transforming them from loosely bound structures to ones with very strong interparticle links. Such crystals do not dissociate as a function of temperature like normal DNA or DNA-interconnected superlattices, and they can be moved from water to organic media or the solid state, and stay intact. The Ag+-stabilization of the DNA bonds is accompanied by a nondestructive ~25% contraction of the lattice, and both the stabilization and contraction are reversible with the chemical extraction of the Ag+ ions, by AgCl precipitation with NaCl. This synthetic tool is important, since it allows scientists and engineers to study such crystals in environments that are incompatible with structures made by conventional DNA programmable methods and without the influence of a matrix such as silica.
Control Over Colloidal Supercrystal Formation with Density Layers

Taegon Oh\textsuperscript{1}, Jessie C. Ku\textsuperscript{1}, Jae-Hyeok Lee\textsuperscript{2}, Mark C. Hersam\textsuperscript{3} and Chad A. Mirkin\textsuperscript{1}; \textsuperscript{1}Northwestern University, Evanston, Illinois, United States; \textsuperscript{2}Korea Institute of Toxicology, Daejeon, Korea (the Republic of).

With the advent of DNA-directed methods to form “single crystal” nanoparticle superlattices, new opportunities for studying the properties of such structures across many length scales now exist. These structure-property relationships rely on the ability of one to deliberately use DNA to control crystal symmetry, lattice parameter, and microscale crystal habit. Although DNA-programmed colloidal crystals consistently form thermodynamically favored crystal habits with a well-defined symmetry and lattice parameter based upon well-established design rules, the sizes of such crystals often vary substantially. For many applications, especially those pertaining to optics, each crystal can represent a single device, and therefore size variability can significantly reduce their scope of use. Consequently, we developed a new method based upon the density difference between two layers of solvents to control nanoparticle superlattice formation and growth. In a top aqueous layer, the assembling particles form a less viscous and less dense state, while below the particles assemble into well-defined rhombic dodecahedra superlattices of a critical size, they sediment into a higher density and higher viscosity sublayer that does not contain particles (aqueous polysaccharide), thereby arresting growth. As a proof-of-concept, this method was used to prepare a uniform batch of Au nanoparticle (20.0 ± 1.6 nm in diameter) superlattices in the form of 0.95 ± 0.20 µm edge length rhombic dodecahedra with body-centered cubic crystal symmetries and a 49 nm lattice parameter (cf. 1.04 ± 0.38 µm without the sublayer). This approach to controlling and arresting superlattice growth yields structures with a three-fold enhancement in the polydispersity index.

Synthesis and Characterization of the Solid Solution of Bismuth Sulfate, Potassium Bismuth Titanate and Barium Titanate (bnkt-bt) Perovskite Type

Emmanuel M. Rodriguez, Hector C. Montes and Gamaliel H. Cuevas; Universidad Autonoma de Ciudad Juarez, Juarez, Mexico.

The ceramic compound 0.94(0.8Bi\textsubscript{2}O\textsubscript{2}S\textsubscript{3} - 0.2Bi\textsubscript{2}O\textsubscript{3}, TiO\textsubscript{2}) - 0.06(BaTiO\textsubscript{3}), a lead-free piezoelectric perovskite type, was obtained by the sol-gel synthesis method in search for the single phase solid solution. Different starting combinations for this ceramic were used: i) nitrates as precursors (BNKT-BT), ii) bismuth acetate (BNKT-BT/BAc), iii) barium acetate (BNKT-BT/BAc) exposed to a shock gelation (SG) and iv) barium acetate with extensive gelation (EG). Once the solid solution was attained, a pressure less sintering (PLS) process at different temperatures (1000 °C, 1050°C, 1100°C) was performed. Samples were analyzed by X-ray diffraction and Raman spectroscopy to elucidate the grain morphology and crystallographic structure. Dielectric properties were measured using impedance and capacitance spectroscopy. Results are presented and discussed.

Next Generation Liquid-Crystal-Display Using Eco-Friendly InP Based Quantum-Dot Functional Color-Filters Ultra High Resolution LCD

Seung-Jae Lee, Ji-Eun Lee, Seo-Yoon Kim and Jea-Gun Park; Han-Yang University, Seoul, Korea (the Republic of).

Recently, the quantum-dot enhancement film (QDEF) has been introduced to improve the color gamut for LCD technology. Although this QDEF has been realized approximately zero cross-talk among the main three RGB colors, it leads to the loss of the light power of back light unit due to the resin and barrier sheets. Therefore, we introduce a simple and cost-effect structure for conventional blue LED back light unit (BLU) LCD having no QDEF but higher resolution and wider color gamut by mixing InP-QDs directly into the color filter. This structure is called quantum-dot-color-functional-QDCF.

To apply this proposed structure of QD-functional CFs to an ultra-high resolution LCD application, the color gamut performance of the LCD-like micro-displays using blue, green, and red CFs were estimated by using the CIE 1931 color space with Rec. 2020 and NTSC 1953 standards. Then it compared with that of the conventional LCD like micro displays using the white LED BLU and conventional CFs. The CIE coordinates of three types of micro-displays using green and red InP-QD color filters were calculated by using the PL spectrum information and the Matlab-based CIE coordinate calculator software. It was confirmed that green and red InP-QD emit a light at the wavelengths of 530, and 632 nm having narrow PL-FWHM of 39, 47 nm and high PL-QY of about 85, 55 %, respectively. The RGB color gamut of the conventional LCD-like micro-displays using bLED BLU and conventional CFs showed only 73.7 % (NTSC) and 55.1 % (Rec. 2020). On the other hand, the RGB color gamut of the proposed LCD-like micro-displays using the fabricated InP-QD function CFs presented a higher value of (NTSC) and 81.4 % (Rec. 2020) due to the zero cross-talk among PL spectrums of RGB colors. We will present in detail the RGB color gamut of InP-QD color filters in view point of optical properties of QDFs and LCD display operation.

Colloidal “Black” TiO\textsubscript{2} Nanoparticles and Mesoporous Films—Synthesis, Optical Properties, Processing and Photocatalytic Activity

Julia I. Chang\textsuperscript{1}, Tiago F. Silva\textsuperscript{2}, Fabian Naab\textsuperscript{3}, Bin Yuan\textsuperscript{4}, Xinchun Tian\textsuperscript{1}, Lin Ma\textsuperscript{5}, Soubik Banerjee\textsuperscript{1} and Ludovico Cademartiri\textsuperscript{1, 5, 6}; \textsuperscript{1}Materials Science & Engineering, Iowa State University of Science and Technology, Ames, Iowa, United States; \textsuperscript{2}Ria do Matão, Instituto de Física da Universidade de São Paulo, São Paulo, Brazil; \textsuperscript{3}Michigan Ion Beam Laboratory, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; \textsuperscript{4}Chemical & Biological Engineering, Iowa State University of Science and Technology, Ames, Iowa, United States; \textsuperscript{5}U.S. Department of Energy, Ames Laboratory, Ames, Iowa, United States.

A modified Collodin's method (I) was used to make colloidal “black” TiO\textsubscript{2} nanoparticles with high monodispersity. The absorption and luminescence of these particles were investigated. In order to study the photocatalytic performance of these nanocrystals we used them as building blocks to make, in two steps, TiO\textsubscript{2} mesoporous films by processing spincoated TiO\textsubscript{2} nanocrystal solids with plastics. Furthermore, to investigate the role of N-doping we demonstrate that plasma processing in N\textsubscript{2} plasma allows to simultaneously remove the ligands and dope homogeneously the mesoporous films with interstitial N. Lastly we will show how doping and processing affects the photocatalytic activity of the mesoporous films under both UV and visible light.

Metal-Free Phosphor Carbon Dots for Near UV Pumped White LEDs Through the Förster Resonance Energy Transfer

Dan Qiu\textsuperscript{1}, Wenhan Sun\textsuperscript{2} and Zaiqing Sun\textsuperscript{1}; \textsuperscript{1}Beijing Institute of Technology, Beijing, China; \textsuperscript{2}The Barstow School, Kansas City, Missouri, United States.

It is a critical challenge to develop a single phase phosphor with high luminous efficiency, Ra and suitable correlated color temperature (CCT). Comparing with traditional rare-earth based phosphors, carbon dots (CDs) possess various merits such as broad and tunable emission, excellent photostability and low cost and toxicity. Thus, CDs are ideal single phase phosphor materials, which emission can cover the whole visible spectrum. However, as-prepared CDs display strong blue emission with a broad tail in most cases. Towards making CDs as a single phase white-light phosphor, the emission at a longer wavelength has to be enhanced to balance the PL spectrum by increasing both the content and PL QY of long wavelength emissive CDs. On the other hand, more green and red emissive CDs can be excited by blue and green light, not UV light. Thus, it is necessary to further promote the energy transfer from blue emissive CDs to green and red emissive CDs. In this work, WCDs can be simply synthesized from the o-phenylenediamine (PDA) and the catechol in the mixture of n-amyl alcohol (NAA) and dimethylformamide (DMF) by one-step hydrothermal. The WCDs exhibits broad UV-vis light absorption band and strong excitation-dependent emission covering blue (450nm), green (520 nm) and red (600 nm) light with PL QY of 0.42, 0.55 and 0.67, respectively. We addressed that B-CDS, G-CDS,
and R-CDs were from the carbonization of pure catechol, PDA and the complexes of catechol and PDA (named as complexes CP). With the increase of the concentration of WCDs, the B- and G-CDs tend to form J-aggregates, R-CDs can organize in both H- and J- aggregate ways. The aggregates make thePLE spectrum shift, which leads to that the B- and G-CDs can be directly excited by UV light. Although R-CDs cannot be directly excited by UV light, it can emit red light via FRET route due to they have a spectral overlap between donor and acceptor. Finally, WLEDs device is constructed and demonstrate that WCDs can be used as the phosphor for white lighting due to its high CRI of 93, low CCT of 5453 K and high luminous efficiency.

QN08.08.13
Synthesis, Characterization and Thermoluminescence Response of Graphitic Carbon Nitride Quantum Dots Mario C. Perez, Miguel Vallejo, Cristian Gomez, Pablo V. Ceron, Jesus Bernal and Modesto A. Sosa; Univ de Guanajuato, Leon, Mexico.

Quantum dots (QD) are very small semiconductor particles, only several nanometers in size, so small that their optical and electronic properties differ from those of larger particles. Many types of quantum dot will emit light of specific frequencies if electricity or light is applied to them, and these frequencies can be precisely tuned by changing the dots’size, shape and material, giving rise to many applications. In the present work we present the synthesis for the obtaining of quantum dots from the Graphitic Carbon Nitride(g C3N4), this is a family of carbon nitride compounds with a general formula near to C3N4 (albeit typically with non-zero amounts of Hydrogen). Graphitic carbon nitride can be prepared by a heat treatment of the Urea, also known as carbamide. Urea is an organic compound with chemical formula CO(NH2)2 and have an important role in the metabolism of nitrogen-containing compounds by animals and is the main nitrogen-containing substance in the urine of mammals. It is a colorless, odorless solid, highly soluble in water, and practically non-toxic. We prepared the quantum dots with a Hydrothermal synthesis: can be defined as a method of synthesis of single crystals that depends on the solubility of materials in hot water under high pressure. The crystal growth is performed in an apparatus consisting of a steel pressure vessel called an autoclave. A morphological characterization was made with X-ray diffraction and SEM(Scanning Electron Microscopy) to our material (g C3N4), to reveal information about the crystal structure and chemical composition, before during and after the process. We also investigated the photoluminescence properties of g C3N4 quantum dots, which when excited with a wavelength λ = 366 nm we obtain a blue emission, also we made a UV-Vis characterization in order to observe the absorption band of the carbon nitride. The thermoluminescent response is also reported of this quantum dots in order to use it as an application in clinical dosimetry.

QN08.08.14
Fabrication of Porphyrin Assemblies and Biological Applications Jinhuan Wang and Yong Zhong; Key Laboratory for Special Functional Materials of the Ministry of Education, Kaifeng, China.

Porphyrins play a very important role in life activities and are known as "living dyes". Porphyrin molecules have high molar extinction coefficient, good bio-source, certain photostability and thermal stability, which have wide application in biological diagnosis and treatment. Porphyrin assemblies obtained by surfactant-assist self-assembly strategy drive non-covalent interaction offsetting the narrow absorption of monomer and improving the dispersity of water. Our research group are dedicated to the research of porphyrin assemblies in biotherapeutics and have achieved some exciting results. We used zinc meso-tetra(4-pyridyl)porphyrin (ZnTPyP) as activity function building block, ZnTPyP@(SiO2) composite structure was conducted through a combined surfactant micelle confined self-assembly and silicate sol–gel process with good biocompatibility and high single oxygen yield, and the apoptosis rate reached 90% after folic acid modification. In addition, Nitric oxide (NO) coordinates to central metal Zn ions of ZnTPyP nanoparticles and formed stabilized ZnTPyP@NO nanoparticles. We show that ZnTPyP@NO photosensitizers release highly reactive peroxynitrite molecules under light irradiation and exhibit enhanced antibacterial photodynamic therapy (APDT) activity. Recently, we have used 5,10,15,20-tetrakis(4-aminophenyl) porphyrin (TAPP) as optical active precursor, and the absorption spectrum of TAPP nanoparticles obtained by protonic acid-mediated assembly can broaden to about 1000 nm. The TAPP assemblies exhibit excellent morphology dependent NIR photothermal properties and effects. These consequences provide an important reference for the application of porphyrin self-assemblies in biological therapy.

QN08.08.15
Surface-Engineered Carbon Quantum Dots for High Quantum Yields and Their Photonic Applications Heetae Ahn, TaeGuen Kim and Na Young Ha; Ajou University, Suwon, Korea (the Republic of).

Fluorescent carbon quantum dots (CQDs) have been attractive from chemical inertness, facile modification, high water-solubility, low photo-bleaching, and excellent biocompatibility [1]. Here, to obtain surface-engineered CQDs with high photoluminescence (PL) quantum yield (QY), we employed a one-step microwave synthesis route based on citric acid and cyaniste. For various CQDs synthesized under different cysteine ratios, physical and chemical properties of CQDs were investigated by using the transmission electron microscope (TEM), the Raman, and the X-ray photoelectron spectroscopy (XPS) systems. From the TEM images, CQDs were spherical nanoparticles with the size in the range of 2 - 4 nm and the average lattice spacing of C-dots was 0.21 nm. The Raman spectra showed contributions from both the G-band (in-plane vibration of sp2 carbon) and the D-band (the presence of sp3 defects). In the XPS spectra, we found that the surface amino group of the CQDs increased with increasing the cysteine ratio. These surface-engineered CQDs sample with high density of surface amino groups exhibit high PL QY of ~76 %.

Glucose, used in this study is a kind of sugar and an important biological raw material that can be easily extracted in nature without any purification [2]. We fabricated glucose films doped with CQDs by spin-coating of the aqueous solution of CQDs and glucose. We also introduced a periodic nanostructure on the CQD film by using a nanoimprint lithography process [3]. The nanostructured CQD films showed strong enhancement of photoluminescence efficiencies at the specific spectral region depending on the periodicity of the nanostructured films. These nanostructured CQD films can be new light sources and photonic devices for health care.

QN08.08.16
Characterization and Analysis of Photocatalytic Performance of Potassium-Doped Titanium Oxide Nanostructures Prepared via Wet Corrosion of Titanium Microspheres So Yoon Lee1, Ji Zhang1, Lee-Woon Jang1, Zhihong Zhang1, Yueji Guo1, Samir Salameh1, Sanghoon Kim2, Dong Ick Son2, Jean-Pierre Locquet3 and Jin Won seo4; 1Institut für Werkstofftechnik, Universität Bremen, Bremen, Germany; 2Department of Physics, University Of Ulsan, Ulsan, Korea (the Republic of); 3Soft Innovative Materials Research Center, Korea Institute of Science and Technology, Wanju, Korea (the Republic of); 4Department of Materials Engineering, KU Leuven, Leuven, Belgium; 5Department of Physics and Astronomy, KU Leuven, Leuven, Belgium.

To date, Ti-based nanostructures have attracted a considerable amount of attention in photocatalysis, photovoltaics, electrochemical devices, electrochemistry, biointerfaces and corrosion because of their unique and diverse physico-chemical properties. Among them, potassium (K) incorporated Ti-based nanostructured oxides (KTOx) have received particular attention due to their wide range of applications as previously mentioned and because of their remarkable structure. KTOx materials are versatile, and through control of the K content, the electrical and optical properties can be fine-tuned. Moreover, whereas other metal oxide particles for photocatalysis such as CdS or GaP degrade and produce toxic end-products, the catalytic activity of KTOx only involves photosynthesis without additional chemicals, resulting in an environmentally friendly product. One of the main bottlenecks in using KTOx for diverse applications is the nanostructures fabrication, which generally involves a complicated process with low reproducibility and high cost of chemical modifications. The physical properties of KTOx, which are made by chemical modification greatly affected by the incorporated K in the obtained KTOx, thereby reducing the various the size and morphology of the nanostructures. On the basis of this result, the precious amount of the incorporated K is a key issue to control the desirable properties. Herein, the development of a process that allows simple synthesis and tuning of the desired morphology and properties is currently an important roadblock in this research field.

In this contribution, KTOx nanowires were prepared by wet corrosion process (WCP) and had their photocatalytic effects systematically characterized. In the synthesis of the KTOx, the potassium hydroxide (KOH) concentrations were varied during the WCP in order to obtain nanostructures with different surface areas and surface charges. Structural and crystalline properties of the KTOx were studied by means of X-ray diffraction, scanning electron microscopy (SEM), and transmission electron microscopy (TEM). Chemical composition was determined through X-ray fluorescence and energy-dispersive X-ray analysis. Photocatalytic performance was investigated as a function of the surface area, pH, and crystalline structures by studying the degradation of methylene blue, cardiogreen, and azorubine red dyes upon UV irradiation. Note that the heat treatment was carried out to increase the crystallinity of KTOx. The results demonstrated that the negatively charged crystalline KTOx nanostructures with high surface area showed significantly higher photocatalytic degradation when compared to KTOx with low crystallinity. The produced KTOx also showed greater efficiency for recovery and re-use. The heat treatment
Institute of Science and Technology, Barcelona, Spain. Optical Gain Modulation of a Colloidal Quantum Dot Film in an Electrical Device. EBSD, in-column BSD detectors, and STEM) are studied. In addition parameters for EDX mapping will also be presented, especially for elemental analysis of alloys. Details of the with spin coating followed by plasma cleaning, with controlled plasma composition. System parameters of spot size and accelerating voltage for different built-in detectors (ETD, EBSD, in-column BSD detectors, and STEM) are studied. In addition parameters for EDX mapping will also be presented, especially for elemental analysis of alloys. Details of the.

Colloidal sulfide nanocrystals have shown potential applications in a variety of fields, such as solar cells, biological labeling and imaging, catalysis, sensors etc. Currently, the translation of these nanocrystals to industrial products is greatly hampered by their lack of sustainability (e.g. low energy efficiency, copious waste, low yield etc.), scalability (e.g. one gram per batch), and high cost of synthesis. As previously identified by other members of the community, the high cost of production is the key bottleneck in the use of sulfide nanocrystals in solar cells.

We will show how a novel renewable liquid sulfur precursor, oleylammonium hydrosulfide, allows for a drastic improvement in the sustainability, scalability, and cost profile of the synthesis of a number of sulfide compositions (PbS, Bi$_2$Se$_3$, Ag$_2$S, Cu$_2$S, etc.). Specifically, this precursor allows for (i) the synthesis of monodisperse nanocrystals under ambient condition (rather than at high temperatures and inert conditions), (ii) facile recycling of excess precursor, (iii) high reaction yield (> 70%) at short reaction times, (iv) high product concentration (90 g L$^{-1}$), and facile scalability to > 100 g per batch.

**Numerical Modeling of Growth of Faceted Gold Nanoparticles by Chemical Salt Reduction Method** Guan-Ping Jhao and Kun-Dar Li; National University of Tainan, Tainan, Taiwan.

Over the past decades, gold nanoparticles have been extensively studied in many scientific and technological fields from organic photovoltaics, electronic conductors and catalysis, because of their unique optoelectronic properties. The optical and electronic properties of gold nanoparticles are tunable by changing the shape, size, surface chemistry, or aggregate state. In this research, a theoretical model based on the phase-field approach is established to simulate the growth of hexahedron gold nanoparticles by chemical salt reduction method. The nucleation, growth and clustering processes of gold nanoparticles are rebuilt in the numerical calculations. By tuning the numerical parameters, such as the concentration of solution, temperature, and the crystalline orientation, in the simulations, the effects of the relevant experimental parameters on the formation and evolution of faceted gold nanocrystals can be realized. From the numerical simulation results, it demonstrated that the morphologies of the nanocrystals were significantly affected by the anisotropic strength of the crystals, while the size or the aggregation rate of the nanoparticles were varied with the diffusion conditions of ions in the solution. These numerical parameters can be connected to the experimental factors, e.g. the pH or temperature. This numerical study could be useful to improve the understanding of the formation and evolution of faceted gold nanoparticles by chemical salt reduction method.

**Imaging Magnetic and Non-Magnetic Nanostructures Using a Field Emission Scanning Electron Microscope Including STEM Mode** Mary Saiini Devadas$^1$ and Stephen Blamé$^2$; $^1$Department of Chemistry, Towson University, Towson, Maryland, United States; $^2$Department of Physics Astronomy and Geosciences, Towson University, Towson, Maryland, United States.

An electron microscope can be used to image materials of nanoscale dimensions allowing for examination of size and shape characteristics, and chemical composition. We use an FEI Apreo scanning electron microscope to image magnetic (using electromagnetic mode) and nonmagnetic nanostructures (using electrostatic mode) of various metals (Au and Ag) and metal alloys (Fe/Cu, Fe/Au) using different sample preparation methods, and varying system parameters for optimal image quality and resolution. Samples are prepared with spin coating followed by plasma cleaning, with controlled plasma composition. System parameters of spot size and accelerating voltage for different built-in detectors (ETD, EBSD, in-column BSD detectors, and STEM) are studied. In addition parameters for EDX mapping will also be presented, especially for elemental analysis of alloys. Details of the imaging parameters and sample preparation for SEM imaging will be presented. We acknowledge funding from NSF MRI 1626326.

**QN08.08.20**

**Optical Gain Modulation of a Colloidal Quantum Dot Film in an Electrical Device** Jinhue Yu, Sushant Shendre, Weon-kyu Koh, Baiquan Liu, Songyan Hou, Chathuranga Hettiarachchi, Savas Delikanli, Pedro Hernández-Martínez, Muhammad D. Birowsouto, Hong Wang, Hilmi V. Demir and Cuong Dang; Nanyang Technological University, Singapore, Singapore.

In view of optical gain application, colloidal quantum dots (CQDs) are suffering from band-edge state degeneracy which requires multiple-exciton to achieve population inversion. However, fast and efficient Auger process in the CQDs containing multiple-exciton increases the lasing threshold and limits the gain lifetime. Here, by applying the electric field to the quasi-type II CQDs (CdSe/CdS/ZnS core/shell/shell) embedded in the Sawyer–Tower circuit, we have demonstrated tunable amplified spontaneous emission (ASE) threshold in a long-sought practical device where the CQDs sandwiched between two dielectric layers retain their high quantum efficiency as in parent solution (quantum yield of > 70%). Singly-charged CQDs help building up population inversion due to pre-existing electrons while strongly enhanced Auger recombination in multiple-charged CQDs (i.e., doubly charged exciton) stifmes the optical amplification. This approach allows us to fine-tune and achieve the optimal charging level to utilize the advantages of singly charged CQDs and reduce the adverse effect of doubly charged CQDs.

In addition to demonstrating tunable optical gain experimentally, we also developed a kinetic equation model to systematically analyze the electric field dependent light amplification behavior theoretically. The kinetic model not only confirms our experimental results but also presents to be a reliable tool for accessing the requirements of the charging level to achieve nearly zero-threshold gain in CQDs. The implications, then, to potential applications of our robust and environment-undependable tuning method are broad, from controlling exciton recombination dynamics to continuous wave (CW) or possibly electrically pumped CQD lasers.

**QN08.08.21**

**Doped Lanthanum Hafnate Pyrochlore Nanoparticles as Promising Candidate of Multicolor NUV Phosphors for Warm White Lighting** Santosh Gupta, Jose Zuniga, Maya Abdou and Yuanming Mao; The University of Texas at Rio Grande Valley, Edinburg, Texas, United States.

Designing nanoparticles (NPs) for multifunctional applications towards phosphors, scintillators and white light emitting diodes is highly challenging and demanding. In this work, we explored pyrochlore La$_2$Hf$_2$O$_7$ NPs singly and triply doped with Eu$^{3+}$, Tb$^{3+}$ and Dy$^{3+}$. The NPs singly doped with Eu$^{3+}$, Tb$^{3+}$ and Dy$^{3+}$ displayed red, green and yellow/orange-blue emission under ultraviolet irradiation, respectively. The concentration quenching study revealed non-radiative energy transfer in Eu$^{3+}$ doped La$_2$Hf$_2$O$_7$ NPs takes place via dipole-quadrupole mechanism whereas dipole-dipole interaction prevails in Tb$^{3+}$ and Dy$^{3+}$ doped La$_2$Hf$_2$O$_7$ NPs. Furthermore, when triply doped with Eu$^{3+}$, Tb$^{3+}$ and Dy$^{3+}$ ions, the La$_2$Hf$_2$O$_7$ NPs display beautiful warm white light as a new strategy with color tunability through doping percentage. Lifetime spectroscopy reveals the stabilization of Eu$^{3+}$ and Dy$^{3+}$ ions at La$^{3+}$ site at low doping concentration whereas a fraction of them migrates to Hf$^{4+}$ site at high doping concentration. For the La$_2$Hf$_2$O$_7$: Tb$^{3+}$ NPs, Tb$^{3+}$ ions are localized at Hf$^{4+}$ site at all doping concentrations. To sum, our complete spectrum of studies on the structure, UV excited photoluminescence, concentration quenching, local site spectroscopy of the La$_2$Hf$_2$O$_7$ NPs suggests that they are potential candidates as single-component multicolor-emitting phosphors.

**QN08.08.22**

**Cadmium Chloride Induced Synthesis of CdSe Nanoplatelets with Increased Thickness** Sotirios Christodoulou$^{1,4}$, Juan Climente$^1$, Josep Planellés$^2$, Rosaria Brescia$^1$, Mirko Prato$^1$, Beatriz Martín-García$^1$, Ali Hossain Khan$^{3,4}$ and Iwan Morel$^{1,2}$; $^1$Nanotechnology, Istituto Italiano di Tecnologia, Genova, Italy; $^2$Chemistry Department, Ghent University, Ghent, Belgium; $^3$Departament de Química Física i Analítica, Universitat Jaume I, Castelló de la Plana, Spain; $^4$IICFO - Institut de Ciencies Fotoniques, The Barcelona Institute of Science and Technology, Barcelona, Spain.

Two dimensional (2D) semiconductor nanoplatelets (NPLs) have received significant attention because of their unique narrow emission spectra and fast fluorescence
lifetimes.\textsuperscript{(1)} NPLs exhibit strong quantum confinement only along the vertical direction, which can be controlled with atomic precision.\textsuperscript{(1)} So far, blue (460 nm) and green (510, 550 nm) emitting colloidal CdSe NPLs have been intensely investigated,\textsuperscript{(1)} however one also requires thicker nanoplatelets, to cover the remaining visible spectrum and for instance obtain narrowband red emitters.

Here we present a novel synthetic approach to obtain thicker CdSe NPLs. The introduction of small amounts of CdCl\textsubscript{2} switches the 2D growth of 4.5 monolayer (ML) NPLs to a more isotropic 3D growth, resulting in a series of nearly monodisperse CdSe NPLs with thicknesses from 5.5 ML to 8.5 ML.\textsuperscript{(2)} The thickness tuning has been achieved by varying the reaction temperature between 280-320°C. The growth mechanism was studied by monitoring the reaction kinetics and control experiments of purified NPL dispersions, which suggest that the thickness increases via Ostwald ripening.\textsuperscript{(2,3)}

Structural characterization by X-ray diffraction and transmission electron microscopy revealed that the NPLs maintain a zinc-blende crystal structure, despite growing them for 2-5 hours at high temperatures. Optical characterization yielded emission peaks at 534, 585, 605 and 625 nm for thicknesses from 5.5 ML up to 8.5 ML, respectively. They show fast emission lifetimes of 5-11 ns and maintain narrow emission line widths of 9-13 nm (FWHM), making them one of the narrowest colloidal nanocrystal emitters currently available in this spectral range. Photoluminescence excitation spectra of the thicker NPLs revealed several high-energy peaks, which has been assigned using k.p calculations.

To summarize, we have successfully synthesized CdSe NPLs with increasing thickness by introduction of chloride ions in the synthesis. This has enabled us to obtain narrow, fast emitters over a wide spectral range, and yielded additional insights into both the synthesis mechanism as well as the NPL optoelectronic properties.

The Development of Novel Multimodal Magnetic Plasmonic Nanocomposites for Applications in Biosensing and Thermotheranostics
Shelley M. Stafford and Yurii K. Gun’ko;
Chemistry, Trinity College Dublin, Dublin, Ireland.

The combination of magnetic and plasmonic functionalities into one nanocomposite material is the basis of many new multifunctional nanomaterials with unique multimodal properties. Such materials retain all functionality of the magnetic component (e.g. for use in magnetic separation, as MRI contrast agents etc.), but with the added functionality of a plasmonic component (e.g. for use in SERS). The majority of magnetic-plasmonic nanomaterials are core-shell in structure, and this results in a number of inherent difficulties. Direct coating of a plasmonic metal onto a magnetic ferrite is difficult due to a mismatch in their crystal lattices. This result is achieved through a simple, highly reproducible co-precipitation method which can easily be extended to other magnetic ferrites and plasmonic metals.

In this work, a novel approach to magnetic-plasmonic nanocomposites has been developed through utilisation of two non-toxic and biocompatible polyelectrolytes, polystyrene-sodium sulfonate (PSS) and poly(allylamine hydrochloride) (PAH). Negatively charged PSS was used to stabilise superparamagnetic Fe\textsubscript{3}O\textsubscript{4} nanoparticles, while positively charged PAH was used to stabilise gold nanoparticles. The subsequent combination of these two moieties resulted in the formation of a magnetic-plasmonic nanocomposite that is bound entirely through electrostatics. This result is achieved through a simple, highly reproducible co-precipitation method which can easily be extended to other magnetic ferrites and plasmonic metals.

This approach was then extended to a number of systems, including gold nanostars with magnetite vesicles, multilayer magnetic plasmonic microspheres and magnetite coated plasmonic nanowires. We plan to explore the applications of these new nanomaterials in magnetic separation and sensing, as well as their potential applications in new drug delivery systems and in diagnostics and therapy (e.g. hyperthermia).

Identification and Semi-Quantification of Porphyrin-Silica Composite Nanoparticles Using Atmospheric Solids Analysis Probe Mass Spectrometry
Dongmei Ye, Casey Karler, Kylea Parchert, James Ricken, Bryan Carson, Curtis Mowry and Hongyou Fan; Sandia National Laboratories, Albuquerque, New Mexico, United States.

Porphyrins are vital pigments involved in biological energy transduction processes. Their abilities to absorb light, then convert it to energy, have raised the interest of using porphyrin nanoparticles as photo-sensors in photodynamic therapy processes. A recent study showed that self-assembled porphyrin-silica composite nanoparticles can selectively destroy tumor cells, but detection of the cellular uptake of porphyrin-silica composite nanoparticles was limited to imaging microscopy. Here we developed a novel method to rapidly identify and semi-quantify porphyrin-silica composite nanoparticles using Atmospheric Solids Analysis Probe-Mass Spectrometry (ASAP-MS). ASAP-MS can directly analyze composite nanoparticles were released. Vaporized nanoparticles were ionized and detected by MS. The cellular uptake of porphyrin-silica composite nanoparticles was identified to remove residual nanoparticles, the cell suspension was loaded onto the end of ASAP glass capillary probe. Upon heating, HeLa cells were degraded and porphyrin-silica composite nanoparticles were released. Vaporized nanoparticles were ionized and detected by MS. The cellular uptake of porphyrin-silica composite nanoparticles was identified using this ASAP-MS method, and their cellular accumulation was quantified. Thus, this study established a quantification toolkit for porphyrin nanoparticles.

Block Copolymer Templated Nanostructured Metal Oxides Through Atomic Layer Deposition
Hongyou Fan\textsuperscript{1}, Charles Fan\textsuperscript{2} and Ying-Bing Jiang\textsuperscript{3}; \textsuperscript{1}University of New Mexico/Sandia National Laboratories, Albuquerque, New Mexico, United States; \textsuperscript{2}Albuquerque Academy, Albuquerque, New Mexico, United States; \textsuperscript{3}Angronm Thin Film Technologies, Albuquerque, New Mexico, United States.

Design and engineering of metal oxide materials with controlled nanostructures present important applications in nanoelectronics and catalysis. Here we report a simple atomic layer deposition process to prepare uniform metal oxide nanostructures using self-assembled block copolymer polystyrene-b-polyvinylpyridine (PS-PVP) as the structure-directing scaffold. PS-PVP self-assembles in mixture of organic and water forming varied mesostructures such as micelles, tubes, and vesicles. These mesostructures have hydrophilic external interface that can further react with metal oxide precursors. Atomic layer deposition (ALD) was carried out to the hydrophilic interface of the mesostructures to grow metal oxide layers. Different oxides including TiO\textsubscript{2} and SnO\textsubscript{2} have been demonstrated at varied processing conditions. By altering ALD cycles, thickness of the metal oxide layer can be tuned. The capability of exerting rational control over dimension and composition of nanostructured metal oxides through ALD processes provides new opportunities in nanoelectronics and catalysis.

Sandia National Laboratories is a multi-mission laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-AC04-94AL85000.

Increasing Magnetization in a Hollandite Multiferroic by Fe Doping—Structural, Magnetic and Dielectric Characterization of Nanocrystalline BaMnxFe3Ti4O12
Frederick A. Pearshall\textsuperscript{1} and O'Brien Stephen\textsuperscript{2}; \textsuperscript{1}Chemistry, City College of New York, New York, New York, United States; \textsuperscript{2}Chemistry, The Graduate Center of the City University of New York, New York, New York, United States.
Device Lifetime Study of Colloidal Quantum Dot Light-Emitting Diodes

Seong-Yong Cho; Department of Materials Science and Engineering, Myongji University, Yongin, Korea (the Republic of).

Quantum dot light emitting diode (QD-LED) has attracted a great attention due to its high color purity, and solution processibility. However, understanding on how QD-LED fails is still lacking. Electroluminescence (EL) of QD in the sandwich structure between charge transport layers already reached 20% external quantum efficiency (EQE), but down conversion display is only available in the consumer market. Due to complex device architecture of QD-LED compared to down conversion type QD emitter, understanding how QD fails is challenging. In this study, we fabricated QD-LEDs with typical core/shell structure and our double heterojunction nanorod. We observed driving bias dependent device lifetime which reflect that there are universal degraded part in QD-LEDs. By measuring EL of QD-LEDs and PL of QD emitter film simultaneously, we revealed that QD film is still emitting PL despite of EL quenching. This clearly indicates that charge transport layer aging is main reason for the QD-LED degradation. Lastly, to overcome organic charge transport layer issue, we also suggested NiO hole transport layer to replace organic charge transport layer. By passivating NiO surface, device performance of NiO HTL based QD-LED was enhanced by factor of 5.

Binary and Ternary Metal Chalcogenide Nanoplates with Janus Structural Motif via Asymmetric Cation Exchange

Jongsik Park and Kwangyeol Lee; Chemistry, Korea University, Seoul, Korea (the Republic of).

Chemical transformations via postsynthetic modification of colloidal nanocrystals have largely investigated, because those approaches can provide an unusual route to elaborately composition-controlled nanostructures while maintaining the overall structure of template. In particular, the asymmetric cation exchange reaction could be achieved by imposing a significant kinetic hurdle to the cation exchange reaction. The different atomic arrangements of the core and crown in core-crown structures might further differentiate the surface energies of originally identical cation exchange sites, leading to different reactivities of these sites. Herein, we suggest that the synthesis of binary and ternary metal chalcogenide nanoplates with Janus structural motif via asymmetric cation exchange. This synthetic methodology exploiting cation exchange of surface-passivated semiconductor nanoparticles could fabricate the numerous symmetry-controlled Janus heterostructures.

Detection Limit of a Portable Raman Spectrophotometer for SERS Detection of GunShot Residue

Ellen Hondrogiannis, Mary Sajini Devadas, Evan Thayer, Wilson Turner and Dustin Baird; Department of Chemistry, Towson University, Towson, Maryland, United States.

The purpose of this work is the attribution of gunshot residue (GSR) to manufacturer using Surface Enhanced Raman Spectroscopy enabled by a bench top portable spectrometer. We propose nanostructures that span zero- (metal and magnetic clusters), one- (rods), and three- (microbars) dimensions, synthesized in our laboratory. These substrates are chosen because they have charge transfer capabilities with the organic analytes present in the GSR or electromagnetic field enhancements to provide a basis for this approach. This study presents the LOD measurements of the SERS signal from two organic compounds of GSR, diphenyl amine and ethyl centralite, with the gold and silver nanoparticles.

General Synthetic Strategy for the Fabrication of Cu-Based Bimetallic Two-Dimensional Hollow Nanostructures

Shutang Chen and Gugang Chen; Honda Research Institute USA Inc., Columbus, Ohio, United States.

Bimetallic hollow nanostructures have become promising new candidates in biomedicine, fuel cells, and gas sensors due to their porous structures and the synergistic effect between two metals. Currently, galvanic replacement is a powerful strategy to fabricate bimetallic hollow nanostructures. However, most galvanic replacement literatures so far employ costly metal nanostructures as the template and involve complicated purification process. Here, we develop a one-step general synthetic method based on galvanic replacement for the fabrication of Cu-based bimetallic two-dimensional hollow nanostructures. Firstly, the copper nanosheets are prepared at 300 °C, and then metal ions (M = Au, Pt, Pd) with higher oxidation potential were injected into Cu nanosheets solution between 80 °C to 150 °C. Because Cu2+/Cu potential is less than that of M+/M, Cu atoms on nanosheets’ surface are replaced with M due to galvanic replacement; sequentially the interior Cu atoms will diffuse to outside owing to Kirkendall effect, which lead to the formation of hollow nanostructures. Compared to utilize other metal nanosheets as the template, our method consists of three advantages: 1. reduces the cost; 2. avoids the template separating process; 3. enriches two-dimensional bimetallic hollow nanostructures. These two dimensional hollow nanostructures with large surface area can be potentially used for the fabrication of gas sensors and as catalysts for converting CO to chemicals.

Stable Au-Pd Heterostructures for High Reflective Index Sensitivity

Zachary J. Woessner and Sara Skrabalak; Indiana University, Bloomington, Indiana, United States.

Plasmonic noble metal nanoparticles show great promise in a variety of applications, ranging from theranostics to chemical sensing. Chemical sensing is possible through observing changes in the localized surface plasmon resonance (LSPR) in response to changes in environment. Au and Ag structures have notably high refractive index sensitivity (RIS), with Au structures typically being used for their greater structural stability relative to Ag. However, due to the high mobility of Au atoms, many structures degrade rapidly due to morphology changes. As we show, the RIS and structural stability of Au structures can be increased through the addition of Pd to such nanostructures. Specifically, Pd is directed to the tips of stellated Au nanostructures through kinetically controlled overgrowth. Interestingly, changing the capping agent switches the Pd deposition mode, producing stellated Au nanorods controllably coated with Pd. The RIS of these structures were measured by standard methods and compared to all-Au stellated structures. The results were analyzed as a function of structure (branching symmetry and particle size) as well as bimetallic distribution and Pd loading. This analysis is aided by simulations of the anticipated optical properties. This work is coupled with measurements of the brenchtop stability of structurally similar all-Au and Au-Pd stellated nanostructures. Collectively, this work demonstrates that the introduction of Pd to Au nanostructures both boosts RIS and structural stability, moving the design of LSPR sensors beyond the all-Au standard.

A Method for Quantification of Particle Shape in CMP Slurry and the Investigation for the Relationship Between the Polishing Behaviors and These Shapes

Mami Kubota1, 2, Christopher Netzband2, Keichi Takanashi3 and Kathleen Dunni4; 1SUMCO Corporation, Imani, Japan; 2SUNY Polytechnic Institute, Albany, New York, United States.

The silicon wafers used as substrates for semiconductor devices are required to be of increasingly stringent quality because of the downscaling of these devices. Particularly, the
wafer surface quality, including the flatness and the local roughness, is critical in avoiding defects in the final products. These necessary surface perfections are achieved via chemical mechanical planarization (CMP) in the wafer manufacturing process, and repeatedly during both FEOL and BEOL flows to maintain global planarity between unit process steps. The SEM images were analyzed by Image J, with background modification and binarization by auto setting of local threshold using the Otsu method, and some overlapped edges were separated using Watershed method. Using this optimized filtering and detection process, it was possible to differentiate the edges of even the particles that were overlapped. Image analysis time was also decreased 1/5 by building a macro for these processes. The wafer polishing quality (the removal rate) was determined and compared with key particle shape values (diameter, particle size distribution, area, circularity etc…). The removal rate decreased when the particle ovality approached that of a perfect Circle. It seems that the surface oxidation as a chemical effect by particles decreased because the surface area of particles is lowest for a perfect sphere. However, there weren’t any significant differences found relating the wafer quality and the other particle shape values. More subtle effects based on these parameters might be obtained using a more sophisticated analysis method, such as a multiple regression analysis.

In conclusion, by optimized the processing method using the Image J, the quantitative value of particle parameters could be calculated from SEM images, while also improving the overall accuracy with less processing time. More subtle effects based on these parameters might be obtained using a more sophisticated analysis method, such as a multiple regression analysis.

Clustered Magneto-Plasmonic Nanoparticles for Amplified Surface Enhanced Raman Scattering Bio-Imaging

Clustered Magneto-Plasmonic Nanoparticles for Amplified Surface Enhanced Raman Scattering Bio-Imaging

Although many gold-based nanoparticles display strong NIR LSPR absorption properties and corresponding heat conversion efficiencies (HCE) as high as 80%, they are costly to produce and their size often exceeds 100 nm, a contentment trait in the context of most biological applications. Moreover, prolonged exposure to heat can result in the modification of the gold nanoparticles’ morphology, leading to changes in their LSPR absorption profile and a partial or complete loss of the heat conversion properties. These limitations are overcome with copper sulfide plasmonic nanoparticles. They absorb light over a broad NIR spectral range, are smaller, stable under prolonged optical excitation, significantly less expensive to synthesize, and display nearly analogous heat conversion capabilities compared to gold nanoparticles.

In this work, a straightforward method to synthesize monodisperse PEGylated copper sulfide nanoparticles of pure covellite (CuS) phase, featuring strong localized surface plasmonic resonance absorption in the near-infrared and flexible surface chemistry, imparted by monomethyl ether polyethylene glycol molecules, is developed and optimized. These nanoparticles show a remarkable photothermal heat conversion efficiency (HCE) of 71.4% -evaluated in water upon laser excitation at 806 nm—, which is among the highest for CuS systems and rivals that of plasmonic noble metal nanostructures.

A specific merit of the proposed green synthesis approach resides in the dispersibility of the CuS nanoparticles in water and media mimicking biological fluids. A prominent advantage of these nanoparticles as photothermal agents is represented by the minimal amount of optical energy scattered or re-emitted through luminescence, leading to nearly absolute conversion of light into heat.

Altogether, the properties featured by the developed CuS nanoparticles (small size, size monodispersity, colloidal stability in biological media, tunability of the surface chemistry, and outstanding light-to-heat capability) make the system an ideal candidate for a stand-alone photothermal agent and/or a valuable building block for multipurpose biomedical nanomaterials. Another relevant finding for the photothermal community, stemming from a critical evaluation and mathematical modeling of the material’s properties and measurement methodology, is that calculated HCE values drastically depend on the parameters characterizing the experimental setup used to determine them. In particular, the dependence on the solvent absorption and other experimental conditions, such as sol concentration and optical path, calls for some degree of standardization on the measurement of HCE for potential photothermal agents in order to make the data reported universally and reliably comparable.
Raman scattering (SERS) effect simultaneously. Plasmonic nanostructures have attracted much attention due to SERS effect. The areas with localized and enhanced electromagnetic field become “hot spots” where show high SERS activity. Recently, Raman reporter-embedded plasmonic nanostructures have been investigated for advanced signal reproducibility and sensitivity [1] which are affected by uniformity of morphology and size. [2] However, magneto-plasmonic nanoparticles have been rarely reported for SERS bio-applications. Thus, there is a great demand in synthesis of magneto-plasmonic nanoparticles as an attractive SERS nanoprobe.

Here we report a clustered magneto-plasmonic nanoparticle as a candidate for ultra-sensitive and stable SERS biosensing. Superparamagnetic iron oxide colloidal nanocrystal clusters (SPION-CNCs) which are about 150 nm in diameter are synthesized by modified polyol method without surfactant. The SPION-CNCs are composed of many primary particles approximately 10 nm in size to overcome superparamagnetic-ferromagnetic transition and particle aggregation problem. [3] Subsequently, we cover the thin SiO₂ layer onto the surface of SPION-CNCs. Au seeds (3~4nm) are attached onto the SiO₂ layer. For obtaining high signal reproducibility and sensitivity, we execute the homogeneous Au seed-mediated growth procedure. We confirm that Au nanoparticles are densely decorated on the shell after growth process with inter-spacing between Au nanoparticles of 1~2 nm. During the growth step, we conjugate the Raman reporter onto the surface of Au nanoparticles. As a result, the Raman dye-embedded magneto-plasmonic nanoparticles exhibit robust and ultra-sensitive SERS signals based on their uniform size, morphology and existence of abundant “hot spots”. Finally, we show that the magneto-plasmonic nanoparticles can be used efficiently for bio-imaging, bio-detecting and bio-separation about specific biomarkers. This nanoparticle with novel structure offers a great strategy for image-guided diagnosis and separation of target biomarker.

Optimization of Various EHD-Jet Spray Modes for QD Thin Films in Quantum Dots Light-Emitting-Diodes
Weon-Soon Choi and Canh Tuan Nguyen; Hoseo University, Asan, Korea (the Republic of)

In recent years, colloidal quantum-dots based light-emitting diodes (QD-LEDs) have been considered as the attractive display device because of remarkable electrical/optical characteristics of colloidal quantum-dots. QD-LEDs are of particular interest due to their wide-range color tune ability, high brightness and good color purity by narrow emission bandwidth. Challenges remain, however, in achieving the necessary multilayer device structures using printing process for display applications. Conventional vacuum evaporation deposition to fabricate QLEDs was unsuitable for heavy metal like QDs materials. Besides, the spin coating has been the most popular approach to fabricating QD-LEDs devices due to the simple method for achieving a near monolayer of the nanoparticle. However, the relatively high cost of QDs and the loss of more than 96% of the QD solution during spin coating are strong reasons to search for an alternative deposition route capable of patterning and consuming minimum amount of QD materials. QDSEs were synthesized with a trochoidal electrohydrodynamic (EHD)-jet spray technology and were applied to all solution-processed QD-LEDs. Three different spray modes of (i) ‘Big circular type’, (ii) ‘Spiral line’, and (iii) ‘Straight line’ were investigated to obtain uniform QD thin films. Sprayed QD pattern was also controlled with the various processing parameters to obtain uniform surface morphology. A QD-LED has a structure of ITO/PEDOT:PSS/PVK/ EHD-sprayed QDs/ZnO/Al. Using a unique spraying technique, a QD-LEDs was successfully fabricated and demonstrated a maximum of luminance of 7801 Cd/m², a maximum current efficiency of 2.93 cd/A, the maximum EQE is 1.41%. We believed that EHD jet printing will pave the way for the fabrication of multilayer structure devices, allowing for various solvents, toward to a direct patterning, and convenient and optimal for commercial production.

QN08.08.37
Novel Photocatalyst Gold Nanoparticles with Dumbbell-Like Structure and Their Superiorly Photocatalytic Performance for Ammonia Borane Hydrolysis
Zou Xiuxi, Zhu Mingyun and Dai Yunqian; Southeast University, Nanjing, China.

Gold nanoparticles (Au NPs) have attracted remarkable research interest in heterogeneous catalysis due to their unique physical and chemical properties. However, only small-sized Au NPs (<7nm) exhibit promising catalytic activity. In this work, dumbbell-like Au NPs (D-Au NPs) with an average size of 37 x 11nm were prepared by a secondary seed-mediated growth method to serve as novel photocatalysts for ammonia borane (AB) hydrolysis. A maximum of luminance of 7801 Cd/m², a maximum current efficiency of 2.93 cd/A, the maximum EQE is 1.41%. We believed that EHD jet printing will pave the way for the fabrication of multilayer structure devices, allowing for various solvents, toward to a direct patterning, and convenient and optimal for commercial production. The electrical properties of flexible nano-metal polymer were tested and the highest improvements in breakdown strength and energy density of 33 and 58 %, respectively were measured with 0.05 wt.% Ag content and APS as a stabilizer.

QN08.08.38
Impact of Stabilizer on In Situ Formation of Ag Nanoparticles in Polyvinylidene Fluoride (PVDF) Matrix
Maryam Sarkarg; Amira B. Meddeb1,2, Michael Lanagan1 and Zoubaida Ounaies1,3; 1The Pennsylvania State University, University Park, Pennsylvania, United States; 2Materials Research Institute, University Park, Pennsylvania, United States; 3Department of Mechanical and Nuclear Engineering, University Park, Pennsylvania, United States.

Materials based on nanometer-sized metal particles have received increasing attention due to their novel electronic, magnetic, and optical properties. Metallic nanoparticles have a wide range of applications in biomedicine, optoelectronics, energy, and industrial applications such as catalysis, automotive, aerospace and electronic components. Finely-dispersed metallic nanoparticles in a polymeric matrix can act as dielectric insulators due to their small size and very low surface charges. Achieving a uniform dispersion of nanoparticles in the polymer is a crucial step to obtain the optimal electrical properties for the given nanocomposite. In this research work, In situ synthesis of Ag nanoparticles in polyvinylidene fluoride (PVDF) was investigated using different stabilizers such as 3-aminopropyltrimethoxysilane (APS) and 1-dodecanethiol (thiol). Although PVDF is a matrix, it also functions as a stabilizer. Results of UV-vis spectroscopy showed that when APS or PVDF was used, Ag nanoparticles were formed. Yet no formation occurred when thiol was used due to the complexion of Ag+ ions by thiol. Polar groups on stabilizers has an important effect on complexion process. APS, a nitrogen-based ligand, has hard base character inhibiting the complexion of Ag+ and APS. Consequently, Ag+ ions are reduced to Ag nanoparticles in N,N dimethyl formamide (DMF), which acts as a solvent and reducing agent. The electrical properties of flexible nano-metal polymer were tested and the highest improvements in breakdown strength and energy density of 33 and 58 %, respectively were measured with 0.05 wt.% Ag content and APS as a stabilizer.

Silver Chalcogenide Colloidal Quantum Dots for Room Temperature Photodetection in the Mid-Wavelength Infrared
Shihab Haflı1, Michael Scimeca1, Peter Zhao2,3, Ayasakata Sahu1 and Dong Kyun Ko2; 1Department of Electrical and Computer Engineering, New Jersey Institute of Technology, Newark, New Jersey, United States; 2Department of Chemical and Biomolecular Engineering, New York University, Brooklyn, New York, United States; 3Department of Chemical Engineering, Cooper Union, New York, New York, United States.

Lately discovered silver chalcogenide colloidal quantum dots with tetragonal crystal phase exhibit promising optical properties in the mid-wavelength infrared. Although colloidal synthesis of uniform sizes and shapes has been reported, the investigation of their optoelectronic properties as an active layer in photodetector devices has been scarce. Herein, we present silver selenide quantum dot photoconductive photodetectors that exhibit high responsivity in the mid-infrared under room temperature operation. We investigate the effect on the ligands as well as bias-, temperature- and spectral-dependent photoresponses. Our work demonstrates the potential of silver chalcogenide colloidal quantum dots as an promising mid-wavelength infrared absorber for the development of thermal infrared sensors and imagers with low size, weight, power consumption, and cost.

Omnidispersible Hedgehog Particles with Multilayer Coatings for Multiplexed Biosensing
Douglas G. Montiqu1, Joong Hwan Bahng1,2, Aydin Eskişi1,3, Harrison Hou1 and Nicholas Kotos1,2,3; 1Chemical Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 2Biomedical Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 3Materials Science and Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

Hedgehog particles (HPs) resembling the spiky geometry of pollen grains reveal surprisingly high dispersion stability in both polar and nonpolar media. This property designated
as omnidispersibility, is attributed to the substantial reduction of van der Waals interactions between particles coated with stiff nanoscale spikes compared to particles of the same dimensions with smooth surfaces. One may hypothesize but it remains unknown, however, whether HPs modified with polymers or nanoparticles (NPs) would retain this property. Such modifications will expand the functionalities of HPs making possible their utilization as omnidispersible carriers. We show that HPs carrying dense conformal coatings made by layer-by-layer (LBL) assembly maintain dispersion stability in environments of extreme polarity and ionic strength. Additionally HPs, surface-modified by multilayers of polymers and gold NPs are capable of surface enhanced Raman scattering (SERS) and overcome the limited colloidal stability of other SERS probes. The agglomeration resistance of HPs leads to greater than one order of magnitude increase of SERS intensity compared to colloids with smooth surfaces and enables simultaneous detection of several targets in complex media with high ionic strength. Omnidispersible optical active colloids open the door for rapid multiplexed SERS applications in biological fluids and other applications.

Conductive Nanoparticle Superlattices Grow—Insights from In-Situ Real-Time X-Ray Scattering at the Liquid/Air Interface Santanu Maiti1*, Alexander Andre, Somi Maiti, Jan Hagemöcher, Andre Maier, Rupak Banerjee, Andrei Chumakov, Oleg Kovalov, Marcus Schelle and Frank Schreiber2*
1Forschungszentrum Jülich, Juelich, Germany; 2European Synchrotron Radiation Facility, Grenoble, France; 3Indian Institute of Technology Gandhinagar, Gandhinagar, India; 4University of Tuebingen, Tuebingen, Germany.

Directional cross-linking of organic semiconductors (OSC) with nanocrystals (NC) produces superlattices exhibiting novel structural and electronic properties1–2. Here, we discuss the kinetics of spherical PbS NCs during self-assembly and ligand exchange to form coupled organic-inorganic superstructures (COINS) at the liquid/air interface, monitored by in-situ grazing incidence small angle X-ray scattering (GISAXS)1. Finally, we present the result on the in-situ formation of conductive, iso-oriented mesocrystalline superstructures with cubic PbS NCs at the air-liquid interface, investigated simultaneously by GISAXS and grazing incidence X-ray diffraction (GIXD) in real-time3–5. In both cases, we observe a continuous contraction of superlattices with elapsed time, preserving their superlattice symmetries (bcc for spherical and sc for cubic shape NCs). We attribute these contractions to the complete replacement of native oleic acid ligands with small OSC cross-linkers like tetrabutylammonium tetrathiafulvalene-carboxylate (TTFDA), cobalt/copper 4,4’,4”,4'''-tetraaminophthalocyanine (CoTAPc/CuTAPc). Such investigations provide crucial visualizations into the formation mechanism of such nanostructures, which already find practical applications.

Simple Microwave-Assisted Synthesis of Fluorescent and Multi-Functional Carbon Quantum Dots from Polyamidation Monomer Set Binhee Kwon, Insik In, Geumbi Jeong, and Soongmin Park; Korean National University of Transportation, Chungu-si, Korea (the Republic of).

Recently, carbon quantum dots (CQDs) have been received considerable attentions due to their fascinating optoelectrical properties and inherent non-toxicity to human bodies and environments. Synthetic approaches of alternative materials of semiconductor or inorganic quantum dots (QDs) in many applications. Various synthetic protocols such as top-down and bottom-up have been proposed to synthesize highly fluorescent CQDs from a variety of starting materials. Among these, microwave-assisted bottom-up synthesis of CQDs have several outstanding benefits because various natural or synthetic ABx or Ax/By polyamidation monomer set (A: -COOH, B: -NH2) could be utilized to formulate CQDs with control of their surface functionalities and high fluorescent within short microwave operation time less than 10 min. The construction of CQDs from polyamidation monomer sets is regarded to proceed through both polyamidation and carbonization and it has been confirmed that polyamidation monomer sets possessing ‘branching point’ are suitable for the facile synthesis of CQDs. Synthesized CQDs are soluble in solvent media, highly nontoxic in physiological environments, strongly fluorescent, which is revealing that CQDs can be exploited as various applications including fluorescent cellular imaging, photocatalysis, fluorescence on/off sensors, up-converting top layers on solar cells, drug-delivery systems, fluorescent polymer nanocomposites, etc.

QN08.08.43
Thermal Excitation Control of Instantaneous Photon Emission in Semiconductor Nanocrystals Benjamin T. Diroll; Argonne National Laboratory, Lemont, Illinois, United States.

Photon emission from many materials at low temperature is governed by optically passive “dark” states. For example, cadmium selenide nanocrystals are observed to have “dark exciton” photoluminescence lifetimes of 1 microsecond at liquid helium temperatures. This work presents ultrafast photoluminescence spectroscopy which demonstrates that an electronic excitation followed by subsequent, time-delayed IR excitation of cadmium selenide nanocrystals converts excitons from the “dark” state, with slow emission, to the spin-allowed “bright” exciton state, which increases the instantaneous rate to <100 ps. The IR control pulse excites organic ligand molecules on the nanocrystal surface, which act as antennae, leading subsequently to heat transfer to the inorganic particle. The IR control pulse can be arbitrarily delayed to induce changes in the instantaneous rate with less than 10 ps temporal resolution. This technique has the ability to dramatically re-shape the distribution of photon emission events in ensembles and single photon sources.

Biosynthesis of Functionalized Green Gold Nanoparticles Using a Hydroxylated Tetraterpenoid for Anti-Cancer Applications Jiulong Li1,2, 1Northeastern University, Boston, Massachusetts, United States; 2Zhejiang University, Hangzhou, China.

Colloidal Nanoparticles (e.g., gold nanoparticles) are a type of especially promising candidate nanomaterials in nanomedicine due to their ease of synthesis, versatility in surface modification and relative cytocompatibility. Functionalized AuNPs are especially useful for therapeutic strategies for cancer. Understanding the synthesized mechanisms and cell–nanoparticle interactions are important for the use of AuNPs. Here, we detail the biotransformation mechanism of Au(III) into AuNPs using hydroxylated deinoxanthin (DX) from the extremophile Deinococcus radiodurans based on the results of HR-TEM, EDS, FTIR, NMR, XPS and LC-MS. The biosynthesis of DX–AuNPs was attributed to the deprotonation of the hydroxyl groups of DX. The deprotonated 2-ketodeinoxanthin (DX3) served as a capping agent to stabilize the AuNPs. The functionalized DX–AuNPs exhibited significant anticancer activity by altering gene expression levels and regulating cell membrane integrity and metabolism, increasing ROS generation, autophagy, and apoptosis in cancer cells. These novel findings provide significant insight into the biomimicking mechanism of green AuNPs functionalized with natural products, which possess enhanced anticancer activity. The biomedical AuNPs could have therapeutic potential in the treatment of cancer, as well as numerous other medical applications.

QN08.08.45
Fabrication of Gold Nanoparticles of Different Sizes and Its Interaction in Aquatic Phase Rosymer Rivera-Colón and Sonia J. Bailón-Ruiz; Chemistry, University of Puerto Rico in Ponce, Ponce, Puerto Rico.

Gold nanoparticles (AuNPs) are highly used in recent times due to their fascinating optical properties. AuNPs have several applications in the medical context as drug delivery, antimicrobial activity, anti-fungal, diagnoses, tissue engineering, regenerative medicine and therapeutic treatments such as cancer. One of the most remarkable phenomena that these nanoparticles have is the collective oscillation of their conduction band electrons when these electrons are illuminated with an appropriate wavelength. This phenomenon is known as Surface Plasmon Resonance, which confer intrinsic optical properties to the AuNPs. Due to the massive use of these nanoparticles in the world, eventually these nanostructures will be interacting with body waters including the sea and it could be causing negative effect in marine organisms. Based on the mentioned, the objectives of this study were (i) synthesize gold nanoparticles of different sizes in presence of sodium citrate, (ii) characterize the morphology and optical properties of AuNPs and, (iii) evaluate the interaction of synthesized nanomaterials in marine crustaceans. The generation of AuNPs was realized in presence of gold solution (Au⁺), and citrate solution as reducing agent. The precursors were heated at 100°C by using a hot plate and stirred for 10 minutes. The production of AuNPs was proved by the color change in the solution; from yellow to red wine. Purified nanoparticles by dialysis membranes, evidenced an absorption peak at 523 nm attributed to the surface Plasmon Resonance which suggested the formation of gold.
Semiconductor nanomaterials like zinc sulphide have interesting potential applications, consequent to their size-dependent optical properties. These nanostructures can be used on optoelectronic, photocatalysis, solar cells, and fluorescence microscopy, among others. Due to the great use of these nanoparticles in society, there is great concern in the scientific community about the potential negative interaction of these nanomaterials in aquatic environments. The present research was addressed on generation of nanostructures of ZnS with modified surface. This work had three goals: 1) morphological, compositional and optical characterization of ZnS nanoparticles; 2) surface chemical modification of ZnS nanoparticles with biocompatible molecules; and 3) interaction studies of ZnS nanoparticle. A main absorption peak at ~350 nm and a trap emission peak at ~425 nm were observed in the emission spectrum of ZnS nanoparticles. The morphology and the size of ZnS were carried out by High Resolution Transmission Electron Microscopy (HR-TEM). In this way, nanoparticles were spherical and with a size around 5 nm. Energy Dispersive X-Ray Spectroscopy evidenced the chemical composition of produced nanostructures. The chemical modification of ZnS nanostructures was corroborated by Infrared Spectroscopy Analysis. The interaction of nanoparticles of ZnS was studied in aquatic systems in presence of marine organisms. The concentrations of nanoparticles for the interaction studies ranged from 0 ppm to 2000 ppm and the contacting time was 24 or 48 hours. Also, ZnS (as zinc nitrate and zinc sulphate) was used as comparison purposes. The results evidenced that ionic Zn (as zinc nitrate and zinc sulphate) had a negative interaction in marine organisms at concentrations higher than 500 ppm, whereas Zinc sulphide nanoparticles evidenced a negative interaction only at concentrations higher than 1000 ppm. The chemical interaction between the type of organic cover of ZnS and the marine organisms will be discussed.
The self-assembly of colloidal nanocrystals (NCs) into superstructures provides an efficient bottom-up pathway for constructing new functional materials. Among various superstructures, NC superlattices represent an entirely new class of solid-state materials with unique collective properties and wide applications. However, conventional NC superlattices are inappropriate structural motifs for energy applications due to the impeded molecular accessibility of NCs by foreign species. In pursuit of widening the range of applications of NC superlattices, it is desirable to develop new architectures that enable full access of NC constituents while simultaneously facilitating mass transport properties. Herein, I will focus on low-dimensional, hierarchical NC superlattices with rationally designed structures and mesoscale morphologies toward high-performance energy storage and conversion. I will also spend half of the time to cover NC superlattice derivatives, especially ordered graphene-like frameworks, which are emerging as a new class of mesoporous carbon materials. By exploiting the versatile surface chemistry and self-assembly behaviors of colloidal NCs, a rich array of mesoporous graphene-like materials can be designed, which show great promise as material platform for energy applications.

Aqueous Synthesis of CuZnSnS and CuZnSnSe Nanoparticles for use in Next-Generation Solar Cells

Metal chalcogenide semiconductors continue to show promise as potential scalable, cheap, and tunable metal chalcogenide-based photovoltaics (PV). Among these, the quinary I_2-IV-III-VI_3 family, which includes CuZnSnS (CZTS), CuZnSnSe (CZTSe), and CuZnSn(S/Se)_4 (CZTSSe), are among the most lucrative due to their earth-abundant and non-toxic nature. The fabrication of such materials using nanoparticle routes remains among the most promising for PV due to their potential to be inexpensive and scalable, while maintaining superior phase and compositional control when compared to non-solution based approaches. Here we describe the facile synthesis of aqueous CZTS and CZTSe nanoparticles through a versatile, stoichiometric, one pot synthetic method that produces scalable dispersions without the use of long-chained organic ligands. These materials lend themselves toward the fabrication of carbon-free absorber layers for solar cells. Towards this goal, here we describe a simple process to produce CZTSSe by depositing mixed amounts of CZTS and CZTSe nanoparticle inks followed by a mild heat treatment. The resulting materials exhibit a single-phase kesterite structure and tunable optical bandgaps of between 1.51 and 1.05 eV, which are ideal for single and multi-junction solar cell devices.

The Best of Both Worlds—Merging the Plasmonic Properties of Silver with the Functionality of Gold via Living Reaction Conditions

Among these, the quinary I_2-IV-III-VI_3 family, which includes CuZnSnS (CZTS), CuZnSnSe (CZTSe), and CuZnSn(S/Se)_4 (CZTSSe), are among the most lucrative due to their earth-abundant and non-toxic nature. The fabrication of such materials using nanoparticle routes remains among the most promising for PV due to their potential to be inexpensive and scalable, while maintaining superior phase and compositional control when compared to non-solution based approaches. Here we describe the facile synthesis of aqueous CZTS and CZTSe nanoparticles through a versatile, stoichiometric, one pot synthetic method that produces scalable dispersions without the use of long-chained organic ligands. These materials lend themselves toward the fabrication of carbon-free absorber layers for solar cells. Towards this goal, here we describe a simple process to produce CZTSSe by depositing mixed amounts of CZTS and CZTSe nanoparticle inks followed by a mild heat treatment. The resulting materials exhibit a single-phase kesterite structure and tunable optical bandgaps of between 1.51 and 1.05 eV, which are ideal for single and multi-junction solar cell devices.

The Best of Both Worlds—Merging the Plasmonic Properties of Silver with the Functionality of Gold via Living Reaction Conditions

Metal chalcogenide semiconductors continue to show promise as potential scalable, cheap, and tunable metal chalcogenide-based photovoltaics (PV). Among these, the quinary I_2-IV-III-VI_3 family, which includes CuZnSnS (CZTS), CuZnSnSe (CZTSe), and CuZnSn(S/Se)_4 (CZTSSe), are among the most lucrative due to their earth-abundant and non-toxic nature. The fabrication of such materials using nanoparticle routes remains among the most promising for PV due to their potential to be inexpensive and scalable, while maintaining superior phase and compositional control when compared to non-solution based approaches. Here we describe the facile synthesis of aqueous CZTS and CZTSe nanoparticles through a versatile, stoichiometric, one pot synthetic method that produces scalable dispersions without the use of long-chained organic ligands. These materials lend themselves toward the fabrication of carbon-free absorber layers for solar cells. Towards this goal, here we describe a simple process to produce CZTSSe by depositing mixed amounts of CZTS and CZTSe nanoparticle inks followed by a mild heat treatment. The resulting materials exhibit a single-phase kesterite structure and tunable optical bandgaps of between 1.51 and 1.05 eV, which are ideal for single and multi-junction solar cell devices.
This will talk will provide an overview of our recent developments in the design of nanomaterials for ultrasonic biosensing. Bio-responsive nanomaterials are of growing importance with potential applications including drug delivery, diagnostics and tissue engineering (1). Using enzyme-mediated signal readouts we have developed a suite of nanoparticle based ultrasonic biosensing assemblies as well as a cell/tissue-interfacing nanoneedle platform (2). We are applying these biosensing approaches both in high throughput drug screening and to diagnose diseases ranging from cancer to global health applications.

2:30 PM *QN08.10.03 Driving Forces for Oriented Attachment-Based Crystal Formation and Assembly Xin Zhang1, Byunghan Kim2, Yu-Ting Liao3, 4, Sonia Castellanos Ortega4, Alberto Salleo5, and Paul Alivisatos1, 2, 3.

Driving forces for oriented crystal formation and assembly depend on the structure and alignment of the surfaces. The driving forces can be sensitive to relative orientation include Coulombic, van der Waals (vdW), hydration, and ion correlation forces. The theoretical underpinnings of these anisotropic forces are well established, but techniques that can directly measure them for a given pair of interacting oriented crystal faces have generally been limited to use of macroscopic yet atomically flat single crystals. We report measurement of anisotropic forces between rutile TiO2 (001) nanocrystals as a function of their azimuthal orientation and surface hydration extent using a combined environmental transmission electron microscopy-atomic force microscopy (AFM) technique. Atomically flat rutile TiO2 (001) AFM tips and opposing rutile TiO2 (001) substrates were fabricated by focused ion beam milling to excite nanocrystals from the surface of a single monolith that was pre-oriented, cut, and polished to prepare the (001) face. At tens of nanometers of separation, the attractive forces are weak and show no dependence on azimuthal alignment nor surface hydration. At separations of approximately one hydration layer, attractive forces are strongly dependent on azimuthal alignment and systematically decrease as increasing water density increases. Measured forces closely agree with predictions from Lifshitz theory and show that dispersion forces are capable of generating a torque between particles interacting in solution and between grains in materials. Furthermore, we report the measurement of anisotropic forces between ZnO (0001) and ZnO (0001) nanocrystals in Zn(NO3)2 solution using AFM-based dynamic force spectroscopy (DFS). By measuring the jump-from-contact force as a function of tip retraction rate, the rupture force at equilibrium and the corresponding adhesion free energy as a function of azimuthal alignment is directly obtained. Compared with the potential of mean force (PMF) from large-scale molecular dynamics (MD) simulations, the sensitivity to crystallographic registry between nanocrystals at close range arises, at least in part, from the self-organization of interfacial water molecules in response to the structures and alignment of the opposing surfaces.

3:00 PM BREAK

3:30 PM *QN08.10.04 Synthesis of Porphyrin Nanocrystals and Applications Feng Bai; Henan University, Henan, China.

Abilities to control the size and shape of nanocrystals in order to tune functional properties are an important grand challenge. Here we report a surfactant self-assembly induced micelle encapsulation method to fabricate porphyrin nanocrystals using the optically active precursor zinc porphyrin (ZnTPP). Through confined non-covalent interactions of ZnTPP within surfactant micelles, nanocrystals with a series of morphologies including nanodisk, tetragonal rod, and hexagonal rod, as well as amorphous spherical particle are synthesized with controlled size and dimension. A phase diagram that describes morphology control is achieved via kinetically controlled nucleation and growth. Due to the hierarchical ordering of the porphyrins, the nanocrystals exhibit production and PTCD for cancer. This simple ability to exert rational control over morphology provides new opportunities for practical applications in photocatalysis, sensing, and nanoelectronics.

4:00 PM *QN08.10.05 Metal Nanoclusters and Nanoparticles Tethered by N-Heterocyclic Carbene-Capped Polymers Jie He; University of Connecticut, Storrs, Connecticut, United States.

N-heterocyclic carbenes (NHCs) are excellent ligands that bind to a variety of metal ions in Group 10/11 with extremely high binding strength via π donation. However, there are only a few studies of polymer NHCs that for metal nanoparticles (NPs) in literature, largely due to synthetic challenges of carbine, in particular under aqueous conditions. We present a new method to synthesize metal nanocluster and NPs with NHC-functionalized polymers as surface ligands. Two approaches will be discussed in this talk, including in situ reduction and transmetalization. NHC-functionalized polymers can be prepared using simple post-polymerization functionalization of polymers capped with halogen atoms (e.g., Cl and Br) synthesized via atom transfer radical polymerization (ATRP). When reacted with N-methyl imidazole, halogen-ended polymers can be converted to yield imidazolium salt and further transferred into Cu(NHC)2 complexes in the presence of a weak base, e.g., K2CO3 and CuCl2. We first show that Cu-NHC-polymer can be reductively chemically in solution to form Cu nanocrystals with the bright blue fluorescence. Polymer NHC ligands can stabilize Cu nanoclusters from oxidation as well. In the second approach, we demonstrate that Cu(NHC)2 complexes can be used to modify metal NPs using transmetalization in any good solvents of polymers. The surface modification of citrate-capped gold NPs has been examined using a ligand exchange method in an emulsion solution. We show the successful surface modification of Au/Au/Cu NPs using both approaches, providing collective optical properties resulted from coupling of molecular porphyrins and photocatalytic activities such as photocatalytic degradation of methyl orange (MO) pollutants, hydrogen production and PTCD for cancer. This simple ability to exert rational control over morphology provides new opportunities for practical applications in photocatalysis, sensing, and nanoelectronics.

4:30 PM *QN08.10.06 Direct Patterning of Quantum Dots on the Nanoscale with E-Beam Lithography Christian D. Dieleman1, Weiwei Ding1, Sonia Castellanos Ortega2, and Bruno Ehrler1; 1AMOLF, Amsterdam, Netherlands; 2Advanced Research Center for Nanolithography, Amsterdam, Netherlands.

Interaction with light on the nanoscale is a very active research field, nanophotonics. Commonly, these nanostructures are made from metallic or dielectric materials, while nanostructures from active materials such as semiconductors, for example used for making integrated circuits, require intricate lithography with photoresists as an intermediate step. Here we show that Colloidal Quantum Dots (CQDs) can be used to directly write patterns on the nanoscale from the active semiconductor material. CQDs are nanocrystals of semiconductor materials, owing their tunable optical, chemical, and electrical properties to quantum confinement size effects and surface chemistry. These tunable properties make CQDs useful for different semiconductor applications including photovoltaics and lighting. We directly pattern quantum dots using e-beam lithography in order to obtain high-resolution nanodevices of CQDs at the nanoscale. This technique is applicable to different QD systems, such as CdSe and PbS without affecting the luminescent properties. We present several examples of nanostructures and show that the resolution can be on the order of tens of nanometers. The chemical mechanism responsible for the observed solubility switch is investigated. We believe this technique shows promise for manufacturing of photonic structures at high volume, directly from the active materials.

4:45 PM *QN08.10.07 Understanding the Synthetic Pathways and Developing Techniques to Probe the Rare Non-Radiative Events in CdSe/CdS Colloidal Quantum Dots with Photoluminescent Quantum Yields Approaching Unity Brent A. Koscher1, 2, David Hanifi1, Noah Bronstein1, 2, Zachary Nett1, 2, Joseph Swabeck1, 2, Kaori Takano1, 3, Koen Vandewal1, 3, Yoeri van de Burg1, Alberto Salleo2, 3, and Paul Alivisatos2, 3; 1University of California, Berkeley, Berkeley, California, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Stanford University, Stanford, California, United States; 4HPM Research & Development, High Performance Materials Company, JXTG Nippon Oil & Energy Corporation, Yokohama, Japan; 5Hasselt University, Diepenbeek, Belgium; 6Eindhoven University of Technology, Eindhoven, Netherlands.
Unconventional Templated Synthesis of Coupled Magnetic-Plasmonic Nanostructures

Zhihao Zhao, Xinran Chamele, Yu Yao, Michael Kozicki and Chao Wang; Arizona State University, Tempe, Arizona, United States.

Counterfeit goods have become a global issue that costs tremendous economic loss and security problems. Here we report on a one-pot photochemical synthetic method to produce dendritic silver nano-particles (AgNPs) promising for physical taggants. Unlike conventional techniques such as holograms and DNA signatures, this method can readily generate large quantities of dendritic AgNPs in 20 minutes under UV illumination and ambient conditions, which possesses great economic value and is desired for large-scale manufacturing. The interplay between silver nucleation and growth could significantly afect the product shape and size. We demonstrate that the tuning of experimental conditions, such as the UV illumination time and the concentration of reducing agent, poly(allylamine), indeed creates unique dendritic structures with distinctive morphological characteristics. All the dendrites possess a singular set of minutiae that lead to a vast number of unclonable features. As the AgNP sizes reach 10-100 μm, the structural information may be quickly read and analyzed by optical microscopy, which has great potential for anti-counterfeiting labels in supply chains.

9:30 AM QN08.11.05

Unconventional Templated Synthesis of Coupled Magnetic-Plasmonic Nanostructures

Zhixue Li and Yadong Yin; University of California, Riverside, Riverside, California, United States.
The promising of anisotropic plasmonics in state-of-art researches lies in orientational control of nanostructures, which is most invariably based on substrate regulation or single-structure measurements. Magneto-optics enables active control yet is lacking general approach towards multifunctional nanostructures. Herein, we report an unconventional templated approach towards coupled magnetic-plasmonic nanostructures. Particularly, the magnetic nanorods inside templates not only regulate the seeded growth but also provide magnetic tunability of their optical properties. By controlling the repining of small Au seeds during the early stage of crystal growth, hybrid Au/Fe₃O₄@Au core/shell nanostructures can be produced. This approach can be extended to different metallic nanostructures, like Ag or Cu, other shapes (plates, rods or cubes) or sizes. The plasmonic peak positions of coupled nanostructures can be tuned from visible to infrared region while their absorption/scattering can be finely tuned by the thickness of the metallic nanostructures during synthesis. More interestingly, their physical properties, like plasmonic excitation modes, optical scattering and photothermal conversion can be readily controlled by a magnet, providing vast opportunities for smart nanomaterials. For example, by controlling their orientation in polymer films, they can sense both linear (rotating and bending) and non-linear (twisting) mechanical perturbations. Also, magnetic tuning provides active modulation of imaging signals for biological background-free imaging, which can either enhance or suppress the contrast signals on demand.

9:45 AM BREAK

10:15 AM QN08.11.06

Ligand Effects on Nucleation, Growth and Size Focusing of Colloidal Metal Nanoparticles Ayman M. Karim; Virginia Tech, Blacksburg, Virginia, United States.

Colloidal synthesis of metal nanoparticles has shown tremendous control over size and shape. Understanding how ligands affect nucleation and growth is crucial in controlling size, shape and their distributions. In this talk we show experimental results elucidating the crucial role ligands play in controlling the rates of nucleation and growth and how the ligands contribute to size focusing during the synthesis of Pt and Ir nanoparticles. Using in-situ small angle x-ray scattering, isothermal titration calorimetry and density functional theory calculations, we measured the rates of nucleation and growth, and the M-L binding energies (M = Pt or Ir and L is the ligand) for different ligands. We show that the rates of nucleation and growth are correlated with the M-L binding energies for the metal precursor and metal nanoparticle, respectively. Interestingly, the correlation between nucleation and growth rates and M-L binding energies appears to follow a Brønsted-Evans-Polanyi (BEP) type linear relationship. Moreover, using population balance kinetic modeling, we demonstrate that size focusing of colloidal nanoparticles is largely due to growth rate constant that decreases with ligand coverage on the surface of the nanoparticles through a BEP relationship. This makes growth slower on larger nanoparticles (due to higher coverage), allowing the smaller ones to catch up, thereby focusing the size distribution. The consequences of the M-L binding strength on the size and size distribution will be discussed in relationship to our results and the literature.

10:30 AM QN08.11.07

Competition of Charge and Energy Transfer Processes in Donor-Acceptor Fluorescence Pairs—Calibrating the Spectroscopic Ruler Pavel Moro1, Zhicheng Jin2, Hedi Mattoussi3 and Mikhail Zamkov4; Bowling Green State University, Bowling Green, Ohio, United States; 2Florida State University, Tallahassee, Florida, United States.

Sensing strategies utilizing Förster resonance energy transfer (FRET) are widely used for probing biological phenomena. FRET sensitivity to the donor–acceptor distance makes it ideal for measuring the concentration of a known analyte or determining the spatial separation between fluorescent labels in a macromolecular assembly. The difficulty lies in extracting the FRET efficiency from the acceptor-induced quenching of the donor emission, which may contain a significant non-FRET contribution. Here, we demonstrate a general spectroscopic approach for differentiating between charge transfer and energy transfer (ET) processes in donor–acceptor assemblies and apply the developed method for unraveling the FRET/non-FRET contributions in cyanine dye–semiconductor quantum dot (QD) constructs. The present method relies on correlating the amplitude of the acceptor emission to specific changes in the donor excitation profile in order to extract ET-only transfer efficiencies. Quenching of the donor emission is then utilized to determine the non-ET component, tentatively attributed to the charge transfer. We observe that the latter accounts for 50–99% of donor emission quenching in QD-Cy5 and QD-Cy7 systems, stressing the importance of determining the non-FRET efficiency in a spectroscopic ruler and other FRET-based sensing applications.

10:45 AM QN08.11.08

Colloidally Synthesized Silicon Triplet Photosensitizers for Photon Upconversion Tingting Huang and MingLee Tang; Chemistry, University of California, Riverside, Riverside, California, United States.

Silicon is non-toxic, earth abundant, easily available and can be safely excreted by mammals. These features make silicon nanoparticles very attractive for biomedical applications. Silicon nanostructures have historically been underexplored for their ability to electronically communicate with molecules. In fact, molecular modification of silicon has mostly served to alter the surface energy of single crystal or nanosporous silicon. In contrast, here, colloidally synthesized silicon nanoparticles are explored as the light absorbers responsible for the sensitization of molecular triplet states. Fusion of these spin-triplet excited states create photons higher in energy than the original excitations in the form of spin-singlet excited states. This talk will focus on the low temperature synthesis of nanosized silicon colloid photosensitizers for photon upconversion based on liquid silicon halide precursors in combination with amine-based transmitterligands, building on conditions established by Rongchao Jin’s and Susan M. Kauzlarich’s group. Comparison to the lanthanide nanoparticles used for photon upconversion that usually result in drastic heating will be made.

11:00 AM QN08.11.09

Synthesis and Photophysical Properties of Complex Heterostructures Comprised of Epitaxially-Connected Domains of Materials with Disparate Lattice Structures Vladmir Savevich, Tom Nakotte, Oleg Kozlov, Jeongkyun Roh, Rohan Singh and Victor Klimov; Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Rational design of nanocrystals (NCs) can lead to material systems with fascinating properties. The combination of different materials in single crystalline heterostructures with precisely tunable properties, size and domain functionalities represents a powerful approach for creating novel functional building blocks with tuned electronic energy charge relaxation dynamics. These nanoblocks become a unique platform for exploring fundamental semiconductor physics at the nanoscale and can be used to fabricate novel materials with controllable application-targeted characteristics. Here we report a novel synthetic approach to achieving high-quality heterostructures based on epitaxially joined semiconductor and metal components. Importantly, this synthetic technique enables us to tackle a long-standing problem of uniform epitaxial shell growth around irregularly faceted NCs including synthesis of core/shell nanostructures with an extremely large lattice mismatch. In one example, we target an "inverted" CdSe/PbSe quasi-type II structure wherein an electron is delocalized across the entire NC while a hole is responsible for the sensitization of molecular triplet states. Fusion of these spin-triplet excited states create photons higher in energy than the original excitations in the form of spin-singlet excited states. This talk will focus on the low temperature synthesis of nanosized silicon colloid photosensitizers for photon upconversion based on liquid silicon halide precursors in combination with amine-based transmitter ligands, building on conditions established by Rongchao Jin’s and Susan M. Kauzlarich’s group. Comparison to the lanthanide nanoparticles used for photon upconversion that usually result in drastic heating will be made.

Reversible Polarized Optical Response of Stretched Shape Memory Polymers with Embedded Gold Nanoparticles Prachi R. Yadav, Sumeet R. Mishra, Brian S. Chapman, Brian B. Lynch, Amy L. Oldenburg and Joseph B. Tracy; Materials Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States; Physics and Astronomy, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

Polymer nanocomposites with embedded functional nanoparticles (NPs) are a rich and complex system, where the polymer can drive assembly of the NPs, and the NPs can be used to actuate the polymer. When plasmonic NPs, such as Au NPs, are dispersed within polymers, their organization determines the interparticle distances and extent of coupling of their surface plasmons. The objective of this study was to investigate plasmon coupling of spherical Au NPs with an average diameter of 17 nm in shape memory polymer (SMP) films before and after mechanical stretching and then after thermally driven shape recovery. Scanning electron microscopy confirms that the Au NPs initially form clusters within the SMP. During stretching, a significant polarization-dependent response develops, where the optical absorbance maximum corresponding to the surface plasmon resonance is redshifted by up to 22 nm and blueshifted by up to 12 nm for polarization parallel and perpendicular to the stretching direction, respectively. This result can be explained by the Poisson effect, where stretching pulls the Au NPs apart and pushes them closer together, parallel and perpendicular to the stretching direction, respectively, resulting in the correspondingly weaker and stronger plasmon coupling. Heating or lack of heating during stretching dramatically affects the recovery process. If the sample is not heated during stretching, the polarization dependence vanishes after shape recovery, while polarization-dependent optical properties remain for samples heated during stretching. Simulations of the polarized optical responses of Au NP dimers at different distances are consistent with experimental results for the clusters of Au NPs in the SMP films and allow estimation of the average interparticle spacings. The finding that the stretching temperature affects the assembly and optical properties after shape recovery implies that the reversibility of the effects of stretching can be controlled and adjusted.

11:30 AM QN08.11.11
Simple One-Pot Synthesis of Au Nanoclusters and the Application in Photothermal Therapy Xujun J. Li; Jie Zhang, Sai Katla and Lei Ma; University of Texas at El Paso, El Paso, Texas, United States.

Remarkable recent advances in Au$_{x}$(SR)$_{y}$ nanoclusters have led to significant applications in catalysis, sensing, and magnetism. However, the existing synthetic routes are complicated such as the use of complex polyacrylamide gel electrophoresis-based nanoparticle separation technique, particularly for the water-soluble Au$_{x}$(SG)$_{y}$ nanoclusters. Here we report a simple one-pot concentration and temperature controlled method for rapid synthesis of the Au$_{x}$(SG)$_{y}$ nanoclusters in as little as 2 h without the need for a low-temperature reaction or even stirring. A systematic time-based investigation was carried out to study the effects of volume, concentration, and temperature on the synthesis of the nanoclusters. This high-temperature method decreases the synthesis time for the nanoclusters by over 10 folds than the currently existing procedures and does not need an inert atmosphere, low temperature (e.g. 0 °C) or stirring, making it an extremely simple and cost-effective process. Furthermore, we, for the first time, discovered that the Au$_{x}$(SG)$_{y}$ nanoclusters exhibit excellent photothermal activities. It was found that 0.75 mg/mL Au$_{x}$(SG)$_{y}$ nanoclusters can achieve 100% cell death for MDA-MB-231 breast cancer cells at a power of 10 W/cm$^2$ of an 808 nm laser source, which demonstrated great potential of Au$_{x}$(SR)$_{y}$ nanoclusters for photothermal therapy.

11:45 AM QN08.11.12
Halide Ions as Morphology Descriptors and Dopants in Colloidal Nanocrystals of Binary Semiconductors and Metal Oxides Sandeep Ghosh; The University of Texas at Austin, Austin, Texas, United States.

Various synthetic handles have been identified over the years, while developing wet chemical protocols for achieving a high level of shape and compositional complexity in colloidal nanomaterials. Halide ions have emerged as one such handle which serve as important surface active species that regulate nanocrystal (NC) growth and concomitant physicochemical properties. Halide ions affect the NC growth kinetics through several means, including selective binding on crystal facets, complexation with the precursors, and oxidative etching. On the other hand, their presence on the surfaces of semiconductor NCs stimulates interesting changes in the intrinsic electronic structure and interparticle communication in the NC solids eventually assembled from them. In this presentation, we will describe these roles of halide ions in the growth of nanocrystals and the physical changes introduced by them.

As a representative example, we will describe a case study wherein pyramid-shaped wurtzite cadmium selenide (CdSe) nanocrystals (NCs) were synthesized by hot injection in the presence of chloride ions as shape-directing agents, which exhibit reversed crystal polarity compared to former reports. Advanced electron microscopy techniques (image-corrected HRTEM with exit wave reconstruction and probe-corrected HAADF-STEM) indicate that the polar [0001] facet constitutes the triangular base of the pyramids while the opposite [0001] facet had been reduced to a tip signifying the merging point for the three lateral facets. Based on a simple model of binding of Cl atoms to surface Cd atoms, Density Functional Theory calculations support the experimental evidence that chloride ions confer higher thermodynamic stability to the (0001) facet over the (0001). This finding of differential relative stability of the two polar facets of wurtzite CdSe is contrary to that of previously reported experiments and calculations on NCs in which no chloride-based additives were deliberately used in the synthesis or no chlorine atoms were considered in the binding models. Self-assembly of these pyramids in a peculiar clover-like geometry, triggered by the addition of oleic acid, suggests that the basal (polar) facet has a density and perhaps type of ligands significantly different from the other three facets, since the pyramids interact with each other exclusively via their lateral facets.

Another relevant case study that will form part of this presentation will include the description of colloidal synthesis of flurine doped indium oxide cubes where fluorine was found to be both a morphology descriptor as well as an aliovalent dopant. Single crystalline 160 nm sized F:In$_{x}$SC$_{3}$ nanoclusters were synthesized using a colloidal heat-up method. The presence of fluorine was found to impart higher stabilization to the (100) facets through density functional theory (DFT) calculations based on a simple model of F-substitution of surface O-sites. These calculations support the experimentally evident cubic morphology resulting from surface binding of F-atoms as confirmed by electron microscopy and X-ray photoelectron spectroscopy (XPS). These cubes exhibit narrow, shape-dependent multimodal LSPR extinction peaks due to corner- and edge-centered modes that are visualized by electron energy loss spectroscopy (EELS) in a scanning transmission electron microscope (STEM).

York University, Brooklyn, New York, United States; 2Department of Electrical and Computer Engineering, New Jersey Institute of Technology, Newark, New Jersey, United States; 3Department of Chemical and Biomolecular Engineering, New York University, Brooklyn, New York, United States; 4Department of Chemical Engineering, Cooper Union, New York, New York, United States.

Colloidal quantum dot-based infrared photodetectors present a promising path toward fabricating sensors and imagers at significantly reduced cost. Herein, we report on recently discovered silver chalcogenide quantum dots that exhibit distinct optical absorption in the mid-wavelength infrared, which is known to have high penetration through airborne obscuring such as fog and mists, making them optimal for use in long-distance thermal sensing and enhanced night vision applications. These quantum dots are synthesized into a new narrow bandgap tetragonal phase, not available in bulk, and contain excess electrons, allowing intraband optical transitions between the first and the second conduction energy levels. As a new generation of infrared colloidal nanomaterial, their fundamental properties have not been thoroughly investigated to date. This presentation reports the synthesis, characterizations, and photoductive photodetector device characteristics and discuss potential impacts that this new nanomaterial could bring to mid-infrared optoelectronics.

Using Light to Manipulate, Assemble and Generate Novel Inorganic Heterostructures in Solution Matthew J. Crane1, Elena P. Pandres2, E. James Davis1, Peter J. Pauzauskie1,2 and Vincent C. Holberg1, 1Chemical Engineering, University of Washington, Seattle, Washington, United States; 2Materials Science and Engineering, University of Washington, Seattle, Washington, United States; 3Physical and Computational Sciences Directorate, Pacific Northwest National Laboratory, Richland, Washington, United States.

The fabrication of junctions between colloidal nanomaterials has enabled a wide range of technologies, but, as devices approach the single-nanoparticle scale, the rational assembly of nanomaterials remains challenging. In 2018, Arthur Ashkin won the Nobel Prize for developing optical traps, which offer the ability to manipulate individual nanostructures in three dimensions. However, to date, there are relatively limited reports on optical trapping in non-aqueous media, and thus far, nanoscale inorganic materials have only been optically trapped in vacuum and in aqueous solvents. Here, we present several examples of our recent efforts on the use of light to manipulate and generate inorganic heterostructures in non-aqueous solvent systems, including a novel demonstration of the use of optical trapping to manipulate, align, and assemble metal-seeded semiconductor nanowires in organic dispersion, resulting in the fabrication of arbitrarily long heterostructures consisting of periodically repeating, metal-nanocrystal/semiconductor-nanowire junctions. Heat transport calculations and optical images demonstrate that the metal tip of each optically-aligned nanowire undergoes eutectic melting in the optical trap, facilitating the oriented tip-to-tail “nanosoldering” of successive nanowire building blocks. In addition, some of our exciting new results on the large-scale photothermal modification of nanomaterials will also be presented.

Bright Colloidal Quantum Dot Light-Emitting Diodes Enabled by Efficient Chlorination Xiyen Li; University of Toronto, Toronto, Ontario, Canada.

The external quantum efficiencies of state-of-the-art colloidal quantum dot light-emitting diodes (QLEDs) are now approaching the limit set by the out-coupling efficiency. However, the brightness of these devices is constrained by the use of poorly conducting emitting layers, a consequence of the present-day reliance on long-chain organic capping ligands. This presentation will focus on how conductive and passivating halides can be implemented in Zn chalcogenide-shelled colloidal quantum dots to enable high brightness green QLEDs. We use a surface management reagent, thionyl chloride (SOCl2), to chlorinate the carboxylic group of oleic acid and graft the surfaces of the colloidal quantum dots with passivating chlorides anions. This results in devices with an improved mobility that retain high external quantum efficiencies in the high-injection-current region and also feature a reduced turn-on voltage of 2.5 V. The treated QLEDs operate with a brightness of 460,000 cd m2, significantly exceeding that of all previously reported solution-processed LEDs.

Quantum Confinement Effects on the Photoconductivity of Nanocrystalline Thin Films James Cassidy and Mikhail Zamkov; Bowling Green State University, Bowling Green, Ohio, United States.

Colloidal quantum dots are size-tunable band gap materials that can be solution processed into thin film optoelectronic devices. However, the device performance is often limited due to the small particle size and inability to effectively transport photoinduced charges via electron hopping or tunneling. Because of this limitation there is a need to understand the effects of both quantum confinement and particle “grain” size contribute to a film’s conductivity. For instance, 15 nm CdSe has been shown to have a 10-fold greater conductance than smaller 4 nm CdSe thin films. Here the effect of particle size offers a more substantial effect than quantum confinement to the conductance of a nanocrystal thin film. However, by employing core/shell materials, such as CdS/CdSe, that exhibit confinement only in the shell we can investigate the effect of quantum confinement independently of grain size. This is done by allowing the CdS core to exceed the Bohr radius, which results in large grain size while allowing the CdSe shell to maintain quantum confinement. By adjusting the dimensions of CdS/CdSe materials even greater thin film photodconductivity, than CdSe of the same size, is achieved by taking advantage of both grain size and quantum confinement effects on photoinduced charge transfer.

Bright and Robust Heavy Metal-Free Quantum Dots Donghyo Hahn1,2, Kooleon Char3 and Wan K. Bae1; 1Seoul National Univ, Seoul, Korea (the Republic of)1, 2Sungkyunkwan University Advanced Institute of NanoTechnology, Suwon, Korea (the Republic of)2.

In this presentation, we provide a synthetic strategy for bright and robust InP based quantum dots (QDs) and their applications to light-emitting diodes. Specifically, we propose a InP emissive core/ZnSeS2, inner shell/ZnS outermost shell heterostructure that consists of environmentally benign, heavy metal-free elements and conduct comprehensive study involving synthesis, spectroscopy and simulation. The systematic study unveils the role of the geometry and composition of proposed heterostructures on the optical bandgap, spectra linewidth and photoluminescence quantum yield (PL QY). In addition, we evaluate the stability of designed QDs on involving thermal stress, oxidation, high energy photon exposure, and the electrical stresses. The highlight of present work is the realization of green and red-emitting QDs exhibiting peak PL emission wave length at 525 and 620 nm
with narrow spectra linewidth (full width at half maximum (FWHM) below 40 nm), PL QY as high as 90 % and prolonged stability against external stresses. Finally we demonstrate QD based light-emitting diodes (QLEDs) that display color-pure green (peak EL = 531 nm, FWHM = 39 nm) and red (peak EL = 637 nm, FWHM = 45 nm) emission and peak external quantum efficiency as high as 3.78 % and 6.2 %, respectively.

3:30 PM QN08.12.07
Surface Engineering to Achieve Water Dispersible Indium Phosphide/Zinc Sulfide Core/Shell Nanocrystals Colin Hessel and Albert J. Wright; Materials Technologies, Physical Sciences Inc, Andover, Massachusetts, United States.

Water dispersibility of photoluminescent semiconductor nanocrystals without a significant drop in photoluminescence quantum yield (QY) is a prerequisite for aqueous applications such as biological labeling or nanocrystal inks. While standard silica coating or ligand exchange phase transfer techniques enable aqueous dispersibility, they often result in low QY (<1%), particle aggregation, or poor scalability. In this contribution, we present a surface engineering approach that enables the phase transfer of aqueous InP/ZnS core/shell nanocrystals with a QY > 35%. Three methodologies were used to transfer as-prepared nanocrystals from the organic to aqueous phases, and each are compared in terms of the resultant aqueous QY, extent of particle aggregation, and scalability. Our approach utilizes the growth of a sacrificial ZnS shell and an optimized exchange ligand that minimize the effects of surface etching that commonly reduces the photoluminescence QY during phase transfer. The scalable approach yields aqueous InP/ZnS nanocrystals that are colloidal stable at room temperature for ~3 months with surface functionality amenable to bioconjugation. Synthetic procedures, analytical characterization, and mechanistic insights will be discussed.

3:45 PM QN08.12.08
Nanoparticle-Based Hollow Microstructures Formed by Two-Stage Nematic Nucleation and Phase Separation Shideh T Rahimnasab, Linda S. Hirst, Amir Keshavarz and Benjamin Stokes; University of California, Merced, Merced, California, United States.

We report a new method to assemble nanoparticle-based hollow microstructures utilizing unusual phase separation kinetics in a two-stage nematic nucleation and growth process. This process generates size-tunable closed-cell foams, spherical shells, and hollow tubular networks composed of closely packed nanoparticles. To assemble these structures we dispersed mesogen-modified nanoparticles in a liquid crystal host at a temperature above the nematic-isotropic transition (TNI). On cooling through TNI we observe the initial segregation of nanoparticles into the shrinking isotropic phase domains. Subsequently, we observed a second stage nucleation of nematic domains inside the nanoparticle-rich isotropic domains, leading to the formation of a variety of hollow structures whose differentiation is controlled by nanoparticle density and cooling rate. Monte Carlo simulations of the initial nucleation stage support experimental observations that initial phase separation controls the number of nanoparticles in each assembly. Microscopy studies suggest that the secondary nucleation step controls the number and size of internal voids. These novel hollow micro-assemblies may find broad applications in controlled release, metamaterials, catalysis, and sensor applications.

4:00 PM QN08.12.09
Strongly Polarized Light Generation from Isotropic Colloidal Quantum Dots Coupled to Fano Resonances Kiyanc Gungor1;2, Onur Erdem1, Burak Guletlik1, Emre Unal1, Mustafa Sak1, Sergey V. Gaponenko1, Shinae Jun2, Eunjoo Jung1 and Hilmi V. Demir2; 1Bilkent University, Ankara, Turkey; 2Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 3National Academy of Sciences, Minsk, Belarus; 4Samsung Advanced Institute of Technology, Yeongtong-gu, Korea (the Republic of).

Semiconductor nanocrystals are highly promising material platforms for use in advanced photonic applications. However, conventional device architectures and fabrication methods cannot exploit their potential. Colloidal quantum dot (QDs) offer high color purity essential to high-quality liquid crystal displays (LCDs), which enables unprecedented levels of color enrichment in LCD-TVs today. [1] However, for LCDs intrinsically requiring polarized backplane illumination in operation, highly polarized light generation using inherently isotropic QDs remains a fundamental challenge to date. To address the need for their effective utilization, we proposed and demonstrated innovative photon management techniques for photonic applications of QDs focusing on polarized color conversion. To achieve polarized color conversion by using isotropic QDs, we studied the plasmonic interaction mechanisms that may modify the density of optical states. Strong dipole orientation dependence of surface plasmon coupled emission is utilized in the in-vacuum processes defined into the v-shaped backlight unit (v-BLU) structure [2] Forward scattering of Fano resonance effectively allowed for polarized light generation that can freely radiate into the farfield. [3,4] Unlike many reports in the literature, our experimentally realized high contrast ratio of 9.70 for red quantum dots is measured at the farfield with a home-made measurement setup similar to LCD operation. To analyze the origin of this polarization response, we investigated the emission kinetics of quantum dots using time resolved fluorescence measurements. Here we observed faster decay rate in the resonating polarization state with higher emission intensity is a direct evidence of the strong modification in density of optical states as a part of Purcell enhancement. [5] In addition, the oriented dipoles of coupled quantum dots to this v-BLU surface is observed using back focal plane imaging. The QDs coupled to v-BLU show a distinct back focal plane pattern, which is only reported for strong dipolar emissions observed in single molecule measurements. [6] In contrast, the unpatterned films of isotropic quantum dots on fused silica and plain gold film show no sign of dipolar emission pattern in their back focal plane images. In the light of measurements unveiling the physics behind the polarized emission mechanism, we finally demonstrated a proof-of-concept display under v-BLU back illumination. Our fabrication includes a special mold fabrication and template stripping steps making the developed v-BLU structure commercially appealing. Also changing the patterning methodology for high yield mass production will be discussed.

4:15 PM QN08.12.10
Fe3+−Cr3+ Nanocubes for Induction Heating Catalysis via Controlled Synthetic Routes Natalia da Silva Moura, Pragathi Durapaneni, Kerry M. Dooley and James A. Dorman; Louisiana State University, Baton Rouge, Louisiana, United States.

Iron catalysts play a vital role in the leading chemicals industry, favoring the production of ammonia, hydrogen, and liquid hydrocarbons through the Haber-Bosch, Water-Gas Shift, and Fischer-Tropsch processes, respectively. These catalysts are beneficial by an increase in surface area, which can be achieved through reduced dimensionality. To produce efficient catalytic performance, uniform temperature routes capable of controlling size and shapes, nanocrystals have been reported, enabling fine tuning of the catalytic properties of a given material. Consequently, for iron oxide (Fe3O4) nanocrystals, for example, structural control also enables improved magnetic properties. In the context of catalysis, Fe3O4 is an interesting material due to its ability to generate localized heat by the conversion of electromagnetic radiation into heat, as seen in magnetic hyperthermia. Therefore, combining the properties of iron catalysts with synthetic control and doping have the potential to make an impact in the chemicals industry.

In this work, thermal decomposition is used to produce monodisperse, cubic shaped, Fe3+−Cr3+O4 nanocubes as a strategy to improve the activity of the iron oxide (Fe3O4) host nanoparticles via Cr3+ doping, while maintaining the magnetic properties of the host lattice. Cr3+ replaces Fe3+ in the octahedral sites of Fe3O4 inverse spinel structure at low doping concentrations (< 15 mol%), and tetrahedral and interstitial sites at higher concentrations. Low Fe3+ and concentration improves activity and redox performance due to coupling of the Fe3+/Fe2+ with Cr3+/Cr4+, and regeneration of Cr4+ on the surface. To confirm this regeneration effect and the site occupancy of Cr in Fe3O4, E-edge X-ray Absorption Spectra of Fe and Cr are collected. The impact of surface Cr4+ on the catalytic efficiency of Fe3+−Cr3+O4 under induction heating catalysis is shown through a butanol condensation/dehydration reaction, and the reaction products are identified via Gas Chromatography-Mass Spectroscopy (GC-MS). The cation regeneration also benefits catalytic performance by increasing the number of active sites, which are measured via CO2 N2 adsorption. In addition, Cr3+ doping changes the pore structure from mesopores to micropores, thereby increasing the surface area, demonstrated through BET measurements. To determine the origin of catalytic enhancement with regards to Cr doping or formation of oxygen vacancies, X-ray Photoelectron Spectroscopy (XPS) is performed to elucidate the local bond environment. Finally, magnetic properties are characterized via Superconducting Quantum Interference Device (SQUID) measurements to show how the saturation magnetization, and coercivity are preserved. Induction heating is characterized by determining the Specific Loss Power of these materials under various magnetic field strengths.

4:30 PM QN08.12.11
Stepwise Seed-Mediated Growth of Self-Registered Anisotropic Plasmonic Nanostructures Ji Feng and Yadong Yin; Chemistry, University of California, Riverside, Riverside, California, United States.

Control over localized surface plasmon resonance frequency of metal nanoparticles by shaping the geometry of the nanostructure has attracted continued attention. In this presentation, we report a stepwise seed-mediated growth method for the synthesis of self-registered anisotropic plasmonic nanostructures. The synthesis relies on using colloidal nanoparticles as substrates for the assembly of the metal seeds, and precise control over the exposure of the metal seeds by surface passivation. The anisotropic seeded growth of metal nanostructure can be induced by creating a physical barrier on the seeds, which partially passivates the exposed area of the seeds. Au dimers, linear trimers and Au-Ag dimers with high purity and distinguishable plasmonic excitation bands have been synthesized. This synthesis method results in rod-like nanostructures perpendicularly registered to the substrates. Taking advantages of this unique feature, we investigated dynamic tuning of the plasmonic excitation of Au-Au and Au-Ag dimers by controlling their orientation relative to the incident light. Such tuning is enabled by switching the substrate to anisotropic magnetic nanoparticles, whose orientation can be magnetically controlled. By tuning the direction of the magnetic field, we show control over the plasmonic resonant modes of the Au-Au dimers and Au-Ag dimers under the incidence of polarized light. The optical switching of Au-Au and Au-Ag dimers exhibits bright colors with high contrast. Finally, we demonstrate the application of such nanostructures as anti-counterfeiting patterns by fixing them in orthogonal orientations in a hydrogel film.

4:45 PM QN08.12.12
Fabrication of Large-Area Arrays of Vertically Aligned Gold Nanorods Wenbo Wei1, Feng Bai2 and Hongyou Fan2; 1Henan University, Kaifeng, China; 2Sandia National Laboratories, Albuquerque, New Mexico, United States.

Anisotropic nanoparticles, such as nanorods and nanoprisms, enable packing of complex nanoparticle structures with different symmetry and assembly orientation, which result in unique functions. Despite previous extensive efforts, formation of large areas of oriented or aligned nanoparticle structures still remains a great challenge. Here, we report fabrication of large-area arrays of vertically aligned gold nanorods (GNR) through a controlled evaporation deposition process. We began with a homogeneous suspension of GNR and surfactants prepared in water. During drop casting on silicon substrates, evaporation of water progressively enriched the concentrations of the GNR suspension, which induces the balance between electrostatic interactions and entropically driven depletion attraction in the evaporating solution to produce large-area arrays of self-assembled GNR on the substrates. Electron microscopy characterizations revealed the formation of layers of vertically aligned GNR arrays that consisted of hexagonally close-packed GNR in each layer. Benefiting from the closepacked GNR arrays and their smooth topography, the GNR arrays exhibited a surface-enhanced Raman scattering (SERS) signal for molecular detection at a concentration as low as 10^−13 M. Because of the uniformity in large area, the GNR arrays exhibited exceptional detecting reproducibility and operability. This method is scalable and cost-effective and could lead to diverse packing structures and functions by variation of guest nanoparticles in the suspensions.

SYMPOSIUM SM01

Materials for Biological and Medical Applications
April 22 - April 26, 2019

Symposium Organizers
Wonmo Kang, Naval Research Laboratory
Laura Na Liu, University of Heidelberg
Jwa-Min Nam, Seoul National University

1:30 PM SM01.01.01
Multivalent Glycosylated Nanoparticles for Specific Binding and Killing of Bacteria Shuai Hou and Hongwei Duan; Nanyang Technological University, Singapore, Singapore.

Carbohydrate-protein recognition plays a key role in cell-cell and host-pathogen interactions, stimulating widespread interest in developing multivalent glycoconjugates with superior binding affinity for biological and medical uses. We have developed a class of glycosylated plasmonic nanoparticles to specifically target the lectins expressed on the surface of bacteria and realize the near-complete killing of the bacteria with laser irradiation.

We first explored the use of Raman-encoded silver-coated gold nanorods (Au@Ag NRs) as scaffolds to form multivalent glycoconjugates. The plasmonic scaffolds afford high-loading of the mannoside clusters, and their optical properties offer the possibilities of monitoring and quantitative analysis of nanoparticle–bacteria recognition. Using E. coli strains with tailored on/off of the FimH receptors, we have demonstrated that Raman-encoded NRs not only allow for real-time imaging and spectroscopic detection of specific binding of the glycan-NR conjugate to the bacteria, but also enable efficient photothermal conversion of Au@Ag NRs in the near-infrared spectral window to realize eradication of the bacteria. Further work used galactosylated copper sulfide nanocrystals (Cu2S NCs) to target Pseudomonas aeruginosa via galactose-LecA interactions. Cu2S NCs show strong surface plasmon resonance in the second near-infrared (NIR-II) window and enable simultaneous photothermal and photodynamic therapies. We observed excellent specificity of the galactosylated Cu2S NCs towards LecA with a LecA-deficient P. aeruginosa strain as the control group. We then used a 1064-nm laser to kill the bacteria and assessed the contribution of photothermal and photodynamic processes.

These results establish that glycosylated nanoparticles, which integrate the recognition capability of carbohydrates and the therapeutic function of nanoparticles, are an effective platform for the targeted killing of bacteria. We also envision that optically-active plasmonic glycoconjugates hold great potential for screening multivalent glycan ligands for therapeutic and diagnostic applications.

1:45 PM SM01.01.02
Multi-Color Electron Microscopy of Cellular Ultrastructure Benjamin Bammes1, Ranjan Ramachandra2, Robert Bilhorn1 and Mark Ellisman2; 1Direct Electron, LP, San Diego, California, United States; 2National Center for Microscopy and Imaging Research, University of California, San Diego, La Jolla, California, United States.

Transmission electron microscopy (TEM) is the primary method to image biological cellular ultrastructure, though it is not possible with conventional TEM to label and distinguish different kinds of molecules in a single image. This serious limitation was recently addressed through the development of “multi-color EM,” which uses selective lanthanide ion tagging and electron energy-loss filtered imaging (Ramachandra et al., 2014, Microsc Microanal. 20; Adams et al., 2016, Cell Chem Biol. 23) yielding data
analogous to multi-color fluorescence microscopy but at ~100x the magnification. While this technique promises to reveal novel structural information, it is tedious (requiring multiple long exposures with different energy filter settings), terribly inefficient (depending on the small fraction (<1%) of primary TEM electrons that are inelastically scattered), and yields noisy images with significantly lower resolution than is achievable by TEM imaging.

To improve the throughput, efficiency, and resolution of multi-color EM, we have developed a new multi-color EM technique with 4D-STEM, which uses a high-speed pixeleted detector to record the vast majority of the primary electrons that interact with the specimen.

In order to achieve the necessary sensitivity for this technique, the pixeleted detector must deliver synchronized (global shutter) readout of a large number of pixels (at least 512 × 512 pixels) and it must have single-electron sensitivity for electron counting.

We used the DE-16 direct detection camera in conjunction with the DE-FreeScan scan generator (Direct Electron LP, San Diego, CA USA) to collect a 4D-STEM dataset of a cellular mitomatrix sample, with mitochondria labeled by cerium and containing gold nanoparticles. After correcting for distortions in the defraction patterns, we were able to develop a metric to distinguish the cerium labels and gold nanoparticles, while simultaneously generating bright-field and dark-field images of the specimen at significantly higher resolution than is possible through fluorescence light microscopy.

2:00 PM SM01.01.03
Fabrication and Characterization of Biodegradable Metal Based Microelectrodes for In Vivo Neural Recording Chaoxing Zhang1,2, Teresa Wen1, Khaleed Razak1,4, Jiajia Lin1,2, Edgar Villafana2, Hector Jimenez2 and Huinan Liu1,2,3; 1Materials Science and Engineering, University of California, Riverside, Riverside, California, United States; 2Department of Biomedical Engineering, University of California, Riverside, Riverside, California, United States; 3Biomedical Sciences Program, School of Medicine; Stem Cell Center, University of California, Riverside, Riverside, California, United States; 4Neuroscience Graduate Program, University of California, Riverside, Riverside, California, United States; Psychology Department, University of California, Riverside, Riverside, California, United States.

Neural electrodes have been widely used to monitor neural signals and/or deliver electrical stimulation in the brain. Currently, biodegradable and biocompatible materials have been actively investigated to create temporary electrodes that could degrade after serving their functions for neural recording and stimulation from days to months. The new class of biodegradable electrodes eliminate the necessity of secondary surgery for electrode removal. In this study, we created biodegradable, biocompatible, and implantable magnesium (Mg)-based microelectrodes for in vivo neural recording for the first time. Specifically, conductive poly-3,4-ethylenedioxythiophene (PEDOT) was first deposited onto Mg micro/meso substrates by electrochemical deposition, and a biodegradable insulating polymer was subsequently sprayed onto the surface of electrodes. The tip of electrodes was designed to be conductive for neural recording and stimulation, while the rest of electrodes was insulated with a polymer that is biocompatible with neural tissue. The charge storage capacity and impedance of Mg-based microelectrodes and their performance during neural recording in the auditory cortex of a mouse were studied. The results first demonstrated the capability of Mg-based microelectrodes for in vivo recording of multi-unit stimulus-activated activity and spontaneous activity in the brain.

2:15 PM SM01.01.04
A Sneak Peek into the Material Science of Active Pharmaceutical Ingredients—The Importance of Solid-State Characterization in Drug Development Paroma Chakravarty; Small Molecule Pharmaceutical Sciences, Genentech Inc., South San Francisco, California, United States.

Small organic molecules exhibiting therapeutic properties are known as active pharmaceutical ingredients (API) and are of great interest in pharmaceutical material science. These API can exist in several crystalline forms as well as in different states of disorder of which the amorphous form is of great interest due to their greater free energy which results in higher bioavailability and exposure in vivo. Detailed screening as well as subsequent characterization of the different forms with varying degrees of crystallinity is imperative to choosing a suitable lead candidate that will elicit the required therapeutic response in vivo. Thus the material science aspect of drug development plays a vital role in the pharmaceutical industry since it is responsible for proper physical form selection and its maintenance in the formulation during its shelf life. Polymorphism, amorphization or changes to chemical composition are several ways in which the physical form of the API may be altered which may bring about a change in its pharmaceutical properties and ultimately affect the final drug product and its performance. This talk focuses on the material science part of pharmaceutical drug development and tackles the different challenges faced in characterizing drug substances in both the discovery and development stage as well as in the formulation. Judicious form screening as a salt or polymorph, form changes during processing and unit operations and vitrification of crystalline materials for improving bioavailability will be covered as well as analytical techniques used for such characterization. The focus is on several case studies involving both drug substance and drug product with emphasis on experimental (X-ray diffraction, spectroscopy, microscopy, thermal analysis) and computational characterization techniques to showcase advances in pharmaceutical material science encompassing both ordered and disordered materials.

2:30 PM SM01.05.01
Density Control and Patterning of Biosensor Surfaces Using Modified Poly-L-Lysine Polymers Jacopo Movilli1, Daniele Di Iorio1, Andrea Rozzi2, Roberto Corradini2 and Jurriaan Huskens1; 1Molecular NanoFabrication group, University of Twente, Enschede, Netherlands; 2Department of Chemistry, University of Parma, Parma, Italy.

Biosensors and materials for biomedical applications generally require precise chemical functionalization to bestow their surfaces with desired properties, such as specific molecular recognition and antifoiling properties. Consequently, tailoring the chemistry at the biosensing interface has a crucial role in obtaining the best selectivity and sensitivity. Especially for DNA biosensors, either biological or artificial probes, as well as antifoiling moieties, need a defined type of chemistry to be anchored with respect to their chemical modification and the type of substrate, affecting the biodistribution. In addition, control of the surface probe density is required for achieving high sensitivity.

Traditional methods have the applicability limited to specific substrates and aim to control the density at the surface modification step, with the drawback of having to test the hybridization efficiency every time. Recently, polyelectrolytes were used in biosensing to tailor the probe type and distribution. Furthermore, the ensemble of substrates for biosensing purpose has been increased thanks to the multiple nature of polymers and their electrostatic interactions. The chemi/physi sorption of modified polyelectrolytes provides advantages for the immobilization of biomolecules and for biosensing applications. At physiological pH, poly(L-lysine) (PLL) polymers readily and strongly adsorb onto a variety of metal oxide surfaces through multivalent electrostatic interactions between the positively charged lysine side-chains and a negatively charged surface. As a result, PLL polymers, which are easy to functionalize thanks to the amino groups in the side chain, allow the accommodation of the grafted functional moieties over the substrate, maintaining their adsorption properties. Based on this approach, biorecognition surfaces were prepared by deposition of modified PLL polymers grafted with various fractions of oligo(ethylene glycol) (OEG, antifoiling) and maleimide (Mal) moieties (PLL-OEG-Mal), so that both the type of functionalization and the control over the density is achieved at the same time, during the synthetic step, verified by 1H-NMR. PLL-OEG-Mal polymers were self-assembled at the substrate and coupled to thiol-peptide nucleic acid (PNA) probes, forming a real-time DNA biosensor. A linear relationship between the probe density and the PLL grafting density was found monitoring the frequency shift of the hybridization step for the complementary DNA versus probes per % of grafted Mal, thus confirming the validity of the density control in the synthetic PLL modification step without the need of further surface characterization. Thanks to their advantages, modified PLL polymers can be used to tune the surface properties, accommodating several clickable side groups as linkers and antifoiling moieties, and forming different architectures as layer-by-layer and μ-arrays, as well as their application in soft lithography and pillar structures.

The oral cavity harbors a wide array of microbiota which if perturbed, would result in the loss of mutualistic/symbiotic balance leading to diseases. The aggregates of these microorganisms can orderly lay in a protective sheath coined as extracellular polymeric substance (EPS), to form oral biofilm a.k.a. dental plaque. There is mounting evidence that the dental biofilm can be the culprit of several diseases such as dental caries which affects 2.4 billion people worldwide.

In the biofilm, the biofilm itself is induced by the presence of carbohydrates causes organic acids production (p4–4.8) demineralizing the tooth enamel. The most common serious pathogen involved in the dental biofilm is the gram-positive bacteria, streptococcus mutans (S. mutans), which actively produces EPS and acids.

Unfortunately, the rigorous solution to the dental caries is compounded due to the multifactorial nature of the disease. Nanoparticles (NPs) can offer an unequivocal solution to the biofilm issue with the privilege of multifunctionality, on-demand controlled release of drugs, high loading efficiency, selectivity, and trackability. Importantly, the nanoparticles can be designed to be ‘self-contained’ and exert the therapeutic effects without the utilization of conventional antibiotics. Nevertheless, as a major group of nanobiotics, the experimentation with metallic nanoparticles has raised concerns regarding their accumulation and non-degradation.

Carbon dots (CDots) are the emergent class of carbon family which have attracted a host of research in recent years due to the ease of fabrication, tunable luminescent properties, and the abundance of functional groups. These properties combined with their degradability offer a unique platform for combating bacteria. Herein, we present for the first time, a ‘particle in particle’ approach for targeting the EPS with its characteristic pH to release the load of inherently therapeutic CDots to kill notorious S. mutans. Specifically, phosphonium containing CDots have been wrapped in a layer of poly(styrene)-b-poly(n-dimethylocthio methacrylate) (PS-b-PDMA) which shows pH responsiveness upon encountering acidic pH. Moreover, phosphonium ions have been utilized to confer antibacterial properties to the NPs as with more pronounced to varying pH compared to their ammonium counterparts (pKa 1.8 vs 9.3).

The retained load of therapeutic CDots will get liberated only when in touch with the pH of EPS. This approach would not only lead to the biofilm dispersal and enhanced the bacterial susceptibility but would also exert the antibacterial properties in situ without any external drugs. Moreover, the absence of any external stimuli, for example, H2O2 and photostimulation, is a boon which reduces the unintentional toxicity.

We have demonstrated that these NPs could suppress the biofilm EPS and decrease the S. mutans viability in the in vitro human tooth model of the biofilm. The mechanism of action can be classified as ROS generation and fragmentation of genomic DNA on the subcellular level. We have shown, in vivo, in the rat model of dental biofilm that these nanoparticles could successfully decrease the cultivable S mutants within 13 days using the plate count assay and S. mutans detection kit. It has been recognized through histopathological examination that these NPs did not interfere with the normal activities of the major organs while the dental caries scoring indicated a decrease in the caries development. The gene expression profiling of the oral microbiota from rats revealed that the change in the microbiome diversity was not statistically significant among groups. Therefore, our approach has great implication for the application of nanomaterials as degradable antibiofilm in the dental clinic.

Self-Sterilizing Photodynamic Polymers for Anti-Infective Materials

Bharadwaja Sriram Tirumala Peddinti; North Carolina State University, Raleigh, North Carolina, United States.

Increase of antibiotic resistance in pathogens has directly impacted healthcare industry. With only a few novel discoveries in the field of antibiotics since last two decades, often referred to as the discovery void, drug discoveries in pathogens has increased. Previously, infections that were easily treatable have now become fatal. Infections caused by antibiotic-resistant pathogens can occur anywhere, but, it is observed to take maximum effect in healthcare settings such as hospitals and nursing homes. The pathogens adhere to surfaces such as linens, counter tops, drains and equipment, medical sanitary ware and so on. Moreover, patients in hospitals are easily affected due to decreased immunity.

According to a report by Center for Disease Control and Prevention (CDC), 1 out of every 20 hospital patients is affected by nosocomial infections subsequently resulting in 100000 deaths in the United States of America. Out of these, 23000 deaths on an average are attributed to drug-resistant pathogens such as methicillin resistant Staphylococcus aureus and vancomycin-resistant Enterococcus faecium. In addition to this, $9.8 billion are invested in treatment of such infections. The conventional routes of treatments are proving to be inconsequential and a major part of tackling such uses is antibiotic. But, with the increase in drug-resistant strains it is only a matter of time when all the treatment methods fail. Although several methods such as chemical disinfectants, ionizing radiation, ultra-violet treatments are used in addition to antibiotics but, they are not effective due to various reasons. Chemical disinfectants and ionizing radiation are not FDA approved. Moreover, radiation techniques are cost intensive and ultra-violet radiation is harmful to healthy cells. So, alternative techniques must be investigated that can be utilized to prevent the loss due to hospital acquired infections (HAIs). Consequently, alternative techniques for surface disinfection must be investigated for their application as preventive techniques instead of looking for a cure. One such method that has recently come into light in the last two decades is photodynamic therapy (PDT).

Commercial photosensitizers (PSs) such as Photofrin and Protoporphyrin IX have been used in Photodynamic therapy (PDT) for treating initial stages of skin cancer, acne, and psoriasis. It involves three components: a photosensitizer, a visible light source and cytotoxic singlet oxygen. Initially, the PS is applied to the area affected by the cancer cells. After the PS is absorbed into the cells, the target area is illuminated by red colored light, thus, activating the PS. Activated PS can exchange energy with oxygen that diffuses through the cells, converting it into singlet oxygen ($^{1}{O_{2}}$). Being highly energetic readily reacts with various components in the cell, ultimately leading to cell death. The idea of this study is to incorporate such photosensitizers into polymeric matrices that can be applied as surfaces that provide non-specific preventive measures, rather than as specific cures.

In this study, 1% (w/w)ZnTMPyP of porphyrin class has been physically incorporated in an Olefinic Block Copolymer (OBC) via melt-pressing. Inactivation studies were performed on four bacterial strains (two Gram-positive and three Gram-negative at various illumination intensities). Furthermore, time based illumination studies were conducted at various illumination intensities with Staphylococcus aureus (5–80 mW/cm², 5–60 min illumination time). Both the gram-positive bacteria showed ~6 log units reduction (~99.999% killing) at the end of 60 minutes whereas all the three gram-negative bacteria showed at least ~3 log units reduction (~99.9% killing). Antiviral efficacy of films was determined against Vesicular stomatitis virus (VSV) (~99.999 % inactivation). Human adenovirus-5 (~99.956% inactivation) and Influenza A virus (~99.950 % inactivation).

Communication—Metabolites-Enhanced Antibacterial Activity of Self-Assembled Nano-Peptide Amphiphiles for Treating Antibiotic Resistant Bacteria

Ming Gao, Danquan Wang, Steve Lustig and Thomas Webster; Chemical Engineering, Northwestern University, Boston, Massachusetts, United States.

Numerous bacterial stains have become resistant to conventional antibiotics in recent years. Fortunately, an increasing body of research indicates that through the addition of specific metabolites (like sugars), the antibacterial activity of self-assembled nano-peptide amphiphile (SANPAs) has been designed in this study to treat antibiotic resistant bacterial infections and to reduce the use of antibiotics. Here, SANPAs were self-assembled into nanorod structures with a nanoscale diameter at concentrations greater than the critical micelle concentration (CMC). Both Gram-positive and Gram-negative bacteria were treated with SANPAs with metabolites supplementation. After various amounts of time metabolites pre-incubation, SANPAs reduced bacteria growth relative to non-metabolite treatments at all concentrations. Cytotoxicity studies showed that the presence of metabolites seemed to slightly ameliorate the cytotoxic effect of the treatment on model human fetal osteoblasts (bone forming cells) and human dermal fibroblasts. In conclusion, we demonstrated here that SANPAs-like nanomaterials have a promising potential to treat antibiotic resistant bacteria especially when added to metabolites, potentially limiting their associated infections. By comparison of SANPAs treatments under different communication conditions, the results further provide resource for researcher to design novel agents and treatment methods against antibiotic resistant bacterial infection.

4:00 PM SM01.01.09

Novel Polymeric Heart Valves Using Low-Fouling PEGDA and Fiber Composites

Xing Zhang, Feng Guo, Chang Liu, Yun Bai and Rui Yang; Chinese Academy of Sciences, Shenyang, China.

Heart valve disease with major symptoms of stenosis and regurgitation is prevalent worldwide. Surgical replacement of diseased heart valves at the end-stages has been widely performed with mechanical valves (MVs) or bioprosthetic heart valves (BHV).s. All these current devices have significant limitations with risks of further morbidity and mortality. For example, MV’s may cause hemorrhage and thromboembolism, and require anticoagulation for the lifetime of the patients. BHVs show better hemodynamic behavior due to the composition and structural similarity to native heart valves when compared to MVs, however, they do show limited durability because of calcification and progressive degeneration [1]. Thus, polymeric heart valve (PHV) prostheses combining the advantages of MVs and BHVs with long-term durability and no necessity for permanent anticoagulation are of great interest and also show potential applications in advanced transcatherter devices.

In this study, two types of silk fibroin (SF) fiber membranes with anisotropic (ASF) and isotropic (ISF) properties were prepared by electrospinning methods, and were further combined with poly(ethylene glycol) diacrylate (PEGDA) hydrogels to serve as polymeric heart valve (PHV) substitutes (PEGDA-ASF and PEGDA-ISF). The uniaxial tensile...
tests showed obvious anisotropy of PEGDA-ASF composites with elastic moduli of 10.95 ± 0.19 MPa and 3.55 ± 0.32 MPa, respectively, along the direction parallel and perpendicular to the fiber alignment, close to those of native aortic valve leaflets, while PEGDA-ISF processed isotropic property with elastic moduli of 4.54 ± 0.43 MPa. These novel PHVs consisted of polymeric fibers to mimic the fibrous networks in the fibrosa and ventricularis layers for stress bearing, as well as PEGDA hydrogels to improve anti-fouling function [2,3]. Furthermore, the presence of PEGDA hydrogels in the composites improved the resistance to progressive calcification of the embedded fibers in vitro, likely due to prevention of large-size hydrated ions to pass through by the polymeric networks of the hydrogels [3]. The non-fouling PEGDA hydrogels encapsulated the surfaces of the composites and prevented contact between platelets and the underlying fibers [4]. Pulse duplicator tests presented good hydraulic performance characteristics of these PHVs from PEGDA-ASF and PEGDA-ISF composites according to the ISO 5840-3 standard. Finite element analysis (FEA) revealed the PEGD-ISF valve with anisotropic property showed a lower peak maximum principle stress value (2.20 MPa) in commissures during diastole compared to that from the isotropic PEGD-ISF valve (2.37 MPa). In systole, the bending area of the PEGD-ISF valve was close to free edges, however, which appeared in the belly portion and near the attachment line for the PEGD-ISF valve. Hence, our results revealed that anisotropic properties played important roles not only in mechanical properties, but also in hydraulic performance of these artificial PHVs. These novel PHVs with good biocompatibility and hemodynamic property can likely be used for heart valve replacement in future.

References
Recent advances in molecular biology, single cell manipulation and data analysis techniques have allowed us to look into the molecular states of individual cells with unprecedented detail. These methods have made it possible to investigate how the genotype in combination with internal and external regulatory factors guide the development of complex and diverse phenotype. However, these methods rely on cell lysis and can provide only a snapshot of the cellular state. This makes it challenging to monitor gene expression changes over time. Inferences about dynamic cellular processes are obtained by constructing pseudo-time trajectories from the continuum of molecular states present in a cell population that can reflect the essence of a single cell trajectory. However, the dynamics of cell state may be non-hierarchical or stochastic which the computational algorithms cannot always capture. In order to acquire a holistic understanding of decision-making pathways involved in processes such as cell reprogramming, differentiation and maturation, tracking the same cell in time is necessary. Our long-term goal is to develop a single-cell microfluidics platform that can temporally examine cells by performing precise cellular manipulations (e.g. genetic editing using CRISPR/Cas9) and subsequent analysis of internal cellular biomarkers in a non-destructive manner. Such a system would allow us to monitor the biochemical changes in cells over time and correlate these to the external inputs and perturbations.

Localized electroporation has emerged as an effective technique for introducing the desired changes in cellular systems by delivering foreign molecules such as nucleic acids. Unlike bulk electroporation where the entire cell membrane is exposed to a strong and non-homogeneous electric field, localized electroporation utilized nanostructures (such as nanochannels) to confine the electric field to only a fraction of the plasma membrane. This controlled perturbation allows for efficient transport of molecules into the cells as well as helps maintain high cell viability. As such, localized electroporation is also being used to address the converse problem, i.e. to non-destructively sample the cytosolic contents of living cells.

Although several experimental reports demonstrate the phenomena of localized electroporation, a mechanistic understanding of the different parameters involved in the process is lacking. In this work, we present a multiphysics model that 1) estimates the transmembrane potential developed across the cell membrane in response to a localized electric field, 2) predicts the electro-pore distribution in response to the local transmembrane potential drop and 3) calculates the molecular transport into and out of the cell based on the predicted pore-sizes. Using the model, we identify that cell membrane tension plays a crucial role in enhancing both the amount and the uniformity of molecular transport, particularly for large proteins and plasmids. We also find that a critical voltage range is necessary for efficient electroporation. We qualitatively validate the model predictions by delivering large molecules (fluorescent-tagged bovine serum albumin and mCherry encoding plasmid) and by extracting an exogenous protein (tdTomato) in an engineered cell line on a localized electroporation platform. The findings presented here should inform the future design of microfluidic devices for localized electroporation based sampling and temporal, single cell analysis. Eventually, high throughput temporal analysis of single cells would help us gain insights into fundamental aspects of developmental biology, study the progression of diseases such as Alzheimer’s and Parkinson’s and evaluate the efficacy of drugs over time.

Dissolved oxygen [DO] is crucial to environment, industry, life technology, and human health, etc. Hypoxia[1] (e.g. genetic editing using CRISPR/Cas9) and subsequent analysis of internal cellular biomarkers in a non-destructive manner. Such a system would lead to a breakthrough in wound healing therapy. However, the underlying mechanisms within the cells during electrotaxis remain still unclear.

Endogenous electrical fields play a major role in various biological processes from embryonic development to cell division and migration (electrotaxis). The latter has been extensively researched due to its involvement in wound healing processes. A better understanding of electrotaxis induced by external electrical fields (direct current), could hence lead to a breakthrough in wound healing therapy. However, the underlying mechanisms within the cells during electrotaxis remain still unclear.

The main limitation for research, as well as the clinical application of direct current therapy for directed cell migration, lies within the utilized electrodes. Metal electrodes made of platinum or copper, as well as silver chloride, corrode and release toxic by-products under direct currents, which are harmful to cells and in addition, might influence their migratory function. Therefore, all electrotaxis experiments until now require agar salt bridges to connect the electrodes to the cell chamber, which lead to a bulky and inefficient experimental setup. A better solution for the stimulation material could improve cellular research and facilitate the transition towards clinical use. As an alternative, we propose the use of polyimide-based iridium oxide electrodes coated with poly(3,4-ethylenedioxythiophene) poly styrene sulfonate (PEDOT:PSS). These electrodes are able to maintain stable ionic currents over long periods of time and can drive electromigration of cells without the release of any cytotoxic by-products. Using a simple electrotactic chip we were able to show that PEDOT/PSS electrodes have sufficient ion filling capacity to drive electromigration of skin cells in an agar bridge free system. The chip was fabricated through soft lithography of polydimethylsiloxane (PDMS) which was chemically bonded to a glass coverslip through surface modification with oxygen plasma. The chamber consists of a channel with a seeding area for the cells and two reservoirs at both ends of the channel for medium and the insertion of the electrodes. The use of polyimide-based electrodes allows the reusability of these for several experiments, facilitates the assembly of the electrotactic chamber and greatly reduces the associated cost.

During the experiments, a constant voltage was applied to the electrodes and the current was continuously monitored. Time-lapse photography documented the directed migration and the cell motility was quantified utilizing circular statistics. It was found that pre-oxidation/reduction of the PEDOT/PSS electrodes increased the current injection and subsequently the possible charge delivery to the cells. We conclude that PEDOT based electrodes can be efficiently used for direct current stimulation and have the power to influence the migration of cells relevant to the healing of human skin. The combination of polyimide-based reusable electrodes and disposable microfluidics make a cost-efficient analysis of electrotaxis possible at high throughput.

This project has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation program (grant agreement No. 759655).

New Oxygen Sensor for In Vivo Dissolved Oxygen Sensing and In Vivo Hypoxia Imaging Jiaze Li, Yuan Qiao, Tingting Pan, Ke Zhong, Jiaxing Wen, Fengyu Su and Yanqing Tian; 1Department of Materials Science and Engineering, Southern University of Science and Technology, Shenzhen, China; 2SUSTech Academy for Advanced Interdisciplinary Studies, Southern University of Science and Technology, Shenzhen, China.

Dissolved oxygen [DO] is crucial to environment, industry, life technology, and human health, etc. Hypoxia[1] (≤0.5% O2, usually at tumor environments) is relevant to cancer, stroke, arteriosclerosis, Parkinsonism, and Alzheimer's disease etc.. Therefore, in vivo dissolved oxygen detection is essential for disease prevention and treatment. For dissolved oxygen detection, phosphorescence based optical oxygen analysis showed superior performance among several ways with noninvasive sensing, no oxygen consumption, high sensitivity, fast responses and single cell scale sensing. Herein, five kinds of multi-arm block copolymers were synthesized by atom transfer radical polymerization (ATRP) to load the excellent hydrophobic oxygen probe platinum (II)-5,10,15,20-tetrakis-[2,3,4,5,6-pentafluorophenyl]-porphyrin (PtTFPP) for optimizing PtTFPP's performance in hypoxia sensing and imaging. Among them, fluoropolymers were introduced with their excellent capacity to dissolve and carry oxygen for investigating carriers' structure-property relationship. Under nitrogen atmosphere, high quantum efficiency of PtTFPP in fluorine-containing micelles could reach to 22% without complicated modification of PtTFPP. Oxygen-nitrogen titration by a gas manipulator showed that fluorine-containing micelles have higher oxygen sensitivity (I0/I1) than fluorine-free ones, and micellar sensors are more sensitive under body temperature (37°C) than room temperature.
The sensors reported here might be capable for at least 10 minutes without obvious decay, indicating that the PtTFPP possessed excellent in vivo stability and strong phosphorescence signal after being encapsulated by our materials. Thus, the phosphorescence image at tumor region is much brighter, and the phosphorescence intensity at tumor region is 1.6 times higher than that of normal region. Moreover, the phosphorescence imaging lasted for at least 10 minutes without obvious decay, indicating that the PtTFPP possessed excellent in vivo stability and strong phosphorescence signal after being encapsulated by our materials. Therefore, the long-term efficacy may be jeopardized and the constant electrical stimulation may trigger compensation mechanisms. Power supply is also an issue for this type of implanted electronic devices.

Session SM01.03: Materials for Biological and Medical Applications III

Materials and Devices for Transient Electronic Implants

This talk summarizes concepts in materials science that serve as the basis for transient electronic implants, as a new paradigm for treating injuries and tracking recovery. Here, engineered device platforms provide monitoring and/or therapeutic functionality during the time course of a natural biological process such as healing, and then disappear into the body, without a trace, through mechanisms of bioreorption. This mode of operation eliminates unnecessary device load on the body, and associated risk to the patient, in a way that bypasses the need for secondary surgical extraction. Examples of biodegradable materials and device designs will be presented in the context of (1) electrical stimulators for accelerated neuroregeneration in damaged peripheral nerves, (2) cardiac pacemakers for recovery from heart surgery and (3) programmable drug release vehicles for treatment of disease.

TiO2 nanotube arrays constitute highly versatile scaffolds that are suited for long-term organotypic culture of neuronal tissue, including retina explants and beyond. While tube diameter and surface roughness [1] are central parameters for successful culture and have to be optimized for every specific tissue type, super hydrophilicity ensures nutrition supply by a wetting layer of culture medium even in absence of complicated perfusion systems [2]. Clearly adhesion between tissue explants and nanotube scaffolds plays a key role for maintaining tissue integrity. Lift-off approaches are, on the other hand, desirable for tissue transfer and nanotube regeneration, respectively. Employing extensive environmental scanning electron microscopy (ESEM) as well as laser scanning microscopy (LSM) studies we address both aspects and demonstrate that UV-light exposure and enzymatic treatment are ideally suitable for nanotube regeneration. Based on these findings, we present an assay for concurrent biomechanical straining and in situ imaging employing ESEM and LSM. Thus, we will be able to find correlations between structural components of retina and their variation in tissue mechanics. This will pave the way for in vitro studies on tissue regeneration and surgery techniques in combination with drug testing.

1:30 PM SM01.03.02 Effective Weight Control via an Implanted Self-Powered Vagus Nerve Stimulation Device

Obesity is a global health issue that is suffered by over 700 million people worldwide.[1] Common approaches for treating obesity include non-surgical (excise) and surgical (invasive) treatments, which normally have a high potential of weight rebound or can introduce serious complications.[2] Recent studies demonstrated that vagus nerve blocking and stimulation have multiple physiologic functions related to food intake, energy metabolism, and glycemic control, which can result in a meaningful weight loss. Nevertheless, like many other electrical nerve stimulation therapies, the electrical signals and corresponding biological activities are very hard to be correlated, particularly for such irregular food taking and stomach peristaltic activities. Therefore, the long-term efficacy may be jeopardized and the constant electrical stimulation may trigger compensation mechanisms.[3] Power supply is also an issue for this type of implanted electronic devices.

Here we present an implanted vagus nerve stimulation (VNS) system that is battery-free and spontaneously responsive to stomach movement. The VNS system comprises a flexible and biocompatible nanogenerator that is attached on the surface of stomach. It generates biphasic electric pulses in response to the peristalsis of stomach. The simulated satiety signals deceive the brain via vagal afferent fibres,[4] and reduces food intake when the stomach is in motion. This strategy was successfully demonstrated on rat models. Within 100 days, the average body weight was controlled at 350 g, 38% less than the control groups. This new VNS system correlated nerve stimulation with targeted organ functionality through a smart, self-responsive device, and demonstrated an outstanding weight control capability better than other electric stimulation strategies. This work also provides a new concept in therapeutic technology using artificial nerve signal generated from coordinated body activities.

11:45 AM SM01.02.05 Non-Swellable, Cytocompatible Hydrogels with Enhanced Stiffness and Toughness

Human skin exhibits high stiffness of up to 100 MPa and high toughness of up to 3,600 J m⁻² despite its high water content of 40–70 wt%. Engineering hydrogels have rarely possessed both high stiffness and toughness, because compliant hydrogels usually become brittle when excess crosslinker is added to make the gel stiff. Furthermore, conventional hydrogels usually swell under physiological conditions, weakening their mechanical properties. Here, we designed a non-swellable hydrogel with high stiffness and toughness by interpenetrating covalently and ionically crosslinked networks. The stiffness is enhanced by utilizing ionic crosslinking sites fully, and the toughness is enhanced by adopting synergistic effects between energy-dissipation by ionic networks and crack-bridging by covalent networks. Non-swelling behaviors of the gel are achieved by densifying covalent and ionic crosslinks. The hybrid gel shows high elastic moduli (up to 108 MPa) and high fracture energies (up to 8,850 J m⁻²). In vitro and in vivo swelling tests prove non-swelling behaviors of the gel. Live/dead assays show 99% cell viability over a period of 60 days.

The study of the restoration of vision is one of the most popular research topics in neuroscience and biomedical sciences. A functional/adaptive retinal prosthesis is highly sought after to combat degenerative eye diseases and build foundational devices for future engineering models. A sub-retinal device requires a specific structure compared to other prosthetics. However, the specifics of this work also require high transparency as a performance metric. Low impedance and high Charge Injection Capacity (CIC) are typical metrics for stimulus electrodes but our chip architecture will place electrode materials anterior to photodiodes, thus a material with high transparency and biocompatibility must be determined.

These electrode characteristics have already been studied extensively in photovoltaics. Therefore in order to provide the best performance for our proposed device it is necessary to extensively test a selection of materials from previous literature. Each of the three categories: Trans-conductive Oxides (TCO), Metal Nanowires (NW), & 2-D materials can yield suitable candidates, such as: Aluminum doped Zinc Oxide (AZO), Boron doped Zinc Oxide (BZO), Indium Tin Oxide (ITO), AgNW/Silver Nanowires + PEDOT:PSS, Carbon Nanotubes (CNT) + PEDOT:PSS, & Graphene with PEDOT:PSS. The primary materials examined in this study are Aluminum doped Zinc Oxide (AZO), Boron doped Zinc Oxide (BZO), PEDOT:PSS for environmental sensors, PEDOT:PSS, and AgNW.

The fabrication of test electrodes has two separate wafer designs. The testing substrate used for electrocharacteristics has a Ti/Au/Ti sandwich structure on Si wafers; on a SiO2 layer 30nm Ti was sputtered, followed by 500nm Au, and then 30nm or Ti. A photoresist pattern was used with wet etching to create a desired wiring pattern. Next, a 1um SiO2 passivation layer was applied and reserved contact/ electrode locations were etched with RIE. Last, an experimental electrode material was sputtered onto the reserved electrode location. For the biocompatibility test and the transparency test, electrode material was sputtered onto 1mm thick quartz glass substrates. The resulting substrate was cut to specifications via optimized saw dicing. Optical testing utilizes the same substrate without dicing measures. Since our device will be mounted in ocular tissue for the long-term biocompatibility concerns become a central issue. An MTS biocompatibility assay test, using Hippocampal neurocytes, was performed on 10mm x 10mm square test substrates on quartz glass. AZO, BZO, & PEDOT:PSS electrodes were successfully formed and Pt and Ti electrode wafers were fabricated for baseline. In the biocompatibility test. Each conductive material is deposited on quartz pillars. The pillars have dimensions of 50um x 50um x 200um. Each pillar is spaced 200um X & Y from other pillars in a grid like fashion. This research currently is verifying the bi-compatibility of flagged materials and we will continue to report on electrode performance compared to referenced research. AZO was a promising material but with initial testing was shown to be incompatible. Statistically speaking AZO is less biocompatible than control condition so is incompatible with our application at this point in time. BZO and AgNW are also being targeted for Biocompatibility testing due to the potential of harmful nanoparticles from the electrode material. PEDOT-PSS is commended for its biocompatibility, electrical, & optical characteristics but process fabrication methods used can lead to undesirable material conditions like optical hazing in the polymer.

The Hippocampal neurocytes in direct contact with our electrode material showed biocompatibility of AZO to be lower than Pt electrodes. Further testing with BZO and AgNW are required because current literature suggests that each of the metallic materials has the potential to release hazardous nanoparticles to the tissue. Optical and electric characteristics have thus far been within expected performance ranges for our desired device.

2:30 PM SM01.03.06 Biomedical Applications of Wireless Surface Heater with Near-Field Communication Temperature Sensor Albert H.Y. Lau and Paddy K. L. Chan; The University of Hong Kong, Hong Kong, Hong Kong.

Hyperthermia (also known as thermal therapy or thermal ablation) has been adopted as one of the cancer treatment approaches in medical surgery. By applying high temperature on the cells, the proteins structure would be damaged and the cell would be destroyed. In general, Radio Frequency (RF) probes are applied onto the target tissues for the ablation process. However, one of the major drawbacks is difficult to apply when the cancer tissues are on the surface of the organs. Here we propose a novel approach to develop surface hyperthermia technique by using oscillating magnetic field induction on metal thin film. In our device, the heat is transferred from the organ surface to the cancer cells through bioheat transfer process. Heat generation process will be modulated by varying the conductance of the metal thin film, the strength and the frequency of the oscillating magnetic field. Optimal parameters such as film geometry, film thickness, magnetic induction distance and ablation time are identified through the combination of in vivo experiment and computational modelling. Near-field communication (NFC) temperature sensor is also integrated in the system enabling a wireless interface for smartphone to monitor and analyze the treatment performance. Based on the steady state heat transfer model and comparing the measured temperatures by the NFC temperature sensor, we can calculate the temperature profile inside the pig liver. By using a input power of 2000W/m2, the highest heater temperature is 443 K in our device which is sufficient for the ablation process. This wireless heater is believed to have high potentials in various kinds of in-vivo testing or non-invasive thermal treatments.

2:45 PM SM01.03.05 Nanowire Sensor Devices for Lab-on-a-Chip Platform Larysa Baraban1, 2, Julian Schlüt1, Bercy Ibarlucea1, 2 and Gianarelio Cuniberti1 2, 3; 1Institute for Materials Science, Max Bergmann Center for Biomaterials Dresden, TU Dresden, Dresden, Germany; 3TU Dresden, Center for Advancing Electronics Dresden, Dresden, Germany.

Tight interaction between nanophysics, materials science and biotechnology led to the emergence of a new class of bioinspired systems that enables to bring the area of biosensors e.g. for cell or molecular diagnostics and analytics to the new level. Very promising candidates for the future diagnostics are the electronic nanobiosensors that have attracted great attention in the last years since they provide rich quantitative information for medical and biological assays without pre-treatment and specific optical labelling of the detected analyte. One dimensional nanostructures, e.g. semiconductor and metallic nanowires serving as backbone of the sensor device, have attracted attention as highly efficient elements due to their high surface-to-volume ratio, which simplifies the detection of biochemical species. Use of nanowires enable to ultimately decrease the dimensions of the sensing area of the device and thus increase the resulting sensitivity of the assay. Finally, nanoscale sensors integrated into lab-on-a-chip system offer attractive opportunity of the multifunctional and multiplexed bio- and chemical analysis that can be performed in real time, directly in-flow. Here we focus on two subsystems for the in-flow analysis at the micro- and nanoscale, represented by (a) silicon nanowires based field effect transistor and (b) metal nanowires assembled as nanocapacitor. We demonstrate the applicability of the systems for the detection single molecules, e.g. influenza or Ebola viruses [1-3], biochemical reactions [4], as well as classify the blood cells in a cytometry format.

Circulating Tumor Cell Microarrays: An Emerging Tool in Cancer Diagnostics

By Xuan Zhang, Jin Hu, Qiu Xie, Bo Zhang, and Masoud S. Loeian

Wednesday Morning, April 24, 2019

In this presentation, we will discuss the use of microarray-based technologies for the detection of circulating tumor cells (CTCs) in blood samples. We will present our recent work on the development of a novel microarray system that is capable of capturing CTCs with high sensitivity and specificity. Our microarray system utilizes an innovative design that allows for the simultaneous capture of multiple CTC clusters, thereby improving the overall capture efficiency.

We have demonstrated the successful capture of spiked CTCs in blood samples, as well as the capture of CTC clusters in patient samples. These results highlight the potential of our microarray system for application in clinical settings, particularly in the early detection and monitoring of cancer.

The presentation will also include an overview of the current state of CTC research and the challenges that remain in this field. We will discuss the potential impact of our work on the development of new diagnostic tools and therapeutic strategies for cancer patients.
Carbon dots, a new class of zero-dimensional carbon-based nanomaterials, have attracted great interest recently in the nanomedicine because of their versatile merits such as biocompatibility, facile functionalization, and tunable photoluminescence properties. In particular, carbon dots have allowed for their biomedical applications to disease diagnostics and therapeutics such as bioimaging and photodynamic therapy. Here, we present the new design of carbon dots with multiple functions that highly inhibit the aggregation of metalloproteins and form Au(A) peptides. The abnormal assembly and aggregation of Aβ peptides in the brain tissue is a major hallmark of Alzheimer’s diseases (AD) that currently affects one in nine people aged over 65 worldwide. Despite numerous efforts made over the past decades, effective suppression of Aβ aggregation is still challenging due to multifactorial pathogenesis involving high levels of metal ions in the brain. Note that copper ions (Cu(II)) have drawn significant attention in AD pathogenesis due to their high activities in binding with Aβ peptides and forming neurotoxic Aβ-Au(Cu) complexes.

To provide a new anti-amyloidogenic strategy in the prevention of Cu(I)-associated Aβ aggregation, we have synthesized the multifunctional carbon dots and demonstrated their capabilities on (i) effective Cu(I) coordination; (ii) interaction of Aβ self-assembly; and (iii) photodynamic inactivation of Aβ peptides. The nitrogen-containing aromatic moieties on as-prepared carbon dot’s surface can act as a key role in interact with Cu(II) and Aβ’s aggregation sites by electrostatic and hydrogen/hydrophobic interactions. Interestingly, the Cu(II) coordination of carbon dots promotes the carbon dots’ absorption and fluorescence enhancement, thus further leads the photoinduced generation of reactive oxygen species (ROS) under light irradiation; the resulting ROS from carbon dots then photodynamically inactivated Aβ peptides (e.g., histidine and methionine) to lose the affinity towards Cu(II) as well as an aggregative property. These carbon dots’ simultaneous and multiple inhibitory effects significantly mitigated the neuronal cytotoxicity of Cu(II)-bound Aβ species, showing high cell survival rate.

In summary, we will introduce the synthesis of multifunctional carbon dots and the various photochemical analyses to validate the suppressing capabilities of carbon dots against Aβ aggregation. Our investigations highlight the significant luminescence properties of carbon dots as promising biocompatible nanoeagents and their therapeutic application in preventing Aβ-induced Alzheimer’s diseases.

8:30 AM  3SM01.04.02
Cancer Nanotheranostics Based on Molecular Self-Assembly Process   Xiaoyuan Chen; National Institute of Biomedical Imaging and Bioengineering, Bethesda, Maryland, United States.

The Nobel Prize in Chemistry 1987 was awarded to Cram, Lelh and Pedersen for their development and use of molecules with structure-specific interactions of high selectivity. Twenty years later in 2016, Nobel Prize in Chemistry recognized supramolecular chemistry and molecular recognition again by awarding Sauvage, Stoddart and Feringa for the design and synthesis of molecular machines. This talk takes cyclodextrin and cucurbituril as examples to develop cancer nanotheranostics that make use of the dynamic and responsive nature of non-covalent interactions. By the formation of host–guest complexes with macrocyclic hosts, the anticancer drugs can be easily formulated to prepare nanomedicine showing satisfactory anti-tumor efficacy and reduced normal organ toxicity.

9:00 AM  3SM01.04.03
Re-Purposing of Frog-Skin Derived Collagen for Wound Healing Applications   Cidiem Cimenoglu; Jun Kit Wang and Chor Yong Tay; 1, 2 School of Materials Science and Engineering, Nanyang Technological University, Singapore, Singapore; 3School of Biological Sciences, Nanyang Technological University, Singapore, Singapore.

Collagen (Col) is a well-studied biomaterial, particularly as wound dressing material due to its superior biological and chemical properties [1]. However, the application of collagen in wound healing remains as a critical issue due to poor adhesion, proliferation and migration of cells. In addition, majority of the collagen-based biomaterials are primarily fabricated from mammalian sources, such as bovine and porcine [2]. There have been many considerations in terms of religious issues. Moreover, the extraction process from mammalian animals is complex, laborious, time consuming and expensive due to the stiff and fibrous nature of bovine and porcine tissue [3]. Hence, alternative sources of collagen are highly desirable, particularly for wounds treatment.

In this study, collagen derived from the skin of the American Bullfrog (i.e. Rana catesbeiana) is explored as nature-derived biomaterials for wound healing applications. We report the successful implementation of an innovative method that can significantly shorten the collagen extraction process by ~50% compared to traditional acid solubilisation method with relatively high extraction yield (~35%). Differential scanning calorimetry (DSC) analysis suggest that the collagen has excellent thermal stability (~41°C), suggesting that it is compatible for skin-contacting as well as for in vivo implantation applications. In vitro studies showed that the bioactivity of the bullfrog skin-derived collagen was well-preserved by supporting the attachment and proliferation of human keratinocytes (i.e. HaCaT), compared to commercially-available bovine collagen. Interestingly, our findings demonstrated that the extracted bullfrog skin-derived collagen can significantly enhanced the wound closure rate of HaCaT in an in vitro scratch wound assay as compared to bovine collagen. At the mechanistic level, we showed that this phenomenon may be attributed to the ultra-fine nano-fibers of the frog-skin derived collagen, which could augment the process of re-epithelialization by modulating the adhesiveness and chemotaxis of the keratinocytes [4]. Overall, bullfrog skin could be a viable waste-to-resource material for the production of non-mammalian collagen with high yield percentage and great wound healing capacity.

A Biodegradable Hybrid Nanoplatform for Synergistically Overcoming Multidrug Resistance   Shengjiao Wang; 1, Ki-Bum Lee and Qiuyi Zhang; 2 Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States; 3Northwestern Polytechnical University, Xi’an, China.

The complexity and heterogeneity of cancer and subsequently developed multidrug resistance (MDR) seriously undermines the therapeutic potential of chemotherapy. Herein, we developed a biodegradable redox heat assisted cancer killing (RHACK) nanoparticle for enhanced treatment of cancer in vitro and in vivo. Unlike conventional anticancer strategies, our hybrid nanoparticle based drug delivery system (DDS) not only target-specifically delivers anti-cancer reagents, but also target heterogenous MDR pathways to achieve sensitization of cancer cells. More specifically, our RHACK nanoparticle-based drug delivery system (DDS) reduces intracellular glutathione (GSH) level, induces ROS generation and simultaneous provide photothermal (PTT), thereby synergistically sensitizing breast cancer towards chemotherapy. Remarkably, our RHACK nanoparticle is constructed from an iRGD conjugated hollow iron oxide core and a manganese dioxide shell (Fe3O4/C@MnO2@iRGD NPs) and shows unique benefits for synergistically overcoming MDR: i) a strong NIR absorption for effective laser ablation of tumor and sensitize the tumor to further chemotherapy; ii) a tunable glutathione-reactive MnO2 shell; iii) a redox-based endogenous biodegradability; iv) a hollow structure for efficient anti-cancer drug loading; v) Fenton reaction and ROS species (hydroxyl radical); vi) Mn4+ as degradation product for induction of intracellular Fenton reaction and ROS species (hydroxyl radical); vii) capabilities of breast tumor targeting and penetration. Based on this unique platform, we successfully demonstrated a robust co-sensitization of a malignant drug resistant breast cancer towards a clinical applied anti-cancer drug in vitro and in vivo by combining PTT, glutathione reduction and Fenton reaction on a single platform. A detailed mechanistic study on the molecular biology pathways further reveals the synergy originate from the regulation over several key genes and proteins including HSF-1 and MDR-1/P-gp, TP53, BCL-2, BAX, Caspase 3/9. Given the heterogeneous tumor microenvironments and the highly complicated drug-resistance pathways in breast cancer, our multifunctional hybrid nanoparticle-based DDS could provide a promising therapeutic alternative for more efficient treatment of breast cancer in clinical applications.

9:30 AM  3SM01.04.05
Top-Down Fabrication of Spatially Controlled Mineral Gradient Scaffolds for Interfacial Tissue Engineering   Alexander Boys; 1, Hao Zhou, 1 Jordan Harrod, 2 Lawrence Bonassar, 1 and Lara Estoff; 4; 1Materials Science and Engineering, Cornell University, Ithaca, New York, United States; 2Ming exposed School of Biomedical Engineering, Cornell University, Ithaca, New York, United States; 3Sibley School of Mechanical Engineering, Cornell University, Ithaca, New York, United States; 4Kavli Institute for Nanoscale Science at Cornell, Comin, University, Ithaca, New York, United States.

Materials engineering is typically divided into “bottom-up” and “top-down” methodologies. While, top-down engineering has been common practice for centuries, these approaches are rarely used with respect to biological systems. We have applied a top-down approach for generating a mineral gradient scaffold in trabecular bone. Mineral gradients are found in a variety of biological systems that link soft tissue and bone. Some of these systems are primarily mechanical, such as the attachments of ligaments and tendons with bone or the interface between cartilage and bone. Other soft tissue-to-bone interfaces are necessary for development, such as the growth plate or the interface present
during endochondral ossification. These interfaces are further relevant to cancer metastasis, as tumors have been found to localize to the growth plate. These systems are complex, requiring a method for producing the mineral gradient present at the interface. With these goals in mind, we fabricated a mineral gradient scaffold through the spatially controlled removal of mineral from bone.

To fabricate this scaffold, cylindrical trabecular bone biopsies were extracted from neonatal bovine femurs. These biopsies were decellularized, followed by partial submersion in a demineralizing solution. Scaffolds were removed from the demineralizing solution at time points of 0, 3, 6, and 9 hours to determine the amount of mineral removed from the biopsy and observed to be the porosity in the trabecular bone. These observations were confirmed by plotting porosity vs. time or the fractional demineralized content and fitting a surface to these data. Scaffolds were segmented into quadrants, and X-ray diffraction was performed on these segments, confirming the presence of a mineral gradient within the scaffold.

To examine the cellular compatibility of the resulting mineral gradient, mesenchymal stem cells were seeded onto these scaffolds. The seeded mineral gradient scaffolds were cultured in osteogenic media, and a live/dead stain was performed. The cells attached to the exterior of the trabecular structure with a viability of ~91%. The scaffolds exhibited high viability and with no differences in viability were observed in the mineralized or demineralized portions of the scaffolds.

Immunohistology was performed to examine the effects of mineral content on cellular behavior. Seeded scaffolds were cultured, fixed, and sectioned for staining. Stains were chosen to determine if stem cells were showing any chondrogenic or osteogenic behavior. Staining profiles revealed differences in cellular behavior between the mineralized and demineralized ends as well as on the exterior and interior of the scaffold. Type I collagen staining was observed throughout the scaffold. Type II collagen staining was consistent on the interior of the scaffold but appeared higher in the exterior regions of the mineralized end of the scaffold versus the demineralized end. Alkaline phosphatase staining was consistent on the exterior of the scaffold but appeared higher on the mineralized interior versus the demineralized interior. These findings reveal that the presence of a mineral gradient drives stem cells to produce proteins associated with chondrogenic and osteogenic cellular behavior.

Overall, we fabricated mineral gradient scaffolds using a top-down engineering approach. These scaffolds, generated using a novel approach to biomaterials synthesis, drive cellular behavior and will be useful in a variety of fields, including orthopedics, development, and cancer research.

Quantum Capacitance Based Amplified Graphene Phononics for Studying Neurodegenerative Diseases

Bijitimala Keisham1, Akop Seksenyan2; 1, Steven Denyer2, Pouyan Kheirkhahi3, Gregory D. Arnone2, Pablo Avalos3, Abhiraj D. Bhimani2, Clive Svendsen4, Vikas Berry1 and Ankit Mehta7; 1Chemical Engineering, University of Illinois at Chicago, Chicago, Illinois, United States; 2Neurosurgery, University of Illinois at Chicago, Chicago, Illinois, United States; 3Chicago Medical School, Rosalind Franklin University of Medicine and Science, North Chicago, Illinois, United States; 4Regenerative Medicine Institute, Cedars-Sinai Medical Center, Los Angeles, California, United States.

Amyotrophic lateral sclerosis (ALS) is the most common adult-onset motor neuron disease, characterized by a rapid loss of upper and lower motor-neurons resulting in patient death from respiratory failure within 3-5 years of initial symptoms onset. Although at least 30 genes of major effect have been reported, the pathobiology of ALS is not well understood. There is a critical need to develop a system which can accurately diagnose this rapidly deteriorating disease. Herein, we report on graphene’s phonon vibration-energies as a sensitive measure of the composite dipole moment of the components of the interfaced cerebrospinal fluid (CSF) to specifically identify patients with ALS disease.

The second-order overtone of in-plane phonon vibration energy (2D) of graphene shifts by 3.2±0.5 cm⁻¹ for all ALS patients studied in this work. Further, the amount of -doping induced shift in phonon energy of graphene, interfaced with CSF, is specific to the investigated neurodegenerative disease (ALS, Multiple Sclerosis and Motor Neuron Disease). By removing a severe roadblock in disease detection, this technology can be applied to study diagnostic biomarkers for researchers developing therapeutics and clinicians initiating treatments for neurodegenerative diseases.

To fabricate this scaffold, cylindrical trabecular bone biopsies were extracted from neonatal bovine femurs. These biopsies were decellularized, followed by partial submersion in a demineralizing solution. Scaffolds were removed from the demineralizing solution at time points of 0, 3, 6, and 9 hours to determine the amount of mineral removed from the biopsy and observed to be the porosity in the trabecular bone. These observations were confirmed by plotting porosity vs. time or the fractional demineralized content and fitting a surface to these data. Scaffolds were segmented into quadrants, and X-ray diffraction was performed on these segments, confirming the presence of a mineral gradient within the scaffold.

To examine the cellular compatibility of the resulting mineral gradient, mesenchymal stem cells were seeded onto these scaffolds. The seeded mineral gradient scaffolds were cultured in osteogenic media, and a live/dead stain was performed. The cells attached to the exterior of the trabecular structure with a viability of ~91%. The scaffolds exhibited high viability and with no differences in viability were observed in the mineralized or demineralized portions of the scaffolds.

Immunohistology was performed to examine the effects of mineral content on cellular behavior. Seeded scaffolds were cultured, fixed, and sectioned for staining. Stains were chosen to determine if stem cells were showing any chondrogenic or osteogenic behavior. Staining profiles revealed differences in cellular behavior between the mineralized and demineralized ends as well as on the exterior and interior of the scaffold. Type I collagen staining was observed throughout the scaffold. Type II collagen staining was consistent on the interior of the scaffold but appeared higher in the exterior regions of the mineralized end of the scaffold versus the demineralized end. Alkaline phosphatase staining was consistent on the exterior of the scaffold but appeared higher on the mineralized interior versus the demineralized interior. These findings reveal that the presence of a mineral gradient drives stem cells to produce proteins associated with chondrogenic and osteogenic cellular behavior.

Overall, we fabricated mineral gradient scaffolds using a top-down engineering approach. These scaffolds, generated using a novel approach to biomaterials synthesis, drive cellular behavior and will be useful in a variety of fields, including orthopedics, development, and cancer research.

Nanolithographically Patterned Surfaces for Quantifying Cellular Adhesion, Migration and Communication

Marc Raphael, Joseph A. Christodoulides, Michael Robitaille, Jinny Liu, Marc Christophersen and Jeff Byers; U.S. Naval Research Laboratory, Washington, District of Columbia, United States.

Cells are continuously performing chemical computations based on a range of inputs from their immediate environment. Two fundamental phenotypes that result from these computations are cell adhesion and migration, which play central roles in development, wound healing and diseases such as cancer. The degree to which cells adhere or migrate is dependent upon a combination of chemical and physical properties of the substrate. However, the complex coupling amongst these physical and chemical cues has made it challenging experimentally to deconvolve their individual contributions. Furthermore, cells dynamically alter their environment by the secretion of proteins. To address these complexities, we have employed a combination of electron beam and optical lithographic techniques to fabricate substrates which incorporate independently tunable topographical and chemical signaling cues, as well as nanosensors for detecting cell secretions. The approach works by patterning two materials on a single chip, one for topography, and the other for chemical functionalization. The first material, quartz, is light microscopy compatible and can be dry etched for 3D topography formation. The second material, gold, is patterned independently of the quartz etching process into nanostructures for use in either interfacing with the cell membrane or detecting protein secretions. I will present results on a range of cell types cultured on multiplexed substrates that integrate nanosensors for quantifying single cell secretions, topographical patterns for directing cell migration and biofunctionalized nanostructures for targeted adhesion studies. Cells at the boundary of two patterns experience a surface-induced competition that can be tracked in real time as they decide to adhere to one surface or migrate to the other. These chips enable quantitative insight into the biology of how local environments influence cellular decisions as well as potential guidance in the design of next generation wound healing materials and implants.

In Vitro Study for Pressure- and Cavitation-Induced Cell Damage During Mechanical Impact

Woromo Kang, Michael Robitaille and Marc Raphael; Naval Research Laboratory, Washington, District of Columbia, United States.

The dynamic response of cells when subjected to mechanical impact has become increasingly relevant for accurate assessment of potential blunt injuries and understanding injury mechanisms. When exposed to a blast, ballistic, or impact, a biological system, e.g., human brain or skin, is rapidly accelerated, which results in an acceleration-induced pressure gradient. In order to study cell behavior under these threats, we have developed a new experimental method that applies a well-controlled mechanical impact to live cells cultivated in a custom-built in vitro setup compatible with live cell microscopy. A drop tower system is utilized to apply the mechanical impact while concurrently visualizing each impact using high speed cameras. The impact amplitude is controlled by changing the vertical height of a movable mass, i.e., drop height, which is then accelerated toward the setup once released. Our experiments show that the maximum pressure in the in vitro setup is very sensitive to the height of cell culture media. As an example, we experimentally correlated drop heights with the onset of cavitation nucleation in different cell culture setups. We find that the critical drop height decreases by about 7 times when the height of cell culture media increases from 1 cm to 4 cm. This result indicates that lower drop heights induce the critical pressure (a material related property) with increasing cell media height and, as a result, implies that impact-induced pressure in biological systems depends on their size due to inertial effects. Another interesting experimental observation is that cells near cavitation bubbles upbaked tripodium iodide, typically not permeable to live cells, which we suspect is due to transient damage to the cell membrane. Our study shows that in addition to acceleration - which is the most commonly used criteria for blunt injury - size of biological systems, e.g., head size, should be appropriately considered for accurate assessment of potential injuries due to mechanical impact.

Gum—Tragacanth-Alginate Beads as an Oral Nutraceutical Delivery System for Improving the Bioavailability of Nutraceuticals

Anupam Apoorva1, Abhiraj D. Bhimani2, 3, Manchikanti Padmavati2 and Swagata Dasgupta2; 1School of Bioscience, Indian Institute of Technology Kharagpur, Kharagpur, India; 2Department of Chemistry, Indian Institute of Technology Kharagpur, Kharagpur, India; 3Rajiv Gandhi School of Intellectual Property Law, Indian Institute of Technology Kharagpur, Kharagpur, India.

The present study delineates preparation, characterization, and application of calcium alginate (CA) - Gum tragacanth (GT) beads carrying phenolic compounds from B. alba plant for oral drug delivery. The CA-GT beads were prepared by ionic gelation method and its physicochemical characterization was carried out by SEM, EDAX and FTIR analysis. The swelling analysis and in vitro degradation assay revealed that the percentage of swelling at different time points varies with the respective change in the GT concentrations in beads. Variation was prominent in compositions with higher GT concentrations.

A critical examination of the drug release profile showed correlation with the percentage of GT in the formulation that retarded the release rate of phenolic compounds. Extract loaded formulations were tested against osteosarcoma cells (MG-63). Cytotoxicity data, live dead staining, nuclear condensation-frAGMENTATION, DNA fragmentation (by TUNEL assay) and cell
migration study together confirmed the therapeutic potential of the CA-GT formulations. The above findings suggest that *B. alba* phenolic extract loaded CA-GT beads could be used as the natural therapeutic source for cancer treatment and an ideal source of nutraceuticals.

**Diagnosis of Vitiligo Through Novel UV Camera Applying Eco-Friendly Blue-Light Emitting Zinc-Blended Quantum-Dot**
Jiho Choi, Il-Hwan Kim, Jun-Sung Park and Jeou-Gun Park; Department of Electronics and Computer Engineering, Hanyang University, Seoul, Korea (the Republic of).

In general, the vitiligo is diagnosed by wood lamp test which is also known as ultraviolet (UV) light test. However, UV light in the wavelength under 400-nm is not visible to the human eyes and cameras. Thus, it is difficult to obtain accurate UV images for analyzing lesions of vitiligo patients. The light incident into the human skin has different penetration depth depending on the wavelength, which means the information of the reflected light differs according to the incident light wavelength. If there were any cameras or sensors that are capable of obtaining UV reflected images of the lesion, more deliberate information such as lesion size, depth, and shape could be obtained through a depth profile according to the penetration depth of human skin along the wavelength.

Here, we developed a novel UV camera applying blue-light emitting quantum-dots (QD) to conventional Si CMOS image sensor (CIS). Synthesized zinc-blend-structure QD absorbs UV light below 400-nm wavelength and emits the 433-nm-wavelength blue-visible-light by energy-down-shift mechanism, having a quantum yield of 75.2%, full-width half maximum (FWHM) of 20.7 nm. The reflected light from the object passes through the QD filter before entering the photodiode of the Si CMOS image sensor. The QD filter completely passes the visible light and only absorbs UV light and QD emits the blue-visible-light. In other words, the QD filter converts UV light, which the conventional image sensors cannot detect, into the blue light so that the image sensor can detect it. This process presents that the image sensor receives a further increased blue pixel’s signal caused by UV intensity. The difference of blue pixels intensity between with and without QD filters can be considered as a detected UV intensity.

In this work, we diagnosed and treated lesions of 2 vitiligo patients through our new QD UV camera. We photographed the UV images of their hands and faces and analyzed them in cooperation with dermatologists. Based on the analysis, we recommended proper treatment and they tracked their treatment progress for 2 months. It was observed that the UV images of the vitiligo lesions showed lower UV pixel intensities than the intact normal skin, which means that the location, size and distribution of vitiligo lesions could be clearly identified through the UV image. The UV pixel intensities effectively showed information of epidermis and dermis where vitiligo lesions mainly exist. Melanocytes reflect and scatter ultraviolet rays to protect the skin from harmful UV rays. So, in UV images of normal skin, melanocytes reflect UV, resulting in high UV intensity. However, in the case of vitiligo lesions, there is less reflection of UV light due to the lack of melanocytes, resulting in low UV intensity. In addition, we can also estimate the extent of melanin pigment deficiency by this UV intensity analysis. The regions with relatively high UV pixel intensity and those with relatively low UV intensity were clearly distinguished in the vitiligo region. The relatively lower UV intensity is relatively large, indicating that lesions are more severe. We confirmed that the novel QD UV camera can accurately discriminate the lesions of vitiligo from the intact region, and also can quantify the severity of the lesion. It is expected that the UV images taken by the QD UV camera will provide guidelines for the diagnosis and treatment of vitiligo. In addition, UV pixel analysis is also considered to be valid for several skin disorders that can be diagnosed by the UV light test such as tinea capitis, erythrasma, albinism, etc.

**Point-of-Care Device for Detection and Measurement of Biomarker Associated of Trauma Brain Injury**
Stephany Uribe, Alexander Rodriguez, Eliana Cervera and Pedro J. Villalba; Universidad del Norte, Barranquilla, Colombia.

Trauma brain injury (TBI) is a problem in public health locally and globally. The consequences of this pathology are serious and its mortality rate is high. TBI severity is classified using the Glasgow coma scale. This scale assigns points to the patient’s eye opening, motor and verbal response based on a qualitative test. Although this method is part of several TBI protocols, its application is susceptible to errors associated to the specific physiological response of each person. Misclassification of the initial TBI severity will in turn impact the therapeutic management causing in many cases delays in proper treatment. In this research work, we are proposing a quantitative method to classify the severity of the TBI, using highly specific serum biomarkers in order to reduce misclassification as well as to provide a fast, easy to use tool for monitoring the patient’s progress. An electrochemical immunosensor has been developed by means of a specific antibody against S100B protein. S100B is a calcium binding protein present in the central nervous system; its concentration increases within the initial hours of the TBI event, its value as TBI biomarker has been demonstrated before. The biosensing platform was created by electrochemical polymerization of a nanodiamond enhanced polyaniline matrix, this matrix was then functionalized with antiS100B by crosslinking reaction after APTMS-GA (siloxane 3-aminopropyltriethoxysilane - glutaraldehyde) initial surface modification. The amount of antibody was optimized for the specific surface active area using different depositing dilutions, the results showed that after 5ug/mL no statistically significant increment in the electrochemical signal is observed. Response of the biosensor to the antigen was recorded using impedence spectroscopy experiments in 0.2 M KCl and 10 mM potassium ferrocyanide as supporting electrolyte. Our results showed the characteristic semicircle behavior at the high frequency range associated to the redox probe of the electrolyte; also, the Warburg line has been observed at the low frequency range.

**Hydrogel-Based 3D Cell Culture Models of Neurological Diseases—Disease Progression and Experimental Therapeutics**
Sara Pedran, Jee-Wei Chen, Jan C. Lumibao, Ana M. Magarinos, Donald W. Pfiff, Jann N. Sarkaria and Brendan A. Harley; 1University of Illinois at Urbana Champaign, Urbana, Illinois, United States; 2Mayo Clinic, Rochester, Minnesota, United States; 3The Rockefeller University, New York, New York, United States.

Functional brain changes represent a significant social and economic burden that has increased considerably over the last decades. The development of new scientific capabilities that are able to analyze brain structure and connectivity has recently revitalized the neuroscience field. Biomaterial based ex vivo models of healthy and diseased brain tissue are among those tools that may help study the complex in vivo brain tissue to better diagnose, treat and develop experimental drugs. Recently, we have developed a novel biomaterials based on methacrylamide-functionalized gelatin hydrogels, and used microfluidic-forming techniques to generate platforms that combine transitions of biophysical and biomolecular properties found in the glioblastoma tumor microenvironment, from the core to the tumor margins (2). Moreover, this biomaterial approach is able to monitor the response of patient-derived xenograft (PDX) cell populations with different molecular signatures; in particular, we have analyzed the amplified and the constitutively activated vIII mutant EGFR receptor. We have also characterized PDX response to targeted inhibitors, such as erlotinib, a tyrosine kinase inhibitor that specifically blocks EGFR.

In addition to tumor tissue samples, these gelatin-based platforms permitted the survival and growth of the large nucleus gigantocellularis (NGC) neurons, considered as the ‘master cells’ for initiating CNS arousal. The better understanding of NGC neurons might help to understand particular characteristics of certain brain disorders (7). Until now, the lack of a physiologically relevant microenvironment for in vitro culture has been associated with unusual cell morphologies and cell death. We showed that NGC neurons were able to survive and differentiate in the presence of HA, and without the assistance of growth factors (8). In this context, 3D in vitro cultures of NGC neurons may allow the analysis of the extracellular matrix contributions and growth factors to their survival, growth and development. Due to the success of these platforms to recreate cerebral tissue peculiarities, we have also cultured neural stem cells within gelatin—HA hydrogels and we are currently working on the development of neurodegenerative diseases models.

Self-Powered Biosensors—Integration of p-n Junction Photodetectors with Colorimetric Reactions Kihyeun Kim, Hyungjin Jang and Min-Gon Kim; Department of Chemistry, Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of).

Electronic devices are one of the most promising candidates for chemical and biological sensor platforms because of their high sensitivity, and application to Internet of Things (IoT). However, a major challenge to developing such sensor systems is the use of battery power owing to its limited life-time, inconvenience of recharging, and insufficient battery level to operate the integrated sensor system.

In this study, we suggest self-powered biosensors by integration of n-IGZO/p-Si photodetectors and enzyme-based colorimetric reactions, which are operated by light sources in daily life environment such as fluorescent light and sunlight. A colorimetric reaction was performed at a polydimethylsiloxane vessel located at the upper side of the IGZO/Si photodetector, which is physically apart from the photodetectors. Photocurrent changes of the photodetectors are induced by the colorimetric reaction depending on target concentration, which enables quantitative analysis. The self-powered biosensors showed high sensitivity towards glucose level in real human samples without matrix effect due to physical separation of the photodetectors and colorimetric reaction part. This sensor platform could pave the way for highly sensitive portable IoT biosensors operating without batteries.

Anti-Adhesive Bio-Degradable Mg Alloy Assisted by Nano-SiO₂ Particles Jaehyoung Son¹, Junkyun Oh¹, Daehyun Cho² and Winfried Teizer³; °Texas A&M University, College Station, Texas, United States; ²R&D Center, Hyundai-Steel, Dangjin, Korea (the Republic of).

Recently the interest in bio-degradable Magnesium alloys as an alternative implant material has increased. Since no surgery is needed to remove the inserted implant, the risk of bacterial infection and the medical burden is decreased. In particular, anti-adhesion is one of the prerequisite properties in medical applications to avoid bacterial colonization on the implant. In this study, biocompatible Mg-Zn-Ca alloys are synthesized by squeeze casting and hydrophobic nano-SiO₂ particles are coated on the alloy surface. In the process, a porous SiO₂ layer is formed and its condition controlled via dip-coating. The human pathogen most frequently found on implant materials, Staphylococcus Aureus (S. Aureus), is prepared through the porous-plating method to evaluate the anti-adhesive properties and the bacteria on the surface are counted by scanning electron microscopy. The result shows that hydrophobically treated SiO₂ particle layers significantly mitigate the bacterial attachment compared to a bare Mg surface and a SiO₂ particle layer.

Development of Tissue-Engineered, Disease-Mimicking Culture Platforms Kristyn Masters; University of Wisconsin, Madison, Wisconsin, United States.

Introduction: Extracellular matrix (ECM) alterations accompany the onset and progression of many diseases. In this work, we sought to develop tissue engineering-based approaches to mimic the disease environment in order to perform prospective analyses that probe the mechanistic role of the ECM in disease etiology. Our specific focus was on calcific aortic valve disease (CAVD), whose pathogenesis is poorly understood, but is known to involve excessive glycosaminoglycan (GAG) accumulation early in the disease process. We implemented two different strategies to create tissue-engineered platforms that mimic elements of early CAVD: 1) construction of engineered environments using traditional “bottom-up” methods, which enable tuning and control of scaffold parameters but fail to capture the complexity of the native tissue. 2) construction of a top-down organ culture platform that retains native complexity, but lacks the ability to precisely control tissue composition.

Methods: To create scaffolds via the bottom-up approach, we copolymerized methacrylated gelatin with either methacrylated hyaluronic acid (HA) or chondroitin sulfate (CS) at concentrations intended to replicate the GAG enrichment found in early CAVD (1x GAG = healthy valve; 4x = diseased) and seeded them with valvular interstitial cells (VICs). To create top-down scaffolds, we transduced scaffolds to overexpress hyaluronic acid synthase-3, an enzyme responsible for HA synthesis. Porcine aortic valve leaflets were treated with feline immunodeficiency virus (FIV) containing a vector for either GFP (FIV.GFP) or human hyaluronic acid synthase-3 (FIV.HAS3) and then cultured for up to 7 days. Cultures were also treated with low density lipoprotein (LDL) or oxidized LDL (oxLDL), which mimicked CAVD risk factors, and analyzed for overall ECM composition, compressive modulus, cell phenotype, and cytokine/growth factor production.

Results: Analysis of CS-enriched scaffolds demonstrated that pathological CAVD enrichment alone was sufficient to promote a change in VIC phenotype or secretion of inflammatory factors. Instead, the main function of increased CS appeared to be sequestration of oxLDL. Sequestered oxLDL increased the secretion of multiple inflammatory cytokines (e.g., IL-6, IL-8, PDGF-BB, MCP-1) by VICs, thereby implicating oxLDL as a potent factor in regulating pathological VIC behavior. Moreover, a positive feedback loop was uncovered where oxLDL increased CS production, which further increased oxLDL retention. These findings suggest that increased CS in early CAVD plays a central role in regulating the onset of inflammation.

Meanwhile, a different role for HA enrichment was demonstrated in both bottom-up and top-down scaffolds. ECM-edited valve organ cultures were generated to achieve a 4-fold enrichment in HA content, with the level of HA enrichment regulated by the amount of virus administered. This result demonstrated the ability to tailor the ECM composition of intact, 3D tissues, thereby providing a novel disease-mimicking culture platform. In both culture approaches, HA enrichment served to stimulate vascular endothelial growth factor (VEGF) production by the VICs, but HA was not involved in LDL/oxLDL sequestration or subsequent inflammatory activity. Instead, HA-induced VEGF production was sufficient to stimulate the proliferation and tubulogenesis of endothelial progenitor cells, suggesting that increased HA in early CAVD may promote the pathological angiogenesis that is a hallmark of this disease.

Conclusions: We developed complementary tissue-engineered platforms to mimic disease pathogenesis, including a novel approach to use intact organ cultures as semi-tunable biomaterials. These platforms were applied to reveal new information about CAVD pathogenesis. The applications of these approaches extend beyond valvular disease, as there are many pathways which involve selective enrichment of specific ECM components.

4:00 PM SM01.05.06
Radioluminescent Nanoparticles for Molecular Imaging and Theranostics Yufu Ren, Justin Rosch, Allison DuRoss, Madeleine Landry, Megan Neufeld and Conroy Sun; Oregon State University, Portland, Oregon, United States.

Molecularly targeted nanoparticles that produce X-ray excited optical luminescence, also known as radioluminescence, enable unique multimodal imaging capabilities not available with current clinical technologies. These functional nanomaterials, often comprised of lanthanide-doped nanophosphors, have also been evaluated as energy mediators for deep tissue photodynamic therapy (PDT) and other X-ray stimulated therapies. As both imaging probes and therapeutic, the application of radioluminescent nanoparticles (RLNP) is limited by their photophysical properties. Here we present the synthesis and characterization of lanthanide-doped nanoparticles with core-shell structure, incorporation of high-Z elements, and their surface modification with biocompatible polymers to improve functional properties for biological applications. In this radioluminescent platform, optical emission can be tuned by selection of dopants, such as Eu³⁺ and Tb³⁺. Utilizing a thermal degradation of organometallic precursors, uniform cubic (~11 nm) nanocrystals were obtained and observed by transmission electron microscopy (TEM). To evaluate the radioluminescence of these nanophosphors a suspension of the particles was irradiated at 130 kV while an emission spectrum was obtained by a spectrophotometer. Emission was improved significantly through protection from surface quenching of luminescent centers. In
Bioengineered 3D Interpenetrating Collagen-Alginate Network to Elucidate the Effects of Biomechanics on Cancer-Associated Fibroblasts (CAFs) Behaviour

Huan Cao and Chor Yong Tay; School of Materials Science and Engineer, Nanyang Technological University, Singapore, Singapore.

Cancer-associated fibroblasts (CAFs) are one of the major types of stromal cells within the tumor microenvironment that support tumor progression by secreting pro-tumorigenic cytokines. In addition, CAFs also play a key role in stromal remodeling during tumor progression, including increased deposition and crosslinking of collagen. In general, the matrix mechanics have been shown to affect various cellular behaviors. However, to our knowledge, limited studies have been carried out to investigate the effects of matrix biomechanical changes on CAFs behavior, particularly in three-dimensional (3D) environment as well as the downstream paracrine crosstalk with the surrounding tumor cells remains elusive. Hence, in this study, a collagen/alginate interpenetrating network (CoAI-IPN) hydrogel system was employed to investigate the phenotypic and functional characteristics of CAFs under 3D environment setting. In general, collagen and alginate have different crosslinking mechanisms, which will allow the precise control of the hydrogel biomechanical properties without affecting its biochemical properties.

Results showed that hydrogel with Young's Modulus from ~108 to 898 Pa was successfully fabricated by varying the crosslinking density of alginate which preserving the biochemical properties. Subsequently, CAFs were encapsulated within the CoAI-IPN hydrogel system. Interestingly, a highly polarized CAFs morphology was observed within compliant CoAI-IPN hydrogel (i.e. uncrosslinked system), but not rigid hydrogel system (i.e. highly crosslinked). This in contrast to 2D cell culture findings, in which stiffer substrate will promote the cell spreading. In addition, the compliant CoAI-IPN hydrogel system also affected the CAFs behavior at molecular level with enhanced nuclear translocation of the mechano-sensitive YAP/TAZ protein and expression, as well as the up-regulation of other CAFs classical markers (i.e. α-SMA and FAP). These findings show that the CAFs phenotype and functional characteristics are highly plastic, which depends on the biomechanics of the microenvironment. Moreover, these understanding from the tumor stroma mechanic-bioactivity relationship studies can shed the lights on the restraint the pro-tumorigenic effects of CAFs in cancer therapy.

Additively Manufactured Scaffolds with Selective Permeability for Biological Applications

Yale Jeon, Min Soo Jeon and Dong Rip Kim; Hanyang University, Seoul, Korea (the Republic of).

Three-dimensional (3D) porous scaffolds with large specific surface area have received considerable interest due to their capabilities of effective cell attachment and growth. For their utilization, the cells are cultured over the pre-fabricated scaffolds, which typically not only accompanies a long-time process, but also arises the challenge to precisely position target cells inside the scaffolds. Here, we utilize an additive manufacturing technique to fabricate nanoporous 3D porous scaffolds in which target biological species are located. The fabricated platform shows the selective permeability such that biological species are confined inside, while chemical species can pass through the porous layers, due to the compliant CoAl-IPN hydrogel system also affected the CAFs behavior at molecular level with enhanced nuclear translocation of the mechano-sensitive YAP/TAZ protein and expression, as well as the up-regulation of other CAFs classical markers (i.e. α-SMA and FAP). These findings show that the CAFs phenotype and functional characteristics are highly plastic, which depends on the biomechanics of the microenvironment. Moreover, these understanding from the tumor stroma mechanic-bioactivity relationship studies can shed the lights on the restraint the pro-tumorigenic effects of CAFs in cancer therapy.

Magneto-Dielectric Hyperthermia Therapy for Adenocarcinoma

Sovesh Mohapatra, Naveen K. Tailor and Soumitra Satapathi; Indian Institute of Technology, Roorkee, India.

In the last few decades, adenocarcinoma has become a major cause of death for millions. Different forms of tumor therapies are in use including chemotherapy and radiotherapy but due to inefficacy of these therapies, it has elicited considerable research interest to explore alternative methods. The use of regional hyperthermia for the treatment of adenocarcinoma can negate the use of harmful chemicals and radiations. In the present study, Ca0.6Fe0.4O3-PVDF has been proposed as the bio-compatible magnetic dielectric composite to provide thermo-regulated prolonged treatment. In a systematic manner, the study has attempted to optimize the bio-compatible magnetic hyperthermia and dielectric thermo-regulation parameters by analyzing a group of composites. Finite Element Method (FEM) analysis has been used to simulate hyperthermia treatment of adenocarcinoma in the glandular cells of prostate gland. Electromagnetic Waves (Frequency Domain) and Bioheat Transfer modules on COMSOL were used to simulate the electromagnetic distribution and heating effect in the system. The localized heating of the magnetic particles due to high frequency electromagnetic waves and the subsequent increase in the temperature makes the cancer cells more susceptible to conventional therapeutic procedures. This leads to effective cell apoptosis.

The approach proposed can be used in the near future for developing novel classes of therapeutic devices for the treatment of adenocarcinoma.

SESSION SM01.06: Poster Session: Materials for Biological and Medical Applications

Wednesday Afternoon, April 24, 2019
5:00 PM - 7:00 PM
PCC North, 300 Level, Exhibit Hall C-E
Oxidative stress during sepsis pathogenesis remains the most important factor creating imbalance and dysregulation in immune-cell function, usually observed following initial infection. Hydrogen peroxide (H\textsubscript{2}O\textsubscript{2}), a potentially toxic reactive oxygen species (ROS), is excessively produced by pro-inflammatory immune cells during the initial phases of sepsis and plays a dominant role in regulating the pathways associated with systemic inflammatory immune activation. In the present study, we constructed a peroxide scavenger manganese-soluted polymeric albumin manganese dioxide (mSPAM) nanoassembly to catalyze the decomposition of H\textsubscript{2}O\textsubscript{2} responsible for the hyper-activation of pro-inflammatory immune cells. In a detailed manner, we investigated the role of mSPAM nanoassembly in modulating the expression and secretion of pro-inflammatory markers elevated in bacterial lipopolysaccharide (LPS)-mediated endotoxemia during sepsis. Through a facile one-step solution-phase approach, hydrophilic bovine serum albumin reduced manganese dioxide (BM) nanoparticles were synthesized and subsequently self-assembled with cationic manganeseoslated dextridye cross-linked polyethyleneimine (mSPM) to formulate mSPAM nanoassembly. In particular, we observed that the highly stable mSPAM nanoassembly suppressed HIF1α expression by scavenging H\textsubscript{2}O\textsubscript{2} in LPS-induced macrophage cells. Initial investigation revealed that a significant reduction of free radicals by the treatment of mSPAM nanoassembly has reduced the infiltration of neutrophils and other leukocytes in a local endotoxemia animal model. Furthermore, therapeutic studies in a systemic endotoxemia model demonstrated that mSPAM treatment reduced TNF-α and IL-6 inflammatory cytokines in serum, in turn circumventing organ damage done by the inflammatory macrophages. Interestingly, we also observed that the reduction of these inflammatory cytokines by mSPAM nanoassembly further prevented IBA-1 immune-positive microglial cell activation in the brain and consequently improved the cognitive function of the animals. Altogether, the administration of mSPAM nanoassembly scavenged H\textsubscript{2}O\textsubscript{2} and suppressed HIF1α expression in LPS-stimulated macrophages and thereby inhibited the progression of local and systemic inflammation as well as neuroinflammation in an LPS-induced endotoxemia model. This mSPAM nanoassembly system could serve as a potent anti-inflammatory agent, and we further anticipate its successful application in treating various inflammation-related diseases.

**SM01.06.02 Magnetic Field-Inducible Drug-Eluting Nanoparticles for Image-Guided Thermo-Chemotherapy**

In Kye Park, Yong Yeon Jeong, Myeong Ju Moon, Sang-Joon Lee, and Yong-Kyu Lee; 1Department of Biomedical Sciences, Chonnam National University, Hwasun, Korea (the Republic of); 2Department of Radiology, Chonnam National University Medical School, Hwasun, Korea (the Republic of); 3Department of Health Administration, Gwangju Health University, Gwangju, Korea (the Republic of); 4Department of Green Bioengineering, Korea National University of Transportation, Chungju, Korea (the Republic of).

Multifunctional nanoparticles integrating cancer imaging and treatment modalities into a single platform are recognized as a promising approach; however, their development currently remains a challenge. In this paper, we synthesized magnetic field–inducing drug-eluting nanoparticles (MIDENs) by embedding superparamagnetic iron oxide nanoparticles (Fe\textsubscript{3}O\textsubscript{4}; SPIONs) and cancer therapeutic drugs (doxorubicin; DOX) in a temperature-responsive poly (lactic-co-glycolic acid) (PLGA) nanomatrix. Application of an external alternating magnetic field (AMF) generated heat above 42 °C and subsequent transition of the PLGA polymer matrix (Γ = 42–45 °C) from the glassy to the rubbery state, facilitating the controlled release of the loaded DOX, ultimately allowing for simultaneous hyperthermia and local heat-triggered chemotherapy for efficient dual cancer treatment. The average size of the synthesized MIDENs was 127.1 ± 3.20 nm in diameter. In vitro studies showed that the MIDENs were cytocompatible and especially effective in destroying CT26 colon cancer cells with AMF application. In vivo studies revealed that the MIDENs enabled enhanced T-contrast magnetic resonance imaging and a significant suppression of malignant tumor growth under an AMF. Our multifunctional MIDENs, composed of biocompatible substances and therapeutic/imaging modalities, will be greatly beneficial for cancer image-guided thermo-chemotherapy applications.

**SM01.06.03 Design and Fabrication of a Piezoelectric Microcantilever Sensor for Measurement of Cardiomyocyte and Skeletal Muscle Force Generation**

Elizabeth Colín, Alisha Colon, Christopher J. Long, Narasimhan Siram Narasimhan, and James H. Hickman; 1NanoScience Technology Center, University of Central Florida, Orlando, Florida, United States; 2Hesperos, Inc., Orlando, Florida, United States.

Piezoelectric materials have the ability to convert mechanical energy to an electrical signal leading to their use in a variety of microscale sensor systems having biological and medical applications such as pressure sensors, chemical sensors, and biosensors. Additionally, the ability of piezoelectric materials to convert electrical signals to mechanical energy has led to their use as microactuators. Microcantilever sensors have been increasingly used in biomedical microelectromechanical systems (bioMEMS) to measure small scale mechanical movement. One application is in the determination of contractile force of various muscle tissues using in vitro human-on-a-chip systems, which have typically used imaging methods or optical laser deflection of cantilevers for calculating contractility. Incorporation of piezoelectric materials into cantilever-based mechanical sensors would enable a direct electrical readout during muscle contraction. Moreover, these cantilevers could be used in reverse, as actuators, to impose a stress on tissues attached to the device. This work describes the design and fabrication of a piezoelectric biosensor cantilever which can act as either a sensing element for tissue contraction or as an actuator to apply mechanical force to cells. A piezoelectric sensing element composed of a thin film of aluminum nitride (AlN) was fabricated on a micromachined silicon cantilever which was subsequently integrated with human primary skeletal muscle or human iPSC-derived cardiac muscle to monitor the contractility of the muscle tissues. An electrical signal generated by the piezoelectric element from the contracting muscle (skeletal or cardiac) was interfaced to a commercial amplifier for recordings. Force generation was calculated from cantilever deflection data generated by spontaneous or stimulated contraction of the cells. The ability of the piezoelectric cantilevers to serve as actuators for applying mechanical stress to tissue constructs was evaluated using an optical beam displacement measurement method to detect the deflection of the piezoelectric cantilever under a periodic waveform of applied voltage. This novel bioMEMS sensor has the potential for incorporation into human-on-a-chip systems for basic physiological investigation and pharmaceutical compound development, cosmetics toxicity testing, and personalized medicine.

**SM01.06.04 Synthesis and Characterization of Biopolymer-Capped Mesoporous Silica Nanomaterials for Drug Delivery**

Cecilia Kinang, Brian Trevyn; 1Chemistry, University of St. Thomas, St. Paul, Minnesota, United States; 2Chemistry, Colorado School of Mines, Golden, Colorado, United States.

Mesoporous silica nanoparticles are an extensively studied material in drug delivery because of its porous nature, stability, and biocompatibility. In this research, MCM-41 type mesoporous silica was studied for use as controlled drug release into the oral cavity. This was achieved through loading of the model dye toluidine blue into the pores of MCM-41 and coating the loaded particles with starch. The starch is digested by the salivary enzyme, α-amylase, allowing for controlled release into the oral cavity. After optimizing the dye loading procedure, the enzymatically mediated dye release of the starch coated particles was monitored over a three-hour period in the presence of and absence of α-amylase. The dye release rate increased in the presence of α-amylase, indicating the efficacy of these materials for enzymatically triggered drug release into the oral cavity.

**SM01.06.05 Specific Interaction of Lactose Modified Graphene Oxide by the Hepatic Asialoglycoprotein Receptor**

Kevin Diaz-Galvez, Erika Silva-Campa, Alexel Burgara-Estrella, Martin Pedroza-Montero, and Jose A. Sarabia-Sainz; Universidad de Sonora, Hermosillo, Mexico.

We describe the evaluation of lactose modified graphene oxide (GO-LA) as potential drug carrier targeted to hepatic asialoglycoprotein receptor (ASGPR). Structural-modification and functional analysis of GO-LA were performed. The structure and morphology of the composite were analyzed by scanning electron microscopy (SEM), and atomic force microscopy (AFM), while Raman spectroscopy was used to track the chemical modification. For the safe application of GO-LA an evaluation of the cytotoxic effect and specific interaction of glycoconjugate were also studied. The SEM and AFM analysis of the GO showed graphene sheets with 2-3 nm layer size and few of them reached the 4 nm. Raman spectrum showed the characteristic peaks of graphene oxide at 1608 cm\textsuperscript{-1} and 1350 cm\textsuperscript{-1} corresponding to G and D bands, respectively. Null cytotoxic effects were observed for GO samples proving the biocompatibility. The biorecognition of GO-LA and the specific absorption to HepG2 cells were confirmed. The high efficacy of conjugation, hemolytic safety, and specific recognition described here lactose modified GO represents a potential drug delivery vehicle to hepatic tissue.

**SM01.06.06 Smart Chitosan Nanoparticles and Their Capacity as a Drug Delivery System**

Alexel J. Burgara-Estrella, Jorge L. Loya-Duarte, Jose A. Sarabia-Sainz, Erika Silva-Campa, Martin Pedroza-Montero and Daniel Fernandez-Quiroz; Universidad de Sonora, Hermosillo, Mexico.

Cancer is one of the leading causes of death around the world. The lifestyle and external factors can increase the cancer risk, no matters economical status and develop of countries. Current therapies such as radiation and chemotherapy alone or in combination are still unsatisfactory, and survival of cancer patients is still low. Therefore, it is necessary to develop a novel therapy that improves survival rates and the quality of life for cancer patients. In this sense, smart nanocarriers constitute an evolving possibility for controlled drug delivery to the tumor, which minimizes side effects in the patient. Among its properties, these systems have the option to respond reversibly to external factors, such as temperature, pH, ionic strength, and others. The chitosan-graft-poly(N-vinylcaprolactam) (CS-g-PVCL) is a water-soluble copolymer that could comply with requirements for
SM01.06.10
Bioconvertible and Biodegradable Polystyrene Nanoparticles for Brain Tumor Targeting

Rui Xiong, Shengtao Yu, Shuaidi Zhang, Volodymyr F Korolovych and Vladimir V. Chonnam National University Medical School, Jeollanam-do, Korea (the Republic of); 2The University of Akron, Akron, Ohio, United States; 3University of Illinois at Chicago, Chicago, Illinois, United States; 4University of Akron, Akron, Ohio, United States; 5Beijing University of Chemical Technology, Beijing, China.

In this study, a novel approach to block a carboketone (CB)-based zwitterionic segment in polyurethanes (PU) to address biocompatibility, anti-fouling properties and tunable mechanical properties has been developed. This zwitterionic PU was synthesized with CB-based diol and CB-based triol, respectively. The hydrolysis of both diol and triol segments at the interface generates zwitterionic CB functional groups that provide excellent anti-fouling properties via the enhanced hydration capacities of CB groups. This thermostimuli-responsive nanoparticle can be utilized for drug delivery and gene therapy applications. Owing to its biocompatibility, thermal stability, tunable mechanical properties and good anti-fouling properties, this CB-based polyurethane can be emerged as a promising candidate for biomedical application. It also can be an alternative replacement for those PUs without anti-fouling properties.
The development of nanoparticles which can be used as a stimuli responsive drug carrier for the treatment of different diseases has been an emerging area of research interest. In our study, we have designed a chitosan-bilirubin micelle (nanoBil) carrying losartan for the treatment of liver fibrosis which is responsive to intrinsic reactive oxygen species (ROS). Bilirubin is hydrosoluble in nature and its carboxyl group was conjugated to the chitosan amine group using the EDC-NHS chemistry to form amphilic conjugate nanoBil. Losartan has proved to be an angiotensin I receptor blocker having hepatic fibrosis reduction capability and it is being used as the therapeutic payload in this study to form nanoBil-losartan micelle. The ROS responsive Nano micelle can release loaded drug inside at the liver fibrotic area, hence liver fibrosis is characterized with high ROS levels.

The release characteristic of nanoBil-losartan was tested by ROS generator to confirm losartan release. The reduction in the hepatic stellate cell activation after the treatment of nanoBil-losartan were analyzed based on the alpha smooth muscle actin (α-sma) expression both in vitro (LX2 cell line) and in vivo studies. Hydroxyproline level as well as histopathological evaluation of the liver showed a decreased collagen content in the treated groups. Both the intravenous and intraperitoneal administration of the nanoBil-losartan resulted in a decreased level of fibrosis in thioacetamide (TAA)/Ethanol induced liver fibrosis C57H6 mouse model. The in vivo and in vitro results suggest that the ROS stimuli responsive nanoBil nanoparticle could be a potent therapeutic option for inflammatory diseases like liver fibrosis which are abundant of ROS.

SM01.06.13 Unexpected Electroanalytical Activity of the Stainless 304 Needle Toward Blood Glucose Determination [Ha]oon Lee, Hong Chul Lim, Pham S. Nguyen, Young-hun Seo, Ji-young Lee, Truong Kha Phu Cuong and Ik-Soo Shin; Soongsil University, Seoul, Korea (the Republic of).

Accurate and precision are essential requirements for chemical analysis. Herein, we developed highly precise amperometric sensor for point-of-care diagnosis of blood glucose. Stainless steel 304 needle was employed as a sensing electrode since it possesses decent electrical properties with low material cost. Especially, we found that it displayed extremely low non-faradaic background current in electrochemical condition as well as highly precise and sensitive current response specifically toward hydrogen peroxide. In blood condition, we confirmed the stainless steel 304 needle immobilized with glucose oxidase showed current signal at -0.15 V (vs SCE) upon the addition of glucose. The amperometric current signal from the modified electrode was highly specific to the blood glucose with negligible response towards interfering species. Moreover, the signal from the glucose was extremely precise with linear correlation in the diabetic blood sugar concentration range of 1-20 mM (y = 2.52328 x 10^3, R² = 0.9952) with negligible standard deviation (σ = 1.78 x 10^-3, n = 5, CV = 0.10 – 0.84 %). These results demonstrate that stainless steel 304 needle electrode hold great potential in electroanalytical biosensors based on redox enzymes relevant to hydrogen peroxide.

SM01.06.14 Excessive Metalloenzymes Condensed DNA Nanoparticles for Tumor Targeted and Drug Delivery [Li]in, Haoran Zhao and Leilei Tian; Sothern University of Science and Technology, Shenzhen, China.

Abstract: As a new and hot spot, the nucleic acid nanotechnology plays a more and more important role in cancer targeted therapy because of its perfect biocompatibility, high sensitivity and functional richness. Including directional drug carrier and release, fluorescent tracking and so on. DNA condensation is a good way to get these kind of carriers. Metal complexes, such as Co(NH3)2, can induce DNA condensation. A recent study found that pyrophosphate magnesium, the RCA reaction by-product, can condense the long single stranded DNA into the tight micro structure. Based on this finding, we report a condensation of single-strand DNA with excessive magnesium ions and form the nanoparticles whose diameter is around 100nm. Furthermore, combined with the programmability of DNA sequence and structure, we finally get an functional Mg-DNA nanoparticle with high doxorubicin loading rate, high tumor-targeting property, high biocompatibility and low toxicity. Due to the wealth of DNA sequence design, this kind of DNA nanoparticles will have a great potential on nano-medical treatment in the future.

Keywords: DNA condensation, tumor-targeted chemotherapy, nanomaterial, drug delivery

SM01.06.15 Physico-Chemical Effects of Gelatin Addition in Carboxymethylcellulose and Calcium Phosphate Cement-Based Nanocomposites [Eesa] Guban and Daygu Ege; Bogazici University, Istanbul, Turkey.

Nanocomposites comprising of biopolymers and calcium phosphate cements (CaP) are promising due to their biocompatibility, non-toxicity, biodegradability and suitable mechanical properties for biomedical applications. In here, a new composite material was synthesized with carboxymethylcellulose (CMC) and gelatin (GEL) as the liquid phase and CaP based powder as the solid phase. In this study, the effect of the addition of different wt% of GEL including 0, 5, 10, 20 in the liquid phase was investigated on the physical properties of the nanocomposites. Physico-chemical characteristics of materials were determined by using Fourier transform infrared (FTIR) spectroscopy, scanning electron microscopy (SEM) and mechanical tests. Swelling analysis was performed after 1, 8, 16, 24 and 48 hours and the degradation of samples was studied after 7 and 14 days. FTIR results showed that there was a physical interaction between CMC and GEL with H bonding which was evident from the peak at 3288cm⁻¹. Disruption in GEL structure was observed from the band at 1600-1400 cm⁻¹. Disruption of GEL structure may increase the interaction between CMC and GEL molecules. After mixing of solid and liquid phases, negative charges on CMC and Ca²⁺ molecules start to interact with each other and produce attraction sites for PO₄⁻ molecules. This lead to an accumulation of hydroxyapatite-like structures. A homogenous and porous microstructure was observed by using SEM in all samples. Mechanical tests showed that GEL improved the strength of the samples up to 20 wt% of GEL. The addition of 20 wt% of GEL decreased the mechanical properties. The compressive strength values were found up to approximately 6 MPa. Swelling results revealed that increasing in GEL concentration cause decrease in swelling until the 16th hour after that 10wt% GEL samples had the lowest swelling which was approximately 28%. Finally, degradation studies indicated that the highest degradation rate was for 10% GEL incorporated samples. Addition of further GEL also reduced the degradation rate. Overall, the addition of GEL improved physical properties of the samples for potential biomedical applications.

SM01.06.16 Enhanced Water Dispersible Carbon Nitride Nanodots Using PE Gylation—Application for Bioimaging Probes [Sing]hee Park, Sungjin Park, Dawoon Jang and Sujin Seok; Inha University, Incheon, Korea (the Republic of).

The PEGylated OCN (PEG-OCN) was well dispersed in water as nanodots with a lateral dimension showed strong photoluminescence in the visible region. Recently, thin 2D materials, such as graphene derivatives, have become an emerging nanosized platform in various biomedical applications, such as biosensors and their unique fluorescent, electronic, and morphological features, and high surface areas. In particular, graphitic carbon nitride (g-C₃N₄), composed of trizaine or tri-s-triazine building blocks containing alternating sp³-hybrid carbon and nitrogen atoms, is a stable metal-free 3D layered material. However, this γ-C₃N₄ has a less water dispersibility because stable 2D tri-s-triazine network. So we first make oxidized carbon nitride(OCN) material by using KMn0₄ in the presence of H₂SO₄. Thus 3D OCN has an oxygen abundant structure. Fluorescent materials are being used for the optical/fluorescence imaging of living cells and animal models. As such, the development of heavy-metal-free, water dispersible, and bio compatible imaging probes is still important. Carbon nitride (g-C₃N₄) is used as a bioimaging probe due to its suitable optical properties, thus enhancing its biocompatibility and dispersibility in aqueous media is required.

In this study, we incorporated short-chain polyethylene glycol (PEG) groups onto a carbon nitride network by the simple N-alkylation of hexaethylene glycolic mesylate with nuclophilic nitrogen atoms on oxidized carbon nitride. Cell-viability testing confirmed that these “heavy-metal-free” organic nanodots were highly biocompatible and noncytotoxic. In particular, the developed nanodots could provide clear confocal images of RAW 264.7 cells without weakening cell activity and displaying any aggregation in a range of concentrations (25-100 mg/mL) with bright-green emission in the cytoplasm.
Microbial carbohydrates have a variety of characteristics and original functionalities comparing with carbohydrates produced by animals and plants. Microbial carbohydrates are natural, non-toxic, biodegradable and biocompatible polymers, GRAS(Generally Regarded As Safe) and their structural diversities lead to a variety of functions. Recently, many novel applications have been developed using microbial polysaccharides such as drug delivery systems, hydrogels, nanoparticles, and materials for tablet-processing press in the pharmaceutical and biomedical industries as well as in the bio-nano engineering. Microbial polysaccharides can be utilized as stabilizer, emulsifier, thickener, gelling agent in food industries. The Microbial Carbide Resource Bank (MCRB) was established to investigate and collect various functional polysaccharides and microorganisms in order to widely utilize the microbial resources. MCRB also take a role as resource bank through microbial modification and offering a storage facility for various microbial carbohydrates and microorganisms. In addition, MCRB will contribute the properties of graphene oxide incorporated calcium phosphate cement-based injectable bone substitutes Ozan Durukan and Dogu Yetis; Bogazici University, Istanbul, Turkey.

Improving the mechanical properties of calcium phosphate cement (CPC)-based injectable bone substitutes (IBS) is crucial to expand their application in the treatment of bone defect. In this study, the effect of graphene oxide (GO) on the mechanical properties of CPC-based injectable bone substitutes (IBS) were studied by using X-ray diffraction (XRD), scanning electron microscopy (SEM), dynamic mechanical analysis (DMA), rheological measurement techniques. Also, the produced IBS samples were analyzed by means of setting time and temperature, injectability, bioactivity and biocompatibility studies. To this end, IBS samples were prepared with 0.5, 1.0, 1.5 and 2.0 wt% GO incorporation. According to the results of the DMA analysis, incorporation of GO increased the compressive modulus of IBS samples after setting of the cement phase. For example, while the compressive modulus of 0.5wt% GO incorporated IBS samples was ~0.2 MPa, the compressive modulus of 2wt% GO incorporated IBS samples was ~0.7 MPa. A sharp increase of the storage modulus (G') and viscosity (Pa.s) in rheological measurement was observed which indicates the gelation temperature and gelation time. The gelation temperature and time were decreased effectively with the addition of GO. XRD analysis of GO incorporated IBS samples showed that the peak intensity and the grain size of CPC increased with respect to wt% of GO incorporation. SEM analysis of GO incorporated samples showed that all the prepared samples were biocompatible. Although the increase of wt% of GO reduced the injectability, overall, the addition of GO as a reinforcement has a positive effect on the mechanical properties and handling of injectable bone substitutes.

SM01.06.21

Bioprinting of autologous tissues encompasses many different steps and accelerating the procedure can be very critical for patients with an urgent need of organs. The physical aspects of self-assembly and the dynamics of multicellular systems used with printing technologies for tissue fabrication are therefore very important. We have developed a microscopic and mathematical model to study tissue fusion, an essential element of self-assembly phenomena during tissue maturation in the post-bioprinting procedure. Here, the model is generalized for different bioink geometries. A mathematical model is introduced and microscopic interactions at the cellular level in the maturation of bioprinted tissues have been studied. The fusion of tissue-like cell aggregates (cellular bioinks) is elaborated with the help of bonds among their adhesion molecules. The model is used to describe the fusion procedure. Consequently, the system energy and self-assembly force are calculated and compared in order to understand the effect of bioink geometries on the acceleration of the maturation of bioprinted tissues. Based on our microscopic and mathematical model, we introduce some topological criteria for bioinks for faster maturation of bioprinted tissues.

A Disposable Electrocatalytic Sensor for Whole Blood NADH Monitoring Hi Gyu Moon, Sung-Hoon Yoon, Ju Kyung Lee and Kyuhong Lee; National Center for Efficacy
Nicotinamide adenine dinucleotide (NADH) play a major role in enhancing in metabolic redox reactions and cellular energy metabolism in living cells. This compound with Nicotinamide adenine dinucleotide (NADH) is key central charge carriers in living cells and are essential in energy metabolism, reductive biosynthesis, and antioxidation. Therefore, the monitoring of NADH in living animals and cells still remains challenging because commercial methods including fluorescence spectra and electrochemical methods have invasive, time consuming, low sensitivity and complex. Herein we developed a one-step monitoring method for NADH via an electrocatalytic reaction using a surface-modified screen-printed electrode (SPE) for forming a self-assembled monolayer (SAM) with high stability. As a result, this electrode has a limit of detection (LOD) of 0.25 µM and a sensitivity of 0.0057 ± 0.0011 µM/µA in pure PBS and a 0.49 µM LOD with a sensitivity of 0.0076 ± 0.0002 µM/µA in cell culture medium. In particular, the applicability of this NADH sensor was shown for the first time in cell viability monitoring via NADH sensing in cell culture supernatants and inflammatory and fibrotic responses by PHMG-poly(hexamethylene guanidine phosphate) via NADH sensing in mouse blood.

Hierarchical Structured Zinc Oxide Nanowires—Polyacrylucid Microfibers Composite for Cancer Immunotherapy

Sang Won Byun1, Bumchul Park1, Prashant Sharma2, 1, Jei Beom Shin1, Jae-Won Lee2, 1, Na-Yoon Jang2, 2, Yu Jin Kim3, 1, Yumi Kim-4, 1, Nam-Hyuk Cho2, 1, 5 and Young Keun Kim-1, 1; 1Materials Science and Engineering, Korea University, Seoul, Korea (the Republic of); 2Biomedical Sciences, Seoul National University, Seoul, Korea (the Republic of); 3Biological Sciences, Seoul National University, Seoul, Korea (the Republic of); 4Research Center for Nanomaterials, Korea University, Seoul, Korea (the Republic of); 5Institute of Endemic Disease, Seoul National University Medical Research Center and Bundang Hospital, Seoul, Korea (the Republic of).

Zinc Oxide (ZnO) nanocomposites have attracted much attention for various biomedical applications, such as drug delivery, bio-sensor, diagnosis and therapy due to biocompatibility and multifunctionality. [1] Therefore, various synthesis methods of this promising material have been extensively studied to control nanostructures. [2] However, there are limitations to synthesize nanostructures by combining ZnO with other polymeric substances, especially fiber structured polymer. Herein, we introduce a unique method for synthesizing ZnO nanowires (NWs) on polyacrylic acid (PLA) microfiber and applied them for cancer therapy. The Hierarchical structured composite nanowire (NWs) and PLA microfibers are synthesized by two simple and effective methods. First, randomly oriented PLA microfibers containing ZnO nanoparticles seeds are electrospun on collector. Subsequently, ZnO NWs are directly grown from the seeds embedded in fiber via hydrothermal method. In addition, the NWs are stably fixed on the fibers and their densities are also successfully controlled according to the amount of seeds. Since the process of growing ZnO NWs from the seeds inside the fiber is a quite unique phenomenon, their growth mechanism and kinetics are also addressed in this paper. Moreover, this inorganic-organic nanocomposite provides a new approach to immunotherapy because there biodegradable, biocompatible and multifunctional properties. Conventionally, in therapy application, ZnO-based composites are directly injected into target cells to release embedded drugs or operate therapy using cytotoxicity. However, this nanocomposite plays a role in transferring only antigens on the nanowires to the cells. We demonstrated the nanocomposites induce immune response against specific target biomarkers and inhibit tumor growth in vivo. ZnO and PLA nanocomposite reduced immune suppressive regulatory T cells and improved the infiltration of T cells into tumor tissues when compared to mice immunized with PLA fibers coated with the antigen. This novel structured nanocomposite provides a new possibility in immunotherapy

Shape Dependent Magnetic Resonance Imaging Performance and Drug Release Behavior of Iron Oxide Nanoparticles

Bibek Thapa1, 2, Daysi Diaz-Diestra1, 2, Angela Luis-Matos1, 2, Juan Beltran-Huara1, Wojciech M. Jadwisienczak1, Brad R. Weiner2, 2 and Gerardo Morelli1, 2; 1University of Puerto Rico, San Juan, Puerto Rico, United States; 2Molecular Sciences Research Center, San Juan, Puerto Rico, United States; 3University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States; 4Ohio University, Athens, Ohio, United States.

Iron oxide nanoparticle (IONs)-based magnetic resonance imaging (MRI) T2 contrast agents (CAs) are broadly designed based on the size of the IONs as governed by quantum mechanical outer sphere theory. In other words, the MRI T2-weighted contrast enhancement efficacy of IONs are generally evaluated based on the size of the IONs and hence, the magnitude of their induced magnetization. Along with this pervasive design strategy, it is worthwhile to study the contrast enhancement efficacy of IONs based on their shape and could be an intriguing strategy to design high-performance MRI CAs. Here, we report the synthesis of silane-PEG grafted spherical, hexagonal and cubic iron oxide nanoparticles (Si-PEG-SIONs, Si-PEG-HIONs, and Si-PEG-CIONs) with comparable size ranging from 12 to 14 nm and their comparative study of magnetic resonance contrast enhancement performances. Our result shows that the Si-PEG-CIONs, Si-PEG-HIONs, and Si-PEG-SIONs exhibit the respective transverse relaxivity (r2) values of 64.6, 428 and 251 mM−1s−1 which are seven, four and three times than that of clinical MRI contrast agent, resovist. Further, we also studied shape dependent drug release behavior of doxorubicin (Dox)-loaded such nanoparticles in breast cancer cells (MDA-MB-231), and our study shows that the Dox-loaded Si-PEG-SIONs release Dox more rapidly than other IONs in intracellular region of the cells which is accompanied by micropinocytosis. Our results are suggestive of shape-based design consideration of iron oxide nanoparticles for non-invasive cancer imaging and controlled release drug delivery platform.

SM01.06.25
Cavitation Bubbles in Biological Soft Materials

Womwo Kang and Marc Raphael; Naval Research Laboratory, Washington District, Columbia, United States.

Soft gels that mimic properties of biological samples are increasingly utilized as tissue simulants for the assessment of potential damage, e.g., blunt injuries, to a human body against rapid mechanical inputs. As a result, capabilities to accurately characterize and predict transient, dynamic response of soft materials under fast loading rate conditions have become critical for such biomedical applications. Here we present (1) a new experimental method for characterizing dynamic cavitation nucleation in biologically relevant soft materials; (2) quantitative characterization on the critical acceleration that corresponds to the onset of cavitation dynamic; (3) pressure gradient and transient bubble dynamics due to mechanical impact. Utilizing a drop tower based system, we have quantified the critical acceleration in soft gels while concurrently visualizing material deformation during cavitation events. Our experiments show that the critical acceleration increases with increasing concentration of gels. Note that gel stiffness increases with increasing concentration. For stiffer gels, more energy is needed for local deformation of a gel associated with bubble expansion and, as a result, larger mechanical inputs, i.e., higher cavitation events. Our experiments show that the critical acceleration in the gel is proportional to the square of the depth of the sample. Our study on how biological soft materials respond to rapid mechanical inputs is an important step to understanding possible underlying injury mechanism(s) in blunt trauma and cavitation-induced brain injury.

Carbon Doping Mediated Active Trap Centres Formation in Porous Alumina for Ion Beam Dosimetry

Sangita Bhowmick1, Saptarshi Pal1, Dip Das1, Vinip K. Singh1, Saif A. Khan1, Sudipto Roybarman1, Dinakar Kanjilal2 and Alok Kanjilal1; 1Shiv Nadar University, Greater Noida, India; 2Material Science, Inter-University Accelerator Centre, New Delhi, India; 3Physics, UGC-DAE Consortium for Scientific Research, Indore, India.

In recent days, one of the major threats for human society is cancer. Hadron therapy in this context is taking attention for targeted cancer and tumor treatment though precise online dose monitoring is an important issue for safety purpose. For hadron therapy, recently carbon ion beam with high linear energy transfer is found to be more effective than the photon beams and to measure the accurate dose delivered to the patient, however, extremely sensitive thermoluminescent/optically stimulated luminescence (TLD/OSL) phosphors are prerequisite. Among several known TL/OSL oxides phosphors, carbon (C)-doped alumina (Al2O3) is favorable for radiation dosimetry, especially in medical field due to its tissue equivalent in terms of radiation absorption, high sensitivity, and simple glow curve. A facile approach to improve thermoluminescence sensitivity of electrochemically anodized porous Al2O3 (AAO) is presented by introducing C ions for ion beam dosimetry. Here, ion implantation technique has been employed for C doping in AAO in a controlled manner. HAADF-STEM, EDS mapping, and SEM studies reveal the evolution of a porous structure followed by the carbon distribution up to a depth of ~200 nm. However, the evolution of optically active F centers of increasing ion fluence has been examined by photoluminescence investigation at room temperature and TL measurement while the chemical nature of such defect centres has been extracted by depth dependent XPS analysis. Here, we will discuss such experimental results in the framework of oxygen vacancy formation, suggesting the substitution of Al2+ ions with C+ in the vicinity of oxygen vacancies as evidenced by X-ray photoelectron spectroscopy (XPS). Further, depth dependent XPS analysis reveals that in addition to the formation of F centers, a fraction of implanted carbon atoms is involved in making conducting channels which eventually
give a differential charging phenomenon at C 1s core level.

Two-Tiered Platform for Sequence-Specific Identification of Nucleic Acid Biomarkers in Complex Biological Fluids

Mashari N. Alangari1, Jovana Veselinovic1, Yuanhui Li1, Juan M. Artes2, Erkin Seke1, Joshua Hihath and Zimple Matharu1; University of California, Davis, Davis, California, United States; 2University of Massachusetts Lowell, Lowell, Massachusetts, United States.

The recent advances in point-of-care diagnostics have led to the development of high-performance electrical sensors that can provide fast measurements with low cost and multiplexing capabilities. However, detection in complex environments is still challenging due to the non-specific adsorption of proteins that may foul the sensor surface leading to signal attenuation. Therefore, nucleic acid purification from biological samples is often a crucial, yet a laborious initial step. In general, a simple and reliable approach for base mismatch detection is yet to be achieved. To address these challenges, we present an approach for a biosensor that consists of two stages for mismatch detection in complex environment with simple purification process occurs in the first stage then the second stage investigates at a molecular level the target’s sequence using single molecule break junction (SMBJ) technique. The first stage forms a nanostructured electrode, where the electrode morphology has been demonstrated to be biofouling resilient. This coating enables both detection of specific targets in a complex biological sample and their subsequent purification using electrochemical methods. The morphology of the electrodes allows small molecules to pass and participate in the bio-electrochemical reaction happening at the electrode surface. Nanoporous gold (np-Au) electrodes can be modified with a DNA capture probe which enables sensitive detection and capture of complementary DNA or RNA targets in the presence of complex media (blood). The surface-bound DNA:DNA or RNA:DNA can then be released by electrochemically cleaving the thiol-gold linkage, eluting the hybrids from nanoporous matrix for further analysis. Complementary to the electrochemical screening approach, single molecule conductance measurements can provide a molecular insight that is unavailable using electrochemical methods. The single-molecule break junction (SMBJ) system employs a movable, nanostructured electrode tip which makes direct contact to a gold substrate. In these measurements, charge transports between the electrodes through a single bridged-molecule. The magnitude of the current passing through the molecule will change drastically compared to tunneling gap. Here, the eluted sample from the first stage can be investigated using SMBJ which can differentiate between perfectly matched vs mutated targets (3-base mismatch). Our results show the difference in conductance values between perfect and mismatch targets in complex media. The advantages of combining these two approaches offer the ability of detection of single-nucleotide polymorphisms, simultaneous identification of multiple targets, high signal-to-noise ratio and low limits of detection.

SM01.06.28
Biomedical Applications for Conducting Polymers—Modulating Axonal Outgrowth via Template-Free Nano-Engineered Surfaces

Anthony M. Kisucky, Martin Autensteiner and Mohammed R. Abidian; University of Houston, Houston, Texas, United States.

Injuries involving the peripheral nervous system (i.e. nerve lesions or transaction) are estimated to count for 2.8% of all trauma cases in the United States; when considered alongside neurodegenerative disorders such as Parkinson’s disease, nerve damage has affected no fewer than 20 million people in the US alone. At present, the “gold standard” clinical intervention is a nerve autograft, which addresses the worst morbidities of nerve injury but is not without drawbacks. Autografts are limited in their ability to repair complex injuries, they often introduce new sensory deficits or neuropathy in the donor region, and may present problems with structural mismatch between donor and repaired nerve fascicles. Artificial nerve conduits are of great interest as a replacement or supplement to autograft-based techniques, but functional recovery remains an issue with current conduit designs. Incorporation of biocompatible Conducting Polymers (CPs) has been proposed to improve neurite guidance and improve conduit performance due to CPs’ electrical, physical, and chemical properties. The roughness of CP surfaces may have an important influence on the rate and directionality of axonal regeneration, but few works have specifically addressed this potential effect.

We have investigated two common biocompatible CPs, poly(pyrrrole) (Ppy) and poly(3,4-ethylenedioxythiophene) (PEDOT), fabricated using galvanostatic (GSTAT) and potentiostatic (PSTAT) methods, and characterized the surface roughness of these two polymers. While Ppy is well-known for its electrical conductivity and physical stability, PEDOT displays superior chemical stability and electrical conductivity, making it an ideal candidate for artificial conduits.

Electrodeposition was performed on microfabricated gold electrodes using a solution of EDOT or Py monomer and poly(styrenesulfonate) under GSTAT (0.1 to 1.5 mA/cm²) or PSTAT (0.5 to 0.95 V) deposition modes over intervals ranging from 1 to 10 minutes. Each surface was analyzed with materials confocal microscopy (MCM) to measure the CP film thickness and surface roughness. Additionally, the impedance and charge storage capacity (CSC) of the films were measured with impedance spectroscopy and cyclic voltammetry, respectively. Our results suggest a dual dependence of all measured properties (roughness, thickness, impedance, and CSC) on both deposition time and applied charge. For example Ppy/GSTAT films on Michigan neural electrodes, roughness (Rq) increased from 2.14±0.25nm to 12.0±0.84nm; CSC also increased from 5.7mC/cm² to 98.7mC/cm²; finally, impedance at 1000Hz decreased from 1.84±5 Ω to 3.83±4 [MRA1] [KAM2]Ω. These measurements were taken from films deposited at 1min, 0.1mA/cm² and 10min, 1.5mA/cm² respectively. Ppy properties exhibited generally linear trends, and PEDOT properties tended to display nonlinear trends. Dorsal root ganglion (DRG) cells will be cultured on these CP films and neurite outgrowth will then be assessed as a function of surface roughness. These results can be leveraged to improve the control of regenerating axons via surface cues.

SM01.06.29
Effect of Insertion of Trimetaphosphate Nanoparticles in Nylon 6,6 Nanofibrous for Dental Applications

Francisco N. Souza Neto1, Danilo M. dos Santos2, Thayse Y. Hosida1, Thamires P. Cavazana1, Leonardo A. de Moraí1, Elisabete Frohlin1, Sergio P. Campana Filho2, Emerson Rodrigues de Camargo2 and Alberto C. Delben1; 1Department of Pediatric Dentistry and Public Health, State University of Sao Paulo, Aracatuba, Brazil; 2Department of Chemistry, University of Sao Paulo, Sao Carlos, Brazil; 3Department of Chemistry, Federal University of Sao Carlos, Sao Carlos, Brazil.

The use of nanocomposite materials can contribute significantly to improve the quality of population life. In this context, nylon 6,6 (N6) is one of the most important engineering plastics in the automobile industry and has been investigated as a bone tissue scaffold. Trisodium trimetaphosphate (STMP) can be used as potential candidates for dental applications due to the anticytotoxic action of STMP when present in a bio-compatible scaffold as N6. Therefore, the present study focuses on the incorporation of STMP in N6 polymeric matrix and was evaluated and correlated to the physiochemical properties of nanocomposites. STMP nanocomposites were prepared by mechanical milling for 48h. N6 and its nanocomposites were prepared by electrospinning technique, and the N6/STMP nanocomposites were processed by adding 2.5, 5 and 10% w/w (STMP:N6). The milling process reduced the particle size of the STMP powders without affecting its crystalline structure. Particle size was reduced of micrometric to nanometric scale after mechanical milling producing particles with ~70 nm and spherical morphology. The phase structure was analyzed by FTIR technique and nuclear magnetic resonance spectroscopies employing 13C-CPTOSS (cross polarization with total sideband suppression). 13C NMR all chemical shifts were well resolved and were assigned according to N6. By FTIR spectra it was observed characteristics peaks of N6 and STMP, showing that, STMP was incorporated in N6. The morphology it was analyzed by Scanning Electron Microscopy (SEM) technique. SEM images showed the formation of nanofibers in N6 and its nanocomposites with ~150 nm of thickness for N6 and thickness higher for N6-STMP nanocomposite, showing the existence of STMP homogeneously distributed over the nanofibers. The thermal behavior was analyzed by TGA and DSC technique. Thermogravimetry analyses demonstrated improved thermal stability of N6-STMP nanocomposites with higher STMP concentration according to its barrier effect. Additionally, the increase in the glass transition temperature in N6-STMP nanocomposites indicated the reduction of polymeric chains mobility. The mechanical properties were evaluated, and N6-STMP -2.5% nanocomposite presented higher elastic modulus, elongation at rupture and tensile strength, presenting as a potential candidate in dentistry. These findings showed a new approach to add STMP nanocomposites by electrospinning in a polymeric matrix, forming stable nanofibers with potential application in dental biomaterials. With this methodology, it was possible using this methodology to insert the STMP nanocomposites in a polymeric matrix and increase the physiochemical properties of the nanocomposites formed.

 Branched Gold Nanoparticles in Anti-Bacterial Applications

Dazhong Fang1, Yujia Wang2, Linlin Sun2 and Thomas Webster3; 1Lexington Christian Academy, Lexington, Kentucky, United States; 2Massachusetts General Hospital, Boston, Massachusetts, United States.

Gold nanoparticles have been studied extensively for the strong capability in cancer treatment and their potential in the anti-bacterial field. Due to the ease of synthesis, chemical stability, and controllable toxicity, gold nanomaterials, especially branched gold nanomaterials, have attracted enormous interest as new biomaterials. This research focuses on the controlled synthesis of branched gold nanoparticles and their antibacterial applications. The surfactantless synthesis method reported by Xie and Wang was utilized to produce the 10 nm level branched gold nanoparticles. The 20 nm to 60 nm level branched gold nanoparticles were studied extensively for the strong capability in cancer treatment and their potential in the anti-bacterial field. Due to the ease of synthesis, chemical stability, and controllable toxicity, gold nanomaterials, especially branched gold nanomaterials, have attracted enormous interest as new biomaterials. This research focuses on the controlled synthesis of branched gold nanoparticles and their antibacterial applications.
nanoparticles were prepared by seed-mediated synthetic route. To investigate the anti-bacterial effects, the branch number and length were modulated by the pH value and 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) buffer concentration. Then, the branched gold nanoparticles were characterized by Ultraviolet-visible spectroscopy (UV-Vis) and transmission electron microscopy (TEM). Moreover, the 10 nm to 60 nm level spherical gold nanoparticles were produced by the method reported by Brown and Natan and utilized as the control group. Furthermore, branched nanoparticles with diverse sizes have been utilized to reduce bacterial growth (e.g., Staphylococcus aureus, Staphylococcus epidermidis, methicillin-resistant Staphylococcus aureus, and Streptococcus) for the anti-bacterial applications.

**SM01.06.31 Bioresorbable Magnesium Screw Degradation in Goats and In Vitro**

**Walter D. Tarr**

Materials Science and Engineering, University of Florida, Gainesville, Florida, United States.

Bioresorbable magnesium alloys can be used as orthopedic medical devices to provide strength during healing and degrade once healing has completed. Magnesium alloys degrade in bodily fluids and produce hydrogen gas which is removed through a body’s natural mechanisms. This study used four goats over 12 months and Hank’s solution in vitro to show the degradation rate of the alpha-275 extruded magnesium alloy. It was found that degradation rate of extruded magnesium screws is significantly slower than as-cast magnesium alloys, while hydrogen gas evolution rates were high enough to cause relatively large hydrogen gas voids inside the femur of the goat. Hydrogen gas gets removed where the screw is exposed outside the bone, but gets trapped inside the marrow region. Magnesium alloy screw show evidence of promoting calcification while hydrogen gas voids provide a scaffolding for which bone grows around. Additionally, geometry of the screw affects the degradation rate and, depending on the contact location with the bone, changes the degradation rate at that region as well. Magnesium alloy screw degradation rates were lower than expected over a year and hydrogen evolution rates were significantly higher than expected.

**SM01.06.32 Targeted Photodynamic Therapy with Hollow TiO\(_2\)-ZnPc-FA Nanophorenes**

**Minerva U. Robles\(^1\)\(^,\)\(^2\), Emma E. Ortiz-Islas\(^1\)\(^,\)\(^,\)\(^3\) and Alfredo A. Martinez-Morales\(^1\)\(^,\)\(^,\)\(^2\)**

\(^1\) Nanotechnology Laboratory, National Institute of Neurology and Neurosurgery, Mexico City, Mexico; \(^2\) Materials Science and Engineering Program, University of California, Riverside, Riverside, California, United States; \(^3\) College of Engineering - Center for Environmental Research and Technology, Riverside, California, United States.

TiO\(_2\) has been widely used as a photosensitizer for solar energy, hydrogen generation, removal of pollutants, and in biomedical applications such as photodynamic therapy (PDT). Despite its successful application in PDT, TiO\(_2\) does not distinguish between healthy and cancer cells, hence killing both. Modification by a targeting cancer agent may provide a more effective solution. In this work, hollow TiO\(_2\) nanophores (HTiO\(_2\)NS) are obtained by using a carbon template-mediated method and functionalized with Zinc phthalocyanine (ZnPc) and folic acid (FA) for enhancing its photocatalytic activity and increasing selectivity of cancer cells, respectively. To study the attachment of FA and ZnPc onto TiO\(_2\)NS, Fourrier-transform infrared (FTIR) spectroscopy is used to characterize the functionalization of HTiO\(_2\)NS. The crystal structure was analyzed using X-ray diffraction (XRD). Size distribution, morphology, and hollowness are characterized by transmission electron microscopy (TEM). Brunauer–Emmett–Teller (BET) was taken with \(N_2\) to measure the surface area and study surface porosity of produced HTiO\(_2\)NS. Furthermore, functionalized HTiO\(_2\)NS with ZnPc-FA are tested in vitro under UV illumination to measure the reactive oxygen species (ROS) generation with a fluorescent probe. A biological test was performed via a microculture tetrazolium assay (MTT) to measure cell death and assess the effectiveness of functionalized HTiO\(_2\)NS by ZnPc-FA. The results show that HTiO\(_2\)NS modified by ZnPc-FA can serve as a potential platform for targeted photodynamic therapy.

**SM01.06.33 Dual Sacrificial Molding—3D Printing of Dual Materials to Create 3D Microchannels with Free Hanging Geometries**

**Jason Wei Huang Goh**\(^1\)\(^,\)\(^2\) and Michinao Hashimoto\(^1\)\(^,\)\(^2\)

\(^1\) Engineering Product Development, Singapore University of Technology and Design, Singapore, Singapore; \(^2\) Digital Manufacturing and Design (DManD) Centre, Singapore University of Technology and Design, Singapore, Singapore.

We fabricated microchannels with overhang and helical geometries by sequential sacrificial molding of two substrates printed by a fused deposition modelling (FDM) 3D printer. Using a 3D model consisting of two complementary materials, we fabricated a sacrificial mold with free-hanging geometries removable in water after the removal of the other substrate used as a support material. 3D printing has become an indispensable tool to fabricate microfluidic devices. In particular, FDM 3D printing has been used to create entire microfluidic devices and to fabricate sacrificial molds in removable materials. Although 3D printing may confer wide freedom of design, the geometry of the attainable sacrificial mold is limited to the capabilities of the 3D printer and associated materials. For example, sacrificial molds made with a single material in FDM cannot offer microchannels with overhang features. 3D geometries such as dual helixes remain challenging to print using FDM printing, and requires the use of auxiliary tools to facilitate printing of geometry suspended in air.

To address these limitations, we demonstrated a method that we termed dual sacrificial molding. In dual sacrificial molding, we used two complementary materials (high impact polystyrene (HIPS) and polyvinyl alcohol (PVA)) to fabricate 3D microchannels with free hanging geometries. PVA was used to model the microchannel, and HIPS was used as a support material for the PVA mold. HIPS in the sacrificial mold was firstly removed by soaking in limonene to reveal the PVA mold harboring the free-hanging geometries. We showed that PVA was intact and retained the original design after the exposure to limonene. Thereafter, the PVA sacrificial mold was embedded in PDMS and subsequently removed by soaking in water. Using this method, we fabricated two representative designs of microchannels such as dual pyramidal networks of microchannels and dual helical microchannels, both of which were not achievable by the 3D printing of sacrificial molds based on a single material.

The capabilities of dual sacrificial molding to produce microchannels harboring free hanging geometries relies on the complementary pairing of two sacrificial materials and respective solvents used to remove them. Unlike direct printing of a sacrificial mold with a single material, our method extends the freedom of design of microchannels attainable by FDM 3D printing. We highlight the potential of using ubiquitously available FDM 3D printers and commercially available filament as sacrificial materials to fabricate complex 3D microchannels in a range of matrices relevant to chemical and biological applications. More specifically, the complementary pairing of PVA and HIPS allowed the retention of a water-soluble mold which is biocompatible and versatile to use with a wide plethora of matrix materials. To this end, we envision that the method presented here could serve as an essential method to fabricate complex vasculature in biologically relevant matrices which would be difficult to achieve with a single sacrificial material and other methods of 3D printing.

SESSION SM01.07: Materials for Biological and Medical Applications VI

Session Chair: Wonmo Kang
8:15 AM *SM01.07.01
Materials for Personalized Mechanomedicine Khalid Salarieh; Department of Chemistry, Emory University, Atlanta, Georgia, United States.

Given that dysregulation of mechanisms contributes to diseases ranging from cancer metastasis to lung disease, it is important to develop methods for measuring the molecular forces applied by cells. This is a difficult problem, as molecular forces are at the piconewton scale (1 kcal/mol ~7pN*nm). To address this issue, we have developed a suite of molecular tension probes that are engineered using PEG polymers, oligonucleotides, and proteins. Tension probes employ plasmic nanoparticles, which provide significant improvement in sensitivity. Fluorescence polarization spectroscopy and super-resolution imaging provide the highest resolution maps of cell forces. I will describe the application of these probes in the study of integrin and T cell receptor mechanobiology. Finally, I will also demonstrate applications of these materials in the area of personalized mechano-pharmacology.

8:45 AM *SM01.07.02
Shape-Changing Hydrogels as Dynamic 3D Cell Culture Environments Andrea Kasko; University of California, Los Angeles, Los Angeles, California, United States.

Engineering cell culture environments that mimic both the 3D and the dynamic nature of tissues is a major challenge in tissue engineering. Even with advanced manufacturing techniques such as 3D printing, it is difficult to produce 3D structures of soft hydrogels, which are otherwise ideal for cell culture.

Self-folding materials allow the generation of cell-friendly structures with 3D complexity across a range of length scales that are difficult to achieve with printing and lithography. Folding is induced by differential stresses generated within a flexible or elastic material. Polymeric materials, and hydrogels in particular, are well-suited for self-folding applications because they undergo pronounced volume and modulus changes in response to cell-friendly stimuli such as water, pH or temperature, to generate differential stresses within. While self-folding hydrogels have been reported, heterogeneities that lead to differential swelling must be pre-patterned into the material, and thus the shape change occurs as soon as the material is placed in a physiologically relevant environment (lacks temporal control). Furthermore, only a few examples utilizing these materials with live cells have been reported.

We have designed photodegradable hydrogels incorporating ortho-nitrobenzyl moieties that permit encapsulation or cell seeding on swollen planar films. Thin sheets are programmed to undergo a 2d to 3d shape change in response to light which induces irreversible folding of the hydrogel sheet due to differential swelling of the degraded and non-degraded regions. This bottom-up approach enables the use of simple 2d precursors to create biologically relevant 3d structures such as tubes and folded containers for cell encapsulation. Unlike other shape-changing polymer systems, such as poly(N-isopropylacrylamide), the o-NB hydrogel system requires no laminated bilayers, pH change or elevated temperatures to induce shape-change. Furthermore, photodegradation based shape-change enables external temporal control of folding that can be induced at time points of choice during cell culture.

Engineering of Mature Human Induced Pluripotent Stem Cell Derived Cardiomyocytes Using Substrates with Multiscale Topography Parisia Pour Shahid Saeed Abadi 1,2, Jessica Gabern 1,2, Shahed Behzadi 1,2, Michael Hill 3, Jason Tresback 4, Tiam Heydari 5, Mohammad Ejtehadi 6, Nafis Ahmed 7, Elizabeth Copley 8, Jianhui Aghavardi 8, Richard Lee 9, Omid Farokhzad 2, 10 and Morteza Mahmoudi 10; 1Department of Stem Cell and Regenerative Biology, Harvard Stem Cell Institute, Boston, Massachusetts, United States; 2Mechanical Engineering-Engineering Mechanics, Michigan Technological University, Houghton, Michigan, United States; 3Department of Physiology, Sharif University of Technology, Tehran, Iran (the Islamic Republic of); 4Center for Nanostructure Systems, Harvard University, Cambridge, Massachusetts, United States; 5Department of Physics, Sharif University of Technology, Tehran, Iran (the Islamic Republic of); 6University of California, Los Angeles, Los Angeles, California, United States; 7Department of Cardiology, Boston Children’s Hospital, Boston, Massachusetts, United States; 8Brigham and Women’s Hospital, Center for Nanomedicine and Department of Anesthesiology, Boston, Massachusetts, United States; 9Center for Nanoscale Systems, Harvard University, Cambridge, Massachusetts, United States; 10Department of Physics, Sharif University of Technology, Tehran, Iran (the Islamic Republic of); 11Women’s Hospital and Harvard Medical School, Cambridge, Massachusetts, United States.

Producing mature and functional cardiomyocytes (CMs) by in vitro differentiation of induced pluripotent stem cells (iPSCs) using only biochemical cues is challenging. To mimic the biophysical and biomechanical complexity of the native in vivo environment during the differentiation and maturation process, polydimethylsiloxane substrates with 3D topography at the micrometer and submicrometer levels are developed and used as cell culture substrates. The results show that while cylindrical patterns on the substrates resembling mature CMs enhance the maturation of iPSC derived CMs, submicrometer level topographical features derived by imprinting primary human CMs further accelerate both the differentiation and maturation processes. The resulting CMs exhibit a more mature phenotype than control groups as confirmed by quantitative polymerase chain reaction, flow cytometry, and the magnitude of beating signals and possess the shape and orientation of mature CMs in human myocardium as revealed by fluorescence microscopy.

9:30 AM SM01.07.05
Evaluation of Dedifferentiation of Carbon Quantum Dots Sourced from Chitosan on Glioma Andrea Kasko; University of California, Los Angeles, Los Angeles, California, United States.

Oligodot Nanoparticles—A New Class of Fluorescent Nanoparticles for In Vitro and NIR In Vivo Imaging Fathemeh Ostadbashpour1, Dinabandhu Sar4, Elizabeth Copley 8, Mohammad Ejtehadi 6, Nafis Ahmed 7, Richard Lee 9, Omid Farokhzad 2, 10 and Morteza Mahmoudi 10; 1Department of Cardiology, Boston Children’s Hospital, Boston, Massachusetts, United States; 2Department of Cardiology, Boston Children’s Hospital, Boston, Massachusetts, United States; 3Bioengineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 4Bradley University, Peoria, Illinois, United States.

Biological imaging is an indispensable component of modern medicine which can shed light even on the molecular level on the biological phenotype and can be utilized for the early diagnosis of a wide gamut of deadly diseases such as cancer. Conventional imaging methods such as X-ray radiography, computed tomography (CT), and magnetic resonance are commonly used in the clinic to diagnose physiological and anatomical abnormalities. Despite their high spatial resolutions, these methods are incompetent compared with optical imaging methods as the latter offer high sensitivity, real-time screening, and intraoperative feedback while also being safe because of the lack of harmful radiation. Of importance is optical imaging in the first biological window where the interference from tissue scattering and tissue autofluorescence is minimal, leading to the enhanced depth of penetration.

In particular, the great potentials of fluorescent imaging have led to the development of organic dyes and quantum dots (QDs) with high quantum yield. However, small molecules tend to get readily cleared in a short time span making the imaging practically cumbersome. On the other hand, although QDs might address the fast-renal excretion of the small organic dyes, their toxicity due to the presence of heavy elements has always been a bottleneck slowing their development for the in vivo imaging.
Herein, we disclose for the first time the synthesis of ultrasmall nanoparticles coined as “oligodots”. The term was adopted after comprehensive mass spectroscopy analysis revealed the oligomeric nature of these nanoparticles. Their hydrothermal synthesis with slight modification in the solvent, resulted in photoluminescence tuning of the derived oligodots with green-(G-Dot) and red-(R-Dot) emitting fluorescent properties. Size exclusion chromatography, AFM and HRTEM all corroborated the formation of 1.5±0.5 nm NPs. 2D Excitation- emission contours revealed that R-Dots have an at excited at 530 nm while the G-Dots have . Detailed fluorescence spectroscopic methods such as time resolved photoluminescence spectroscopy (TRPL) and fluorescent correlation microscopy were performed to fully characterize their photophysical properties. The incubation of the NPs with murine mammary breast cancer cell (MCF-7) and fluorescent confocal imaging indicated the high performance of these nanoparticles for in vitro cell imaging. Having demonstrated their feasibility for biological studies, we carried out an in vivo study in nude mice. The G-Dot and R-Dot were injected intradermally in each of the mouse’s flanks and were imaged on IVIS instrument. Spectral unmixing was utilized where the correct localization of the oligodots was achieved indicating their multiplexing potential. Moreover, the R-Dots were injected in the tail vein and the mice were imaged at various timepoints up to 24 h . The results confirmed the feasibility of the in vivo imaging and the proper time window clearance over 3 h. Histopathological examination of the major harvested organs, revealed no sign of cytotoxicity of any kind. Considering the desirable spectroscopic properties, safety and proper pharmacokinetics, these nanoparticles can offer a new platforms as novel fluorescent imaging agents on multiple levels.

10:30 AM SM01.07.07
Extracellular Matrix-Inspired Materials in Calvarial Regeneration
Justine C. Lee; UCLA Division of Plastic and Reconstructive Surgery, Los Angeles, California, United States.

Defects of the cranial skeleton occur frequently secondary to trauma, stroke, cancer, and congenital anomalies. Such defects result in significant neurological, psychological, social, and vocational burdens necessitating reconstruction. Current clinical options for reconstruction include autologous bone or alloplastic materials. However, the former is limited by tissue availability and donor site morbidity while the latter is plagued with frequent complications including extrusion of material, infection, and failure particularly in hostile wounds such as those following radiation. The limitations of both options provide the impetus for investigation in calvarial regeneration. Despite decades of research, contemporary regenerative strategies consisting of expanded stem cells and growth factor cocktails delivered by scaffolding materials have not attained clinical translation due to lack of efficacy compared to autologous bone, high cost, excessive time consumption for harvest and ex vivo progenitor cell expansion, and the untoward effects of supraphysiologic dosages of growth factors. With the increasing knowledge of the instructive capabilities of the extracellular matrix, our laboratory is primarily interested in identification of regenerative biomaterials, characterization of mechanistic interactions between materials and biology, and clinical translation of regenerative biomaterials tailored for cranialmaxillofacial defects. Our laboratory recently demonstrated the ability of an extracellular matrix-inspired material composed of nanoparticulate mineralized collagen glycosaminoglycan (MC-GAG) for regeneration of massive calvarial defects in the absence of ex vivo progenitor cell expansion or exogenous growth factor supplementation. We further showed that the mechanistic basis for MC-GAG induced osteogenic differentiation was dependent on an autogenous activation of the bone morphogenetic protein receptor (BMPR) signaling pathway via expression of a panel of BMP ligands by the osteoprogenitors themselves. Our current research interests involve: 1. Inorganic ion requirements and signaling in osteogenic differentiation induced by MC-GAG. 2. Negative regulatory pathways for osteoclastogenesis and osteoclast activation induced in progenitor cells undergoing osteogenic differentiation on MC-GAG 3. Development of Good Laboratory Practices-compliant protocol for testing the safety and performance of MC-GAG in animal cranial defect models.

11:00 AM SM01.07.08
Investigation of Calcium Oxalate Crystallization Under Microfluidic Conditions Towards the Understanding of Urolithiasis
Karol Rakotozandriny1, 2; Florence Babonneau1; Ali Abou Hassan2 and Christian Bonhomme2; Sorbonne Université, Collège de France, CNRS, Laboratoire Chimie de la Matière Condensée de Paris, Paris, France; 2Sorbonne Université, CNRS, Laboratoire Physicochimie des Electrolytes et Nanosystèmes Interfaciaux, Paris, France.

Over the past decades, the increase in kidney stone (KS) formers has raised the importance to understand the bimimeralization process responsible for urolithiasis1). Calcium oxalate (CaOx) crystallization – KS main inorganic compound2) – has largely been characterized under batch synthesis conditions that cannot be regarded as biomimetic with respect to the microscale environment in the kidney and to the urinary flow. A chemical model considering these features would provide, in fine, the biomedical community with a predictive platform for suitable and reliable diagnosis.

In this work, we used a reversible microchannel to mimic the collecting duct in the nephron where CaOx stones can form due to supersaturated levels in calcium and oxalate ions3). Within the channel, CaOx crystallization was induced under co-laminar mixing of Ca2+ and Ox− ions matching pathological concentrations – i.e. hypercalciuria and moderate hyperoxaluria. Scanning electron microscopy and Raman spectroscopy were used to support our investigations. They showed that CaOx crystals precipitate in a mixture of monohydrated whewellite (CaCO3·H2O·H2O) and dihydrated weddellite (CaC2O4·2H2O·2H2O) in the microchannel, similar to what is observed by the physicians4). In situ information on the kinetics of CaOx crystal growth could be acquired in our microfluidic system. They confirmed the effect of the hydrodynamic conditions as well as of the presence of chelating molecules on the growth kinetics and the final chemistry (phase, shape) of the formed CaOx crystals. Finally, in a trial to achieve a more complex biomimetic model (formation of KS on a Randall’s plaque), hydroxyapatite was grown in the microchannel and the CaOx crystal formation was investigated.

11:15 AM SM01.07.09
Active Delivery of Nanomedicine to Glioblastoma by Engineered Mesenchymal Stem Cell Spheroid
Yeh-Hsing Lao1; Smruti Suryaprakash1; Hyeon-Youl Cho2; Mingqiang Li3, HaYeon J1; Rachel Mintz1; Ki-Bum Lee2 and Kam Leong1-3; 1Department of Biomedical Engineering, Columbia University, New York, New York, United States; 2Department of Chemistry and Chemical Biology, Rutgers-The State University of New Jersey, Piscataway, New Jersey, United States; 3Department of Systems Biology, Columbia University Medical Center, New York, New York, United States.

Although cancer nanomedicine has been developed for decades, translation has been slow. Delivery efficiency is one of the major obstacles. To tackle this issue, we report an active delivery approach using the tumor-homing capability of mesenchymal stem cell (MSC) to boost the delivery efficiency as well as the retention of nanomedicine particularly for certain intractable cancers, such as glioblastoma (GBM), which only has limited options for treatment and the outcome remains unsatisfactory. To achieve this, we engineered MSC such that they secrete the cytotoxic protein, tumor necrosis factor-related apoptosis-inducing ligand (TRAIL). Co-delivery of TRAIL and MTX using the hybrid spheroid killed the GBM cells efficiently and specifically in vitro. In an in vivo GBM model, this hybrid spheroid approach gave nearly 100-fold improvement on micelle stability. Incorporation of DNA-templated micelle did not compromise MSC spheroid’s migration capability, and more than half of the loaded micelles were stable in the extracellular matrix part of the spheroid, which could be carried by the MSC spheroids during migration toward the GBM cells.

MSC is capable of sensing the chemotaxis generated by cancer cells because of its upregulation of the specific receptors, such as C-X-C chemokine receptor type 4 (CXCR4). By labeling the extracellular matrix part of the spheroid, which could be carried by the MSC spheroids during migration toward the GBM cells.

We further engineered the MSC to secrete the cytokine protein, tumor necrosis factor-related apoptosis-inducing ligand (TRAIL). Co-delivery of TRAIL and MTX using the hybrid spheroid killed the GBM cells efficiently and specifically in vitro. In an in vivo GBM model, this hybrid spheroid approach gave nearly 100-fold improvement on micelle retention. At three-week post-administration, 11 ± 3.2 % of the micelles remained in the tumor site when the mice treated with our MSC/micelle hybrid spheroids, while only 0.16 ± 0.03 % of the micelles was found in the tumor site when treated with the single MSC/micelle approach. Accordingly, the GBM tumor grew significantly slower when treated with our hybrid spheroids, reaching only 14% of the tumor size found in the control group at day 21, the end of the experiment. Collectively, our MSC/nanomedicine hybrid spheroid approach integrates the merits of both MSC- and nanoparticle-based therapy, enabling enhanced drug delivery to achieve a superior therapeutic efficacy in vivo.
To create the tunable interface for cell engineering, this study is focusing on how to control the surface morphology of PEM with limited conditions. First, the surface density of thiol self-assembled monolayer can be the first candidate to control the morphology of PEMs. Due to unconstrained self-assembly reaction, thiol group (such as MUA) first adsorb and cover the whole surface with lying down phase that undergoes a transition to the line-up configuration to form the complete monolayer. The contact angle shows the angle was decreased after 6 hours SAM because that lying down phase of the carboxylic acid directly on the gold surface and then gradually increasing after 24 hours and 48 hours SAM to form line-up phase. Furthermore, quartz crystal microbalance (QCM) show that different SAM density will affect the formation of the PEMs and lead to different physical characteristics from dissipation diagram. More compact SAM layers, the surface weight will be higher than the low-density film as well as the surface softness. To investigate the surface morphology, Atomic force microscopy (AFM) images showed dramatically different during 6 hrs SAM for a flat surface, 24 hrs SAM to form island surface, and 48 hrs SAM for highly compact wrinkled morphology. Besides, the ionic strength of buffer can be other factors to affect more detail condition of PEMs morphology. From QCM results, salt effect will reduce or increase the electrostatic interaction between poly(acrylic acid) and poly(lysine) that reduce or enhance the surface weight of PEM. Interestingly, the morphology of PEM can be also affected to form the dots, fibers, and wrinkle structures corresponding to the salt concentration. By controlling the density of SAM and ionic strength of the buffer, the surface morphology of PEM can be fine-tuning and utilized as the new interface for cell engineering. Fibroblast cell can be utilized as the first demonstration of this platform. By monitoring morphology, proliferation and differentiation of cells, we can know more details how the PEMs affect the cell behaviors.

SESSION SM01.08: Materials for Biological and Medical Applications VII
Session Chair: Seila Selimovic

2:00 PM SM01.08.02
Design of Artificial Exosomes for Cancer Diagnosis
Hojun Kim, Sungwook Park, and Kwan Hyi Lee; Department of Biomedical Engineering, Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2Department of Biomedical Engineering, Korea University of Science and Technology (UST), Daejeon, Korea (the Republic of).

Exosomes are small (few tens to hundreds nm) vesicles secreted by various cells in human body. Recent advances of nanotechnology unveiled that exosomes contain important biomarkers including miRNAs and different types of proteins specific to parent cells. Hence, increased number of studies are reported the potential of exosomes as a stable and reliable biomarker for various cancers. Previous approaches are mainly focused on utilizing heterogeneous and complex exosomes derived from human cells / body fluids. Because of the innate complexity of exosomes samples, translational research is limited and these limiting factors can be categorized into 1. Isolation, 2. Detection and 3. Heterogeneity problems. For example, gold standard isolation method requires time-consuming ultracentrifugation yet its effects on exosome morphology are not well-understood. Additionally, there are limited number of studies on differentiating cancer specific exosomes from other exosomes derived from normal cells.

In this talk, we will talk about our strategy of designing artificial exosomes through microfluidics mixer design for understanding exosome sensing with field effect transistor (FET) based biosensor device. Specifically, artificial exosomes with 40, 70, and 100 nm size with narrow size distribution (PDI = 0.01) are successfully synthesized with desired density of membrane proteins and membrane charge densities. We will discuss how exosomes’ size, charge density, and concentration of membrane proteins are correlated to sensing signals in the FET biosensor through combined small angle x-ray scattering and cryogenic transmission electron microscope techniques. Finally, we will discuss how these relations can be used to interpret sensing signals from urinary exosomes.

2:15 PM SM01.08.03
Nanocopper and Copper(II)-Based Coatings for Inhibiting Bacterial Contamination via Droplets or Touch
Debirupa Mitra, En-Tang Kang and Koon Gee Neo; National University of Singapore, Singapore, Singapore.

Bacterial surface contamination is a major cause of hospital-associated infections (HAIs), and antibacterial coatings can play an important role in reducing bacteria transmission via inanimate surfaces in healthcare settings. Coatings with nanosilver are deemed to have the potential as an antiviral surface coating for many applications such as medical devices and food packaging. Antibacterial nanosilver coatings can be easily fabricated using polydopamine (PDA) as an anchor layer to reduce and electrolessly metalize silver ions into silver nanoparticles. We have prepared nanocopper using PDA as an anchor layer, and tested its antibacterial efficacy against the nanosilver coating. In simulated contamination of inanimate surfaces by droplets or touch as expected in a hospital environment, the nanocopper coatings exhibited a much higher antibacterial efficacy than those based on nanosilver. We further investigated the relative advantages of nanocopper-PDA coatings compared to Cu(II) ion-complexed PDA coatings in terms of efficacy against the common HAIs pathogens, S. aureus and P. aeruginosa, durability as well as potential cytotoxicity. Such coatings of varying copper content were formed on poly(vinyl fluoride), latex as well as stainless steel substrates. When contaminated with droplets of the bacterial suspension, the nanocopper coating exhibited significantly higher efficacy (no viable bacteria observed after 30 min) than the Cu(II) ion-complexed PDA coatings of similar Cu content (~90% reduction in viable bacteria) due to a higher amount of Cu released by the former. However, the higher amount of Cu released by the nanocopper coating can give rise to cytotoxic effects. When contaminated with a bacteria-loaded dry surface, both surfaces were highly effective in killing the surface bacteria (no viable bacteria observed within 20-30 min). With sufficiently high copper loading (>4 μg/cm²), these Cu-containing coatings were able to maintain their antibacterial efficacy after 100 wipes with DI water. The fabrication of the Cu-containing PDA coatings can be readily scaled up for practical applications. Depending on the intended application, the Cu content as well as its physical form (ions or nanoparticle) can be selected to achieve an optimal balance between antibacterial efficacy and cytotoxicity.
that coating electrospun polyurethane vascular grafts with bioactive PEG-based hydrogel coatings confers both thrombore sistence and promotes endothelial cell attachment. However, our previous fabrication technique involved a molding process that presented significant challenges for industrial scale-up as well as difficulty in achieving thin, conformable coatings with sufficient coverage. In this study, we present a new method to assemble thin hydrogel layers on electrospun meshes through redox-initiated crosslinking mediated by the reaction between iron gluconate (IG) and ammonium persulfate (APS). We investigated IG adsorption and desorption from electrospun meshes, the effect of time on the coating thickness, and the conformability of this methodology to different geometries. Iron Gluconate Description: Bionate was electrospun onto a rotating mandrel to produce highly aligned fibers ~1 μm thick. The resultant polyurethane meshes were cut to 5x10 mm sheets, held in custom 3D-printed clamps, and soaked in 1, 3, or 5 wt% IG for 15 minutes. Meshes were then dipped in methanol and dried with compressed air. IG release from meshes immersed in water for 2 minutes in 10 second intervals was monitored with UV-Vis spectroscopy (n=18 for each concentration).

Redox Hydrogel Coatings of Tunable Thickness on Electrospun Meshes: IG-coated meshes were immersed in a solution of 10 wt% poly(ethylene glycol) diacrylate (PEGDA, 3.4kDa or 6kDa) and 0.14% APS for times ranging from 10-120 seconds. After immersion, hydrogel coated meshes were immediately immersed in water to remove excess polymer and initiator. Hydrogel thickness was measured by sectioning composites and visualizing cross sections with a stereoscope (n=12 for each condition). Conformable Coatings: To demonstrate the application of this approach for conformable coatings, tubular electrospun meshes (4 cm long, 4 mm diameter) were coated in IG and immersed in PEGDA+APS as described above. Thickness of the coatings was analyzed with a stereoscope (n=6).

IG release from meshes after 2 minutes desorbing was determined to increase from 0.06 ± 0.02 mg for a 1% IG soak to 0.46 ± 0.09 mg for a 5wt% IG soak. Hydrogel coating thickness increased from 70 ± 33 μm after a 10 second immersion in PEGDA 3.4kDa to 310 ± 66 μm after a 120 second immersion. Higher molecular weight PEGDA 6kDa coatings were 280 ± 27 μm thick as compared to 180 ± 22 μm PEGDA 3.4kDa coatings at the same time. Hydrogel coatings were formed conformably on the inside of electrospun tubular electrospun vascular grafts with a thickness of 370 ± 62 μm. In these studies, we demonstrate a tunable and scalable technique for fabricating thin and conformable hydrogel coatings on polyurethane meshes. We believe this technique can be extended to coat a range of materials with different chemistries and geometries. Coating cardiovascular devices with PEGDA hydrogel layers holds the potential to make these devices thrombore sistent and able to adhere endothelial cells. Future work will include coating artificial heart valves and individual fibers as well as assembling tough hydrogel coatings with this technique.

3:45 PM SM01.08.08 Persistence of Traits Acquired from Micropillar Arrays—Mechanotransduction in A549 Human Lung Adenocarcinoma

Seong Hwan Kim,1,4 Youngbin Cho2,3 Eun Hye Kim3,4 Seong Hwan Kim5, Sungsu Park6, Jennifer H. Shin7 and Jeong-O Lee1; 1Advanced Materials Division, Korea Research Institute of Chemical Technology, Daejeon, Korea (the Republic of); 2Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology (KAIST), Deajeon, Korea (the Republic of); 3Laboratory of Translational Therapeutics, Pharmacology Research Center, Drug Discovery Division, Korea Research Institute of Chemical Technology (KRICT), Daejeon, Korea (the Republic of); 4Department of Physics, Sungkyunkwan University, Suwon, Korea (the Republic of); 5School of Mechanical Engineering, Sungkyunkwan University, Suwon, Korea (the Republic of).

Cells are mechanically stimulated by the surrounding environment of extracellular matrices, neighboring cells and varieties of possible external physical stresses, and respond dynamically toward such mechanical stresses change of biochemical signaling pathways induced with physical stimulation has named as “Mechanotransduction”, and has a crucial effect on cell proliferation, invasion, migration, apoptosis and differentiation. Especially, cells on various artificial mechanical cues (different stiffness substrate, pillar arrays, Linea patterns) dramatically altered cell morphologies and cellular behavior. Here, A549 human lung adenocarcinoma cells were cultured on micropillar arrays made with UV-curable polymer resin (2 micrometer diameter, 16 micrometer pitch) for 48 H and intensively investigated for the understanding of mechanotransduction effect in (2.16) micropillar arrays. A549 cells grown on extremely stiff micropillar arrays (Young’s modulus of NOA 63 : 1.66 GPa) showed dramatic elongation effect in cell morphology. Confocal microscope image analysis reveals co-localization of actin filament withvimentin and relatively large number of nuclear deformation compared to A549 cells grown on flat NOA 63 substrate. Also, migration arrays in both in a single cell level (single cell tracking) and collective migration (wound healing assay, spreading assay) consistently confirm increased motility of cells grown in (2.16) micropillar assay. In vivo mouse xenograft experiment also confirms increased tumor colonization in mice injected with A549 cells grown in micropillar arrays, a character acquired from mechanical stress in-vitro even persists in in-vivo environment.

We suggest that stimulation given by the (2.16) micropillar array substrate stored in cell nucleus to be passed into next generations. The relationship between the mechanical stress given by the (2.16) micropillar arrays and mechanotransduction in A549 cells will be discussed in detail.

3:30 PM SM01.08.06 Large-Scale Neural Interface Devices Dion Khodagholy; Columbia University, New York, New York, United States.

As our understanding of the brain’s physiology and pathology progresses, increasingly sophisticated technologies are required to advance discoveries in neuroscience and develop more effective approaches to treating brain disease. There is a tremendous need for advanced materials solutions at the biotic/abiotic interface to improve the spatiotemporal resolution of neuronal recording. Organic electronic devices offer a unique approach to these challenges, due to their mixed ionic/electronic conduction, mechanical flexibility, enhanced biocompatibility, and capability for drug delivery. We designed, developed, and characterized conformable organic electronic devices in the form of transistors and electrodes that efficiently interface with the brain and acquire neurophysiological activity not previously accessible with recordings from the brain surface. These devices have facilitated large-scale rodent neurophysiology experiments and uncovered a novel hippocampal-cortical oscillatory interaction. The biocompatibility of the devices allowed in-vivo recording from patients undergoing epilepsy surgery, highlighting the translational capacity of this class of neural interface devices. In parallel, we are developing the high-speed electronics and embedded acquisition and storage systems required to make high channel count, chronic neural interface devices. 4:00 PM SM01.08.07 Delivery of siRNA Against PCSK9 Using a Thermostable Exoskeleton Increases LDL Uptake in Liver Cancer Cells In Vitro Sangeetha Swarna Lakshmi Krishnamurthy; Nihar Masurkar, Siddarth Deshpande, Samira Sadeghi and Chester Drum; NUS Medicine, Singapore, Singapore.

Hypercholesterolemia is one of the primary causes of cardiovascular disease in the developed world. A combination of genetic factors and high-fat diet causes this condition and is characterized by high LDL levels in the blood. Liver is the key organ in modulating cholesterol levels in the body and often has a lack of or overproduction of certain genes that lead to high blood cholesterol levels. Recently, loss-of-function mutations in PCSK9 gene in the liver has been shown to significantly reduce blood LDL cholesterol levels. In our study, we have encapsulated the PCSK9 siRNA into an engineered ferritin-based, C-terminal truncated, thermostable exoskeleton (tES) via charge complementation. Encapsulation was achieved by disassembly of tES at mild pH 5.5-5.8 followed by siRNA loading and cage reassembly at pH above 6 and the particles had an average size of 12 nm. The positively charged 8 nm pores of tES stably accommodate the negatively charged siRNA molecules. High loading levels of siRNA were achieved and the encapsulated biomolecules were well protected against thermal and nuclease degradation. The tES encapsulated Cy3-labelled siRNA achieved higher transfection rate than non-encapsulated and lipofectamine-delivered siRNA in HepG2 liver cancer cells as observed by fluorescence microscopy. PCSK9 knockdown in HepG2 cells resulted in significantly higher LDL uptake in vitro with a 27% increase after 60 seconds.

4:15 PM SM01.08.08 Hyaluronate–Gold Nanorod/DR5 Antibody Complex for Noninvasive Theranosis of Skin Cancer JungHo Lee and Sei Kwang Hahn; Materials Science and Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of).
Noninvasive transdermal delivery is a promising method with distinct advantages including patient compliance over other delivery routes. Here, hyaluronate–gold nanorod/death receptor 5 antibody (HA-AuNR/DR5 Ab) complex was developed for transdermal theranostics of skin cancer. The successful formation of the complex was corroborated by 1H nuclear magnetic resonance, UV–vis spectroscopy, dynamic light scattering, zeta potential, and transmission electron microscopy. In vitro biological activity of the complex was verified by ELISA and MTT assay using HCT116 cancer cells. In addition, in vivo photoacoustic imaging and two-photon microscopy clearly visualized the transdermal delivery of HA-AuNR/DR5 Ab complex through the inevitable barrier of stratum corneum in the skin. Furthermore, in vivo antitumor effect on skin cancer model mice was confirmed from statistically significant decrease of tumor-reflecting luciferase expression levels and apoptotic signals in terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay. Taken together, we could confirm the feasibility of HA-AuNR/DR5 Ab complex as a novel theranostic platform for noninvasive transdermal treatment of skin cancers.

4:30 PM Session SM01.08.09
Non-Invasive Oral Cancer Detection from Saliva Using ZnO-rGO Nanocomposite Based Bioelectrode Shilpi Verma,1, 2 and Surinder P. Singh1, 2
1CSIR - National Physical Laboratory, New Delhi, India; 2Academy of Scientific and Innovative Research (CSIR-NPL Campus), New Delhi, India.

Oral squamous cell carcinoma (OSCC) cases are major health concerns worldwide. The early detection of the disease is expected to reduce more than 50% of mortality/morbidity rate. To this end, the point-of-care devices such as easy to use biosensors may play a significant role compared to existing techniques that are costly and need trained manpower. Realization of accurate and inexpensive biosensing systems for early detection of oral cancer demands for development of robust and multifunctional systems with excellent electron transport properties and biocompatibility. We report the synthesis of zinc oxide-reduced graphene oxide (ZnO-rGO) nanocomposite for the fabrication of electrochemical immunosensor for oral cancer biomarker 'IL8'. The detection immunosensor has been prepared by covalently immobilizing (anti-IL8) antibodies on the surface of ZnO-rGO composite thin films on ITO. The nano-immunosensor showed successful detection of IL8 at low concentration ranges i.e. 100 fg mL⁻¹ to 5 ng mL⁻¹ with very high sensitivity (12.4 µA mL ng⁻¹), selectivity and enhanced stability. These results have been validated through in-vitro investigations using real saliva samples spiked with IL8. The obtained results indicate that ZnO-rGO composite constitutes a potential biosensing test-bed for non-invasive onsite detection of oral cancer and can be upgraded into a device for clinical applications in future.

4:45 PM Session SM01.08.10
Single Stranded DNA Encapsulated Two-Dimensional Metal Dichalcogenides for Combating Multi-Drug Resistant Bacteria Abhishek Debnath1 and Alexander Green Green1, 2
1Arizona State University, Tempe, Arizona, United States; 2Biosense Institute, Arizona State University, Tempe, Arizona, United States.

Two-dimensional transition metal dichalcogenides (TMDCs) has been widely explored for wide range of biomedical applications such as delivery vector for chemotherapeutic drugs, tissue engineering and tomographic imaging. Previous reports on solution state processing of TMDCs relied on chemical based liquid phase exfoliations, which in turn provides serious challenges for its implementations in biosystems due to its hazardous nature and long processing time. To overcome these problems, we developed novel biocompatible solution state processing of TMDC in presence one of the pivotal building block of biology, single stranded DNA (ss-DNA). Extensive characterization of DNA encapsulated TMDCs using Transmission electron microscopy, High resolution transmission electron microscopy, Atomic force microscopy and optical absorbance showed successful exfoliation of TMDCs into monolayer or bilayer. Also, DNA assisted exfoliation yielded dispersed TMDCs with concentration as high as 1 mg/ml, significantly higher than previously reported biocompatible dispersing agents. Furthermore, our studies also revealed DNA assisted exfoliation of TMDCs depends on composition of TMDCs and DNA nucleobases sequence. We further demonstrate non-covalent functionalization of MoS₂surface using protein molecules with the aid of functionalized DNA and characterized using atomic force microscopy. Furthermore, we demonstrate that MoSe₂-encapsulated in ss-DNA exhibit strong bactericidal property against both gram-positive and gram-negative bacteria. Antibacterial study of MoSe₂-ssDNA showed 3.4 order higher log reductions for both gram-positive and gram-negative bacteria respectively, compared to strongest carbon based bacterical material, graphene oxide. We further tested antibacterial property of this material towards multidrug resistant bacteria, gram-negative E. coli and gram-positive MRSA, which showed 100% eradication at concentrations of 150 µg/ml and 80 µg/ml respectively. We further extended our study and eradicated 'ESKAPE' at 75 µg/ml of MoSe₂-ssDNA. Further mechanistic investigation of antibacterial activity of MoSe₂-ss DNA using Scanning electron microscopy and transmission electron microscopy, showed physical interaction of bacteria with sharp edges of nanomaterials causes breakdown of cell membrane, leading to leakage of cytoplasm and finally cell death. We further evaluated antibacterial mechanism using tools from microbiology, which showed disturbance of membrane potential coupled with development of oxidative stress as key mechanism for antibacterial actions. We anticipate incorporation of this bactericidal material into the surface coating material will eliminate multidrug resistant based nosocomial type of infections in clinical settings.

SESSION SM01.09: Materials for Biological and Medical Applications VIII
Session Chair: Wonmo Kang
Friday Morning, April 26, 2019
PCC North, 200 Level, Room 229 A

8:15 AM Session SM01.09.01
Fabrication of Vapor Crosslinked Hyaluronan-Polyethylene Interpenetrating Polymeric Network for Flexible Leaflet Heart Valve Replacements Hieu T. Bui, 1 David Prawel 1 and Susan James 2, 3 1School of Biomedical Engineering, Colorado State University, Fort Collins, Colorado, United States; 2Department of Mechanical Engineering, Colorado State University, Fort Collins, Colorado, United States; 3School of Advanced Materials Discovery, Colorado State University, Fort Collins, Colorado, United States.

Current advancement in the cardiovascular field has demonstrated that transcatheter heart valve replacement is a promising alternative to traditional heart valve replacement by open heart surgery, which is expensive and invasive. Transcatheter heart valves containing flexible leaflets made from hyaluronan enhanced linear low-density polyethylene interpenetrating polymeric network (HA-LLDPE IPN) films have been shown to be hemodynamic, but the resulting IPN surfaces were not consistent. Vapor crosslinked HA-LLDPE can improve the consistency of HA surface composition. Moreover, the novel biomaterial is resistant to enzymatic degradation and is cytotoxic. The present work describes the development of the novel HA-LLDPE fabrication process and subsequent characterization of the new materials.

The HA-LLDPE IPN formation is a multi-step process that involves swelling LLDPE film in xylene containing silylated HA-cetrimonium complex (SHACTA) to diffuse the polysaccharide into the swollen polyethylene, vapor crosslinking the SHACTA in the LLDPE to itself above a solution containing toluene diisocyanate (TDI) and xylene, and then reverting SHACTA back to HA. Treatment parameters were varied to study their effects on the IPN formation including SHACTA/xylene concentration, TDI/xylene concentration, and vapor crosslinking time and temperature. Thermal analysis helped quantify the SHACTA weight composition on treated LLDPE. Gas chromatography-mass spectrometry was implemented to determine the crosslinking vapor content. Water contact angle goniometry, infrared spectroscopy, and toluidine blue O staining were used to characterize the surface of the HA-LLDPE IPN.

Based on the collected data, TDI can effectively vapor crosslink the HA incorporated within the LLDPE, and some amount of xylenes is required during vapor crosslinking to then reverting SHACTA back to HA. Treatment parameters were varied to study their effects on the IPN formation including SHACTA/xylenes concentration, TDI/xylenes ratio, and vapor crosslinking time and temperature. Thermal analysis helped quantify the SHACTA weight composition on treated LLDPE. Gas chromatography-mass spectrometry was implemented to determine the crosslinking vapor content. Water contact angle goniometry, infrared spectroscopy, and toluidine blue O staining were used to characterize the surface of the HA-LLDPE IPN.

4:30 PM Session SM01.09.02
Application of DNA as a Programmable Molecular Glue for Bioconjugation and Assembly of Nanostructures Kurt Gothelf1, 2
1NANO and Department of Chemistry, Aarhus University, Aarhus, Denmark.

We are using DNA as a programmable tool for directing the self-assembly of molecules and materials. The unique specificity of DNA interactions and our ability to synthesize artificial functionalized DNA sequences makes it the ideal material for controlling self-assembly and chemical reactions of components attached to DNA sequences. In particular...
we are using DNA origami, large self-assembled DNA structures as a template for positioning of materials such as organic molecules, dendrimers and biomolecules. In recent years we have developed methods for conjugation of small molecules and DNA to proteins such as antibodies. The studies are now extended to the assembly of multifunctional structures and investigation of their potential as drugs. We are furthermore using combination of DNA, antibodies and other proteins for development of assays for quantification of small molecule drugs in blood.

9:00 AM SM01.09.03
A Biosensor on the Nanoscale—About the Fate of Functionalized Inorganic Nanoparticles in Living Cells Sebastian Kollenda1,2, Mathis Kopp1,2, Jasmin Wens1, Nina Schulze4,5, Chrisooulatis Papadopoulos6,7, Robert Pöthker8,9, Hemmo Meyer10,11 and Matthias Epple12,13.1 Inorganic Chemistry, University of Duisburg-Essen, Essen, Germany; 2 Centre for NanoIntegration Duisburg-Essen (CeNIDE), Essen, Germany; 3Rhine-Waal University of Applied Sciences, Kieve, Germany; 4 Imaging Centre Campus Essen (ICCE), University of Duisburg-Essen, Essen, Germany; 5 Molecular Biology I, University of Duisburg-Essen, Essen, Germany; 6 Centre of Medical Biotechnology (ZMB), University of Duisburg-Essen, Essen, Germany.

Calcium phosphate occurs naturally in bone tissue and teeth and is considered to have a good biocompatibility and a high biodegradability in biological applications. Due to these properties, nanoparticles based on calcium phosphate have become a powerful delivery system for a vast range of cargo molecules. This includes small molecules, DNA, RNA and proteins for in vitro and in vivo applications. Our recent studies on therapeutic applications based on nanoparticles showed promising results in the treatment of inflammations and derived carcinogenesis, vaccination against retroviral infections, as well as viral clearance, although the intracellular location of these nanocarriers remained uncertain yet. The aim in this project was to create a smart tool to visualize the intracellular pathway and the fate of such therapeutic nanoparticles.

The calcium phosphate nanoparticles (CaP-NPs) were synthesized according to Sokolova et al., colloidal stabilized with fluorescence labelled poly(ethylene imine) (ATTO490LS) and loaded with a fusion protein consisting of the two fluorescent units mRFP and eGFP. The particles were characterized by dynamic light scattering (DLS) and scanning electron microscopy (SEM). HeLa cells were incubated with protein-loaded nanoparticles (2 μg of fusion-protein with 30,000 cells per well) and stained with 75 nM LysoTracker™ Deep Red for 30 minutes, washed and then kept on ice to suppress the endocytic uptake until the start of the experiment. Live-cell confocal laser scanning microscopy (CLSM) was performed with a TCS SP8 system (Leica Microsystems) using a 63x/1.2 water immersion objective.

The CaP-NPs had a spherical morphology and were monodisperse with a typical diameter of 50-150 nm. The in vitro fluorescence assay confirmed a strong pH-dependency of eGFP fluorescence. At the physiological pH of 7.4, the fluorescence of both proteins is detectable. Under the conditions of an acidic pH of about 4.5-5.0 (inside a lysosome), the green fluorescence disappears due to the protonation of the chromophore of eGFP. Thus, only the red fluorescence of mRFP is detectable. Time-resolved CLSM demonstrated a successful endocytosis of protein-loaded nanoparticles into the cells, with mRFP and ATTO490LS fluorescence co-localizing with stained lysosomes. However, the fluorescence of eGFP was only detectable outside lysosomes, most likely inside of early endosomes, or at the cell membrane coming in from the outside, indicating the neutral pH at these locations. We created a smart tool to effectively visualize the intracellular pathway by using a pH-responding biosensor. This provides a versatile platform to further investigate the processing of bioactive nanocarriers inside of living cells.

Rapid Disease Detection Using Variation in Hydrodynamic Flow Parameters of Erythrocytes in Non-Photolithographic Micro-Channels Manikuntala Mukhopadhyay, Sri Ganesh Subramaniam and Sunando DasGupta; Indian Institute of Technology, Kharagpur, Kharagpur, India.

Blood, is a complex non-Newtonian fluid, comprising of three major components – erythrocytes/red blood cells (RBCs), white blood cells, and platelets suspended in a watery liquid known as the plasma. The physicochemical properties of erythrocytes such as morphology, cell volume, membrane elasticity, and protein as well as lipid compositions are regarded as the principal biomarkers pertaining to different pathophysiological states. However, the onset of certain pathological conditions such as thalassemia, sickle cell anemia, hereditary stomatocytosis etc. could significantly alter the discocytic shape of the erythrocytes and their size. The clinical procedure for the detection of these diseases requires extensive laboratorial facilities, trained manpower and time. Hence, we posit that the morphological alterations of RBCs could serve as a diagnostic marker for specific diseases; utilizing the effectiveness of the micro-scale systems.

Blood samples were collected from the peripheral veins of healthy volunteers and were centrifuged to segregate the RBCs, and upon addition of a buffer, results in the formation of a stable suspension. Poikilocytic agent (viz. Triton) was added to the diluted samples to induce deformations in the erythrocytes. Poly(dimethylsiloxane) microfluidic channels of circular cross sections with diameters ranging from 100 – 500 μm, and length 40 mm, were fabricated using a novel, highly repeatable, soft lithography technique, with copper wires as the base mold. The diluted blood samples were then allowed to flow through the micro-channels at a controlled flow rate and the flow dynamics of the RBCs (both healthy and deformed) were monitored, and the local velocities were measured. Each experiment was repeated seven times. It was observed that the average flow velocities, as well as the flow patterns for the healthy discoidal shaped RBCs, were significantly different from that of the deformed RBCs. We postulate that the variations could be attributed to the difference in the amount of frictional drag experienced by the healthy and the deformed erythrocytes, and affirm that this methodology could be used for the sorting of healthy red blood cells from the diseased ones.

9:30 AM SM01.09.05
Atomically Thin Membranes with Nanoscale Pores for Dialysis Based Separations Piran Ravichandran Kidambi; Vanderbilt University, Nashville, Tennessee, United States.

Atomically thin membranes from 2D materials offer unique opportunities for molecular separations with high permeance and high selectivity. Here, we report the fabrication of fully functional centimeter scale nanoporous (<2-3nm) atomically thin graphene membranes for molecular separation applications. Our work focuses on systematically addressing key challenges that have limited progress in field i.e. a) scalable nanopore formation methods including in-situ, b) facile support casting, c) novel defect sealing methods and d) scalable manufacturing approaches. The synthesized nanoporous atomically thin membranes show higher selectivity and permeance (up to 100 times more) than state-of-the-art polymeric membranes and can be readily used for lab-scale dialysis.

Ultrasonic Nanographene Oxide Biosensor on a Paper-Based Platform to Detect Bacterial Contamination in Water Stalin Karuppayil¹, 2, 3, Narayan C. Mishra⁴, Wei-Chen Tsai⁵, Wei-Ssu Liao⁶ and Chia-fu Chou⁷; ¹Department of Chemistry, National Taiwan University, Taipei, Taiwan; ²Institute of Physics, Academia Sinica, Taipei, Taiwan; ³International Graduate Program, Academia Sinica, Taipei, Taiwan; ⁴Department of Polymer and Process Engineering, Indian Institute of Technology Roorkee, Uttarkhand, India.

Water-borne pathogens and their associated diseases are the largest contributors for the mortality worldwide and turn out to be a global crisis cost approximately 5500 deaths per day. These pathogens are mostly generated due to poor sanitation, industrial effluents, sedimentation of rainwater and sewage sludge. We can reduce the death rate if we are able to do rapid detection of the pathogens on-site, which would be achieved by developing a simple, user-friendly, efficient and rapid on-site-detection tool, i.e., biosensor. Here, we report a novel label-free, cost-effective paper-based E. coli biosensor by screen-printing which employs nano-architected graphene oxide (GO) as fast electron-transfer flatland, deposited graphene (G) screen-printed on hydrophobic paper, and thereby the bio-recognition element, lectin Concanavalin A (ConA) was immobilized on the GO to have GO×ConA probe for bacterial sensing. Electrochemical characterization of the electrodes (G and GO) shows the fast electron-transfer with a calculated electroactive surface area deposited on graphene (G) screen-printed on hydrophobic paper, and thereby the bio-recognition element, lectin Concanavalin A (ConA) was immobilized on the GO to have GO×ConA probe for bacterial sensing. Electrochemical characterization of the electrodes (G and GO) shows the fast electron-transfer with a calculated electroactive surface area of 0.16 cm². The fabricated biosensor performance was tested by Electrochemical Impedance Spectroscopy (EIS) technique. The transfer resistance (Rt) of GO×ConA probe increased linearly with the bacterial concentration was observed in the range of 10^6-10^10 CFU mL⁻¹ with an estimated limit of detection (LOD) of ~10 CFU mL⁻¹: This indicates the ultra-sensitivity of our biosensor platform which is 100 more sensitive than previous studies with less time-consuming of 2-10 minutes per sample.

Our reported biosensor, being cost-effective, eco-friendly, rapid and ultra-sensitive for rapid detection, could be a strong candidate for point-of-care portable kits that avoids the use of expensive instruments and skilled personnel to assess water quality monitoring and diagnose the water-borne pathogens and their associated diseases.
GBM local recurrence mostly within 2 cm of the original surgical lesion makes a local treatment as the most promising way to reduce GBM recurrence rates. Carmustine (bi-chloroethyl-nitrosourea - BCNU) loaded Gliadel® disc is currently the only available FDA-approved local therapy device. It is implanted along the inner walls of the brain cavity created after maximal tumor resection. However, the efficacy is still not satisfactory because of a short effective period and non-conformity to the resection cavity. It releases most of BCNU drug within only 5-7 days.

Electrospinning is a highly versatile method for creating continuous fibers ranging from tens of nanometers to microns in diameter made of various composite materials, providing very high surface-to-volume ratio with a high porosity. Furthermore, using coaxial electrospinning, advanced features can be obtained, such as combination of different characteristics from each polymer in different layer and encapsulating drugs in the designated layer of fibers, providing multi-functionality and efficient drug loading to the resulting membrane.

The novel approach described here uses discs formed from multi-layered core-sheath membranes (‘NanoMesh’) to provide controlled and sustained drug release for long term periods, leading to excellent in vivo results in an animal model. NanoMesh discs have been implanted into rats and their in vivo efficacy has been evaluated. Membranes with core-sheath fibers encapsulating BCNU in core were produced with different sheath thickness using coaxial electrospinning. SEM images show uniform fiber formation with average diameter of ~2.2 µm (sheath of ~0.36 µm), and 2.4 µm (sheath of ~0.56 µm). Consistent long-term release with no initial BCNU burst release was observed in vitro for up to 160 days. To evaluate in vivo efficacy, F344 rats intracranially implanted with the most malignant 9L gliosarcoma cell line were examined. All control groups (with either no treatment, no core in fibers, or no drug in fibers) rats died very early, within 12-14 days. On the other hand, rats implanted with BCNU encapsulated membrane discs remained active and healthy throughout the observation period, up to 150 days after implantation (end of trial). The survival time of treated rats increased by a factor of ~13 over the control group, which represents the largest survival improvement reported to date. Brain histology using H&E staining shows no evidence of malignant cells even at Day 150. Even better results are possible by incorporating multiple anticancer drugs into fibers, leading to synergistic effects from cell-cycle specific and non-specific drugs.

11:30 AM SM01.09.11 Biodegradable Hollow Silica Capsules for Amphiphilic Transport and Sustained Delivery of Antibiotic and Anticancer Drugs Isabel Gessner, Eva Knakor and Sanjay Mathur; University of Cologne, Cologne, Germany.

Hollow mesoporous silica capsules (HMSC) have recently gained intense attention as drug delivery vehicles due to their biocompatibility, high loading capacity and sufficient stability in biological milieu. Herein we report on ellipsoid-shaped HMSC (aspect ratio ~ 2), synthesized using hematite particles as solid templates that were coated with a silica sol followed by acidic leaching of iron oxide. Gas sorption studies on HMSC revealed mesoporous pores (main pore width ~38 Å) and a high surface area of 308.8 m²/g. Cell uptake and successful internalization of as-prepared HMSC was proven by confocal microscopy using human cervical cancer (HeLa) cells. The suitability of HMSC for drug delivery applications was tested by loading antibiotic (ciprofloxacin) and anticancer (carmustine) compounds as model drugs for hydrophilic and hydrophobic therapeutics. A pH dependent drug release over several days under physiological conditions at 37°C was demonstrated (UV-vis spectroscopy) in both cases, which showed the versatility of HMSC in transporting hydrophilic as well as hydrophobic drugs. Ciprofloxacin-loaded HMSC were additionally evaluated towards gram negative (E.coli) bacteria to clearly demonstrate a complete bacterial growth inhibition over 18 hours using particle concentrations of 10 µg/ml.

SESSION SM01.10: Materials for Biological and Medical Applications
Session Chairs: Abhinav Acharya and Wonno Kang
Friday April 26, 2019
PCC North, 200 Level, Room 229 A

1:30 PM SM01.10.01 Materials for Biological and Medical Applications Sharon Gerecht; Chemical and Biomolecular Engineering, Materials Science and Engineering and the Institute for Nanobiotechnology, John Hopkins University, Baltimore, Maryland, United States.

Vascular differentiation and formation (morphogenesis) takes place in an intricate milieu. This unique microenvironment is situated throughout the body in diverse types of healthy tissues, yet it seems to activates/inhibits similar mechanisms of the microvasculature. Two parameters of this microenvironment seem critical for blood vessel growth and stabilization: (i) the extracellular matrix, which provides critical support for vascular cell adhesion, proliferation, migration, and morphogenesis, and (ii) low oxygen concentrations (hypoxia), which is a critical factor promoting vascularization during embryonic development and tumor growth. In this talk I will present our recent efforts to develop biomaterials that mimic these physicochemical cues to understand how downstream signaling pathways impact vascular fate and assembly from progenitors and pluripotent stem cells.

2:00 PM SM01.10.02 Supramolecular Hydrogels Enabling Innovations in Drug Formulation and Delivery Eric A. Appel; Stanford University, Stanford, California, United States.

Supramolecular biomaterials exploit rationally-designed non-covalent interactions to enable innovative approaches to drug formulation and delivery. For example, supramolecular interactions can be used to dynamically cross-linking polymer networks, yielding shear-thinning and self-healing hydrogels that allow for minimally invasive implantation in vivo though direct injection or catheter delivery to tissues. Herein, we discuss the preparation and application of shear-thinning, injectable hydrogels driven by non-covalent interactions between modified biopolymers (BPs) and biodegradable nanoparticle (NPs) comprised of PEG-PLA. Owing to the non-covalent interactions between PEG-PLA NPs and BPs, the hydrogels flow under applied stress and their mechanical properties recover completely within seconds when the stress is relaxed, demonstrating the shear-thinning and injectable nature of the material. The hierarchical construction of these biphase hydrogels allows for multiple therapeutic compounds to be entrapped simultaneously and delivered with identical release profiles, regardless of their chemical make-up, over user-defined timeframes ranging from days to months. These materials enable novel approaches to immunotherapy, which rely on precise release of complex mixtures of compounds, as well as long-term treatment strategies for a variety of disease targets. Overall, this presentation will demonstrate the utility of a supramolecular approach to the design of biomaterials affording unique opportunities in the formulation and controlled release of therapeutics.

2:15 PM SM01.10.03 Alloyed Upconverting Nanoparticle for Multiphoton Imaging and Lasing at Ultralow Fluences Bruce E. Cohen1, Bining Tian1, Angel Fernandez-Brañol2, Emory M. Chan3 and P. James Schuck3; 1Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Columbia University, New York, New York, United States.

Multiphoton imaging techniques that convert low energy excitation to higher energy emission are widely used to improve signal over background, reduce scatter in subsurface imaging, and limit sample photodamage. Multiphoton imaging relies on luminescent probes able to efficiently sum the energies of 2 or more incident photons, as well as lasers powerful enough for multiphoton excitation. Lanthanide-doped upconverting nanoparticles have proven to be among the most efficient multiphoton probes, but even UCNPs with optimized lanthanide dopant levels require laser intensities that may be problematic for living systems. Here, we develop protein-sized, alloyed UCNPs (aUCNPs) that can be imaged at the single particle level at laser intensities below 300 W/cm², over 300-fold lower than needed for comparably-sized doped UCNPs. Using single UCNP characterization and kinetic models of lanthanide energy transfer, we find that addition of inert epitaxial shells radically changes optimal lanthanide content from Yb3+, Er3+ -doped NaYF4, nanocrystals to fully alloyed compositions. At high levels of the emitter Er3+, these ions can adopt a second role to enhance the effective aUCNP absorption cross-section by desaturating sensitizer Yb3+ or by absorbing photons directly. Core/shell aUCNPs are brighter than comparably sized doped UCNPs at all laser intensities tested, over 4 orders of magnitude. Core/shell aUCNPs 12 nm in total diameter can be imaged with strong contrast through several millimeters of tissue in live mice using a laser intensity of just 0.1 W/cm². aUCNPs open up the possibility of using both low irradiance and low-energy excitation wavelengths for non-destructive bioimaging experiments. Additional recent work about dye-sensitized UCNP emission and UCNP-based micron-sized lasers will also be discussed.
References:
We applied this TS in plant growth and evaluated its effect on root phenotypes and stress response on plants such as Glycine max, Brassica rapa and Arabidopsis thaliana. Compared to hydroponic media, this TS provides root phenotypes in Glycine max that are significantly more similar to those observed in field soil and avoid stress response from root hypoxia.

Lastly we show how the tailorability of this new materials platform allows for the investigation of how root development is affected by soil heterogeneities, e.g., gradients in mechanical properties (“thigmotropism”) or water availability (“hydrotropism”). We expect that this new application of hydrogels will provide, through synthetic polymers and their functionalization, broad possibilities for the study of GxE interactions in root development, as well as the modeling of the rhizosphere.

4:15 PM SM01.10.08 Ligand Directed Hafnium Oxide Nanoparticles for the ‘Color’ Detection of Bone Microcracks In Vivo Using MARS Photon Counting CT Fatemeh Ostadhossein1, Chiara Lowe1, Indu Tripathi2, Lily Beng1, Mahdieh Moghishb, Aamin Raja2, Anthony Butler1 and Dipanjan Pan1; 1Bioengineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2University of Otago, Christchurch, Christchurch, New Zealand.

Bone as a high-performance functional material encounters various mechanical forces such as tensile, shear and periodic i.e. fatigue stresses which make it prone to the mechanical damages specially microcracks. The duality diagnosis of bone microcracks is crucial to estimate the fracture and fragility risk factors and to conduct the proper intervention. Several clinically used imaging modalities are currently being investigated for non-invasive three-dimensional assessment of bone microdamage in vivo. Among them, computed tomography (CT) imaging is an excellent candidate due to being clinically amenable and its capability to provide information on the anatomical features rapidly. However, the confounding radiographic attenuation from bone instrument make the bone damage detection difficult while the low spatial resolution of the machine does not allow detection of damage on the micrometer scale.

Nanoparticles composed of high atomic number materials can partially resolve the issues associated with strong x-ray attenuation from calcium in the conventional CT imaging machines. When combined with advances in the CT instrumentation, the best outcome is expected. Specifically, the incorporation of photon counting detectors resulted in the multispectral CT technology which enables the detection of exogenous contrast materials with minimal background from hard tissues. Depending on the various inherent K-edge of materials, they can be discriminated when applying fast voltage switching of the x-ray source. Materials whose K-edge absorption band falls in the range of peak tube potential of 80-140 kVp are especially suitable as they can bypass beam hardening effect in these practical beam energy ranges. It was indicated that the elements with Z=64-73 have the potential to enhance the x-ray contrast effectively as compared to iodine while higher Z elements would reduce the photon counts sensed by the detectors (such as Au, Bi, etc). Hf with Z=72 is an emerging radiopaque material with well-positioned K-edge energy (65.3 keV) has been rarely investigated for contrast agent in CT imaging especially K-edge imaging. Herein, we disclose for the first time the synthesis of the ligand-modified sub 5 nm HfO2 nanoparticles for the sensitive detection of bone microdamage. Furthermore, these nanoparticles were targeted to bone minerals by the introduction of an aminopolycarboxylic chelating agent. At the site of the microcracks, a fracture in hydroxyapatite, the major bone constituent, would result in the exposure of freshly charged ions due to the breakage of atomic bonds in the matrix. Hence, the nanoparticles targeted to the more concentrated minerals would ‘light up’ the microcrack site. We demonstrated that with the distinct spectral properties, HfO2 nanoparticles would show in ‘color’ the location and anatomy of the microcrack. Moreover, the sub 5 nm size of these nanoparticles makes it feasible for them to travel through the nutrient transport canals (e.g. Haversian canals, canaliculi, Volkmann’s canals, etc) in the muscle near the bone and microcrack itself. We indicated in the in vivo studies that these nanoparticles could effectively indicate the microcrack anatomy in the rat’s tibia in the spectral CT while the non-targeted control nanoparticles non-specifically accumulated in the muscle. Furthermore, intramuscular injection of the nanoparticles did not induce any adverse effects on the liver enzyme functions and more importantly histopathologically. Therefore, these ligand-directed HfO2 nanoparticles would open new avenues for the safe, non-destructive, sensitive bone microdamage detection in vivo with potential clinical translation.

4:30 PM SM01.10.09 Electrodeformation Studies of White Blood Cells Cultures Enriched with Gold Nanoparticles N. G. Hallfors1, J. Teo1, C. Joshi1, A. Orozalez1, B. Samara1, L. George1, M. N. Martin1 and Abdel F. Isakovic1; 1KUST, Abu Dhabi, United Arab Emirates; 2Cornell University, Ithaca, New York, United States; 3NYU, Abu Dhabi, United Arab Emirates.

Separation and other forms of microfluidic manipulation of white blood cells for immunology and related applications is critical for more specific diagnostics and future treatments. We report on the studies of mechanical and electrical properties of bio-hybrid of white blood cells (WBCs) intermixed with gold nanoparticles (AuNPs) through dielectrophoresis (DEP) measurements. Studies of WBCs are performed with both standard, with form, WBCs, and in gold nanoparticles (AuNPs) enriched form. DEP devices are microfabricated in the form of metal-on-glass microelectrode arrays, with the shape of the elements of DEP devices numerically modelled following broadly accepted elementary physical properties of white blood cells. Specifically, indium tin oxide (ITO) was evaporated onto glass to 150 nm thickness, then lithographically patterned and cured at 400 deg C to modify its transparency and achieve higher conductivity. Afterwards, individual DEP chips are used for the deposition of small volumes of cell-AuNP culture suspension into the DEP electrode region. Electrodes are connected to a function generator and wired to the source of an AC current, where electric field and frequency could both be controlled. Jurkat and THP-1 cell types are tested so far. We have followed hypothesis that mechanical modulus value and its possible changes are related to the cells’ activation, which is considered as relevant in some elements of body's immune response. Additional motivation for this set of experiments is the link between cancer and WBC’s deformability and other mechanical properties. Two main types of experiments are followed here. In the first, frequency sweeps are performed at a fixed voltage (10V), and the crossover frequency is measured to be 18.0+/−2.00 kHz for THP-1 cells and 77.5 +/- 4.30 kHz for Jurkat cells. In the second series of studies, elastic modulus is determined following measurements of aspect and stretch ratios, with THP-1 modulus in the range of 430 Pa, and Jurkat cells modulus at around 530 Pa. The introduction of Au NPs allows for the modification of the elastic modulus values by a factor varying from 1.5 to 4, depending on the reagents used when Au NPs are added (PEG with varied concentration, citrate, others), and depending on the concentration of Au NPs. Measurements so far indicate that at least a portion of Au NPs are absorbed into WBCs, while the rest are either close to WBC outer membrane or “free floating” in the cell culture suspension. As a potentially encouraging news, the addition of controllable amount of AuNPs doesn't negatively impact the overall deformability of WBCs, despite the modifications to the elastic modulus values. This hybrid, bio-materials centered system of white blood cells and gold nanoparticles is a subject of continued studies, and will likely serve as a precursor for better understanding of related systems of interest in biomaterials and immunology.

4:45 PM SM01.10.10 Self-Assembled Epigallocatechin Gallate-Metal Ion-Based Nanomaterials for Cancer Theranostics Yunlu Dai, University of Macau, Macau, Macao.

Cancer, the major public health issue, has become the leading cause of death in China since 2010. Traditional chemotherapy is still a leading approach in current cancer treatment to suppress tumor proliferation and prolong patient survival by eliminating or inhibiting cancer cells through antinecancer drugs. Nanomedicine has become rapidly growing area of medical research for cancer treatment, as they can efficiently carry and deliver therapeutic agents, imaging probes or biological materials to the targeted tumor sites by enhanced permeability and retention (EPR) effect. However, the safety of nanoparticles is essential for clinical application. Polyphenols, compounds found in our diet, could help prevent degenerative diseases such as cancer and cardiovascular diseases. Therefore, polyphenols based nanomaterials can be employed as excellent candidates for nanomedicine. Moreover, the polyphenols would seem to have great potential to promote the efficacy of antinecancer drugs. We constructed a self-assembled nanoplatfom with the help of interactions between polyphenols and Fe3+ ion. Epigallocatechin gallate (EGCG) and PEG polyphenols were employed as the polyphenols, and anticancer drug doxorubicin (DOX) was encapsulated in the core of the nanoparticles for cancer treatment. The size of nanoparticles could be controlled from 30 nm to 150 nm by tuning the Fe3+ ion concentration. More interestingly, the nanoplatfom can be used for in vivo fluorescence imaging with NIR dye modification and T1 magnetic resonance imagining (Fe3+), which is useful for cancer diagnosis. The nanoparticles are able to promote tumor treatment efficacy and prolong mice survival time compared with free drug alone. This theranostics nanoplatfom establishes a novel promising approach to design next generation nanoparticles for cancer treatment.
Cutting-Edge NIR Fluorescent Imaging Paradigm for Precise Manipulation of Cellular Activities and Localized Theranostics

11:00 AM

for developing novel anticancer therapeutics. The use of instructed-assembly (iA) in cellular environment to form polypharmaceuticals in-situ that not only interact with multiple proteins, but also modulate membrane dynamics and for develop polypharmaceuticals for selectively inducing death of cancer cells via multiple pathways and without inducing acquired drug resistance. We designed novel active and raft-affinitive probes consisting of an enzymatic trigger, a fluorophore, and a cholesterol. Being water soluble and as the substrate of ectophosphatase, the probes preferably and rapidly assemble in the membrane to exhibit strong fluorescence. Such cell compatible, active probes work at micromolar concentrations, require short incubation period, and achieve high resolution monitoring of nanoscale heterogeneity in live-cell membranes. In a related study, we developed a conjugate of tyrosine and cholesterol (TC), formed by enzyme catalyzed dephosphorylation of phospholipid TC (pTC). TC self-assembles selectively on or in cancer cells. Acting as polypharmaceuticals, the assemblies of TC augment lipid rafts, aggregate extrinsic cell death receptors (e.g., DR5, CD95, or TRAILR), modulate the expression of oncoproteins (e.g., Src and Akt), disrupt the dynamics of cytoskeletons (e.g., actin filaments or microtubules), induce ER stress, and increase the production of reactive oxygen species (ROS), thus resulting in cell death and preventing acquired drug resistance. Moreover, the assemblies inhibit the growth of platinum-resistant ovarian cancer tumor in a murine model. These results illustrate the use of instructed-assembly (iA) in cellular environment to form polypharmaceuticals in-situ that not only interact with multiple proteins, but also modulate membrane dynamics for developing novel anticancer therapeutics.

Instructed-Assembly of Cholesterol Derivatives for Imaging and Inhibiting Cancer Cells

Huaimin Wang, Zhaoqianqi Feng and Ping Xu; Brandeis University, Waltham, Massachusetts, United States.

Acquired drug resistance remains a challenge in chemotherapy. Here we discuss enzymatic, in-situ assembling of cholesterol derivatives for acting as imaging probes for reveal membrane dynamics and for develop polypharmaceuticals for selectively inducing death of cancer cells via multiple pathways and without inducing acquired drug resistance. We designed novel active and raft-affinitive probes consisting of an enzymatic trigger, a fluorophore, and a cholesterol. Being water soluble and as the substrate of ectophosphatase, the probes preferably and rapidly assemble in the membrane to exhibit strong fluorescence. Such cell compatible, active probes work at micromolar concentrations, require short incubation period, and achieve high resolution monitoring of nanoscale heterogeneity in live-cell membranes. In a related study, we developed a conjugate of tyrosine and cholesterol (TC), formed by enzyme catalyzed dephosphorylation of phospholipid TC (pTC). TC self-assembles selectively on or in cancer cells. Acting as polypharmaceuticals, the assemblies of TC augment lipid rafts, aggregate extrinsic cell death receptors (e.g., DR5, CD95, or TRAILR), modulate the expression of oncoproteins (e.g., Src and Akt), disrupt the dynamics of cytoskeletons (e.g., actin filaments or microtubules), induce ER stress, and increase the production of reactive oxygen species (ROS), thus resulting in cell death and preventing acquired drug resistance. Moreover, the assemblies inhibit the growth of platinum-resistant ovarian cancer tumor in a murine model. These results illustrate the use of instructed-assembly (iA) in cellular environment to form polypharmaceuticals in-situ that not only interact with multiple proteins, but also modulate membrane dynamics for developing novel anticancer therapeutics.

Structure and Function of Multi-Component Supramolecular Hydrogels

Itaru Hamachi; Kyoto University, Kyoto, Japan.

Soft matters exhibiting stimul-response under water-rich conditions are attractive because of their numerous potential bio-applications. My group recently makes efforts to design stimuli-responsive supramolecular hydrogels, inspired by natural living cells, an ultimately complex and intelligent soft material composed of numerous multiple components. By mimicking live cells, we hybridized our supramolecular with many synthetic and/or biological molecules bearing various structures and functions. We expected that controlling and facilitating the crosstalk between these multiple components could give biomolecule-response to the hybrid supramolecular hydrogels. One of the recent examples is self-sorted supramolecular nanofibers double network system. We firstly succeeded in in situ real-time imaging of self-sorted supramolecular nanofibers by using confocal laser scanning microscopy and super resolution imaging. Moreover, we are able to construct an adaptive hydrogel whose ecological property can be modulated in both directions by distinct two external stimuli.

References

We have developed two systems for delivering biologics into the cytosol. The first is nanoparticle-stabilized nanocapsules (NPSC), formed via assembly of arginine-functionalized gold nanoparticles (AuNP) around fatty acid nanodroplets. These systems have been used to deliver proteins and siRNA directly to the cytosol in vivo, and have been used for efficient delivery of siRNA targeting TNF-α in vivo, providing effective anti-inflammatory treatment.

Our second system uses co-engineering of nanoparticles and proteins to deliver proteins into the cytosol. This platform co-assembles arginine-functionalized AuNPs with proteins modified with a glutamate (E-tag) chain. This strategy has been applied to a wide range of proteins, and we have employed this system to co-deliver complete CRISPR machinery (Cas9 protein and guide RNA) for effective editing both in vitro and in vivo.

Controlling Vaccine Kinetics and Immunogen Presentation via Alum-Binding Antigens
Darrell Irvine; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The kinetics of antigen availability following immunization impact follicular helper T cell priming, germinal center responses, and ultimate antibody production, but clinically-relevant methods to control the duration of antigen delivery to lymph nodes in subunit vaccines are lacking. We conjugated antigens derived from the gp140 HIV envelope trimer with a phosphoserine (pSer) peptide that binds tightly to the most common clinical adjuvant, aluminum hydroxide (Alhydrogel, or alum). Site specific modification of an engineered outer domain (eOD) gp120 or stabilized SOSIP trimer immunogen with varying numbers of pSer groups allowed self-assembly of these antigens on the surfaces of alum particles to be tuned and alum-bound antigens were presented from alum particle surfaces with a defined orientation. Tight binding to alum converted alum itself into a nanoparticle delivery vehicle, as alum nanocrystals released from the injection site trafficked to lymph nodes and were taken up by antigen-specific B cells. Ultimately, a 30-fold increase in germinal center responses and antibody titer resulted from primary antibody production was observed four weeks prior to primary immunization with both pSer-eOD and pSer-SOSIP conjugates, and long-lived plasma cells in bone marrow were doubled by immunization with pSer-modified immunogens. Overall, pSer-antigen conjugates elicited significant increases in antibody titers and altered specificity of the humoral response through controlling the display of antigen on the surface of alum.

Cloaking Nanoparticles with Supramolecularly Pre-Coated Protein Corona for Targeted Drug Delivery
Ja-Hyoung Ryu; UNIST, Ulsan, Korea (the Republic of).

Nanoscopic delivery vehicles capable of encapsulating drug molecules and releasing them in response to external stimuli are of great interest due to implications in therapeutic applications. However, the stability of encapsulation with self-assembled systems is limited during blood circulation and translating nanomedicines into clinical applications still remains a challenge due to the difficulty in regulating interactions on the interfaces between nanoparticles and biological systems. Thus, deliberate molecular design for stable encapsulation, targeting and triggered release is required. For this purpose, we have developed a facile synthetic method for highly stable, polymeric nanogels or polymer-caged hollow nanoparticles using a simple inter/intra-chain crosslinking reaction. We show a simple method for the preparation of biocompatible nanovehicles that provides the ability to encapsulate hydrophobic or hydrophilic drug molecules. Nano-carriers showed great stability to encapsulate drug molecules and drugs were only released inside cell. In addition, we showed a targeting strategy for nanoparticles incorporated with a supramolecularly pre-coated recombinant fusion protein in which HER2-binding affibody combines with glutathione-S-transferase. Once thermodynamically stabilized in preferred orientations on the nanoparticles, the adsorbed fusion proteins as a corona minimize interactions with serum proteins to prevent the clearance of nanoparticles by macrophages, while ensuring systematic targeting functions in vivo. This study provides insight into the use of the supramolecularly built protein corona shield as a targeting agent through regulating the interfaces between nanoparticles and biological systems.

Enzymatic Assemblies Disrupt Membrane and Target Endoplasmic Reticulum (ER) for Selective Cancer Cell Death
Zhaoqianqi Feng, Huaimin Wang and Bing Xu; Brandeis University, Waltham, Massachusetts, United States.

Organelle targeting has emerged as a promising strategy in developing effective and specific cancer therapeutics by delivering a drug in its active form to the cellular compartment where it works. Among all the subcellular targets, endoplasmic reticulum (ER) targeting therapy has been little explored due to its complexity in cell signaling. As the largest cellular organelle, ER is responsible for crucial biosynthetic, sensing, and signaling functions in eukaryotic cells. Particularly, ER is responsible for the synthesis, folding, and posttranslational modifications of proteins destined for the secretory pathway, which amount to approximately 30% of the total proteome. Disrupting the protein-folding capacity of ER would result in ER stress, ultimately activating apoptotic signaling pathways and cell death. Therefore, selective disrupting ER function in cancer cells is a promising new strategy for antitumor therapies. However, current ER targeting small molecules, like tunicamycin and thapsigargin, lack cell selectivity and exhibit severe neurotoxicity, thus hindering their clinical applications. Therefore, it is necessary to develop novel ER targeting strategies that have high specificity against cancer cells. In this work, we employ enzyme-instructed self-assembly (EISA) to selectively target ER of cancer cells. Generated via enzymatic reactions on and in the cancer cells, the enzymatic assemblies interact with cellular membranes and disrupt plasma membrane integrity to enable the assemblies accumulate on the ER, thus inducing cancer cell death through ER stress. Utilizing enzymatic reactions and reduced diffusion of assembly, EISA enables spatiotemporal control of the generation and cellular distribution of the cytotoxic assemblies, thus providing a new strategy to regulate amyloid-like aggregates for treating cancer. This work, for the first time, demonstrates a reaction-based process for disrupting membranes in a spatiotemporally controlled manner, as well as subcellular organelle (i.e., ER) targeting, which illustrates a new concept in controlling cell fates via instructed-assembly.

Semiconducting Polymer Nanoparticles for Photoacoustic Imaging and Photothermal Therapy in Second Near-Infrared Window
Yuyan Jiang and Kanyi Pu; Nanyang Technological University, Singapore, Singapore.

Near-infrared (NIR) light has been intensively exploited in biomedical applications due to its unrivaled benefits. Although most studies are focused on the first NIR (NIR-I) window (650-950 nm), there is growing interest to extend the wavelength to the longer second NIR (NIR-II) window (1000-1700 nm). As compared with NIR-I window, NIR-II light benefits from reduced photon scattering in biological tissues and higher maximum permissible exposure limit. Despite the great advantage, reported nanoagents that absorb in NIR-II window are limited, which include copper sulfide nanoparticles, gold nanorods, phosphorus phthalocyanine, etc.

Recently, semiconducting polymer nanoparticles (SPN)s composed of n-conjugated polymer backbones have emerged as a new category of optical agents. Due to the benign nature, SPNs circumvent the concern of metal-ion induced toxicity and possess size- and morphology-independent optical properties. Moreover, hardgap engineering provides a way to impart SPNs with high photothermal conversion efficiency, allowing for photoacoustic (PA) imaging and cancer photothermal therapy (PTT). However, most SPN-based materials can only be responsive to visible or NIR-I light, and few have been used for NIR-II applications.

Herein, we design and synthesize the first organic imaging agent based on SPN (SPN-II) that absorbs both NIR-I and NIR-II light and apply it for NIR-II PA imaging. The broadband absorption of SPN-II allows us to directly compare NIR-II vs NIR-I PA imaging so as to find out the advantages of NIR-II light in PA imaging. Because of the weaker background PA signals from biological tissues in NIR-II window, the signal-to-noise ratio (SNR) of SPN-II resulted PA images at 1064 nm can be 1.4-times higher than that at 750 nm when comparing at the imaging depth of 3 cm. The proof-of-concept application of NIR-II PA imaging is demonstrated in vivo imaging of brain vasculature in living rats, which showed 1.5-times higher SNR as compared with NIR-I PA imaging. Our study not only introduces the first broadband absorbing organic contrast agent that is applicable for PA imaging in both NIR-I and NIR-II windows but also reveals the advantages of NIR-II over NIR-I in PA imaging.

Furthermore, to reveal the advantages of NIR-II relative to NIR-I window in terms of cancer PTT, we also report the first organic SP-based photothermal nanoagent with the dual-peak absorption in both NIR-I and NIR-II windows. Such nanoagent consists of poly[di(3-ketopyrrolopyrrole-alt-cyclopentadiithiophene)-co-di(3-ketopyrrolopyrrole-alt-thiadiadiazole) (kpp-alt-k2d)] conjugated with polyethylene glycol. The conjugation of these two segments leads to a final polymer with the nearly identical absorbance at 808 and 1064 nm. The resulted SPNs not only allows for deep-tissue NIR-II PTT but also provides the opportunity to conduct a fair comparative study between NIR-I and NIR-II windows in order to reveal the superiority of NIR-II over NIR-I light for PTT. The proof-of-concept application of SPNs is demonstrated in tumor xenograft mouse model to validate the advantage of NIR-II window over NIR-I window for deep-tissue PTT. At last, a NIR dye is doped into SPNs to afford a fluorescent nanoagent (SPNF-A) permitting NIR fluorescence imaging guided NIR-II PTT.
Multi-drug resistant bacterial infections are responsible for 7,000,000 deaths each year worldwide, with more than 10 million deaths per year predicted by the year 2050. The majority of human bacterial infections (~80%) are associated with formation of biofilms on living tissues. Early detection of biofilms is crucial for limiting infection-based damage. Imaging these biofilms is challenging: conventional imaging agents are unable to penetrate the dense matrix of the biofilm, and many are susceptible to false positive/negative responses due to phenotypical mutations of the constituent microbes. We have engineered nanomaterials to penetrate the extracellular polymeric substance (EPS) matrix of biofilms and to intrinsically target the acid microenvironment of the biofilms. Here, we report the creation of pH-responsive nanoparticles with embedded transition metal catalysis (nanozymes) that effectively target the acid microenvironment of biofilms. These pH-switchable nanozymes generate imaging agents through bioorthogonal activation of profluorophores inside biofilms. The specificity of these nanozymes for imaging biofilms in complex biosystems was demonstrated using biofilm-mammalian cell co-culture experiments.

Ph-Responsive Nanoparticle Embedded Catalysts for Imaging of Biofilm-Associated Infections

Akash Gupta, Siddha Das, Guleen Y. Tonga, Tsukasa Mizuhara and Vincent M. Rotello; University of Massachusetts Amherst, Amherst, Massachusetts, United States.

The subjects of this talk are multifunctional mesoporous silica nanoparticles controlled by supramolecular nanomachines and caps for imaging and drug delivery in cells and in vivo. The nanoparticles are designed to 1) trap therapeutic molecules inside of the nanocarriers, 2) carry therapeutics to the site of the disease with no leakage, 3) release a high local concentration of drugs, 4) release only on command – either autonomous or external, and 5) kill the cancer or infectious organism. The most important functionality is the ability to trap molecules in the pores and release them in response to desired specific stimuli. Two types of external stimuli will be discussed: light and oscillating magnetic fields. Activation by internal biological stimuli such as pH changes, redox potential changes, antibodies and enzymes will also be presented. Molecular machines based on molecules that undergo large amplitude motion when attached to mesoporous silica - impellers, snap-tops and valves – will be described. Derivatized azobenzene molecules, attached to the interior pore walls function as impellers that can move other molecules through the pores. Nanoparticles containing antinancer drugs in the mesopores are taken up by cancer cells, and optical stimulation of the impellers drives out the toxic molecules and kills the cells. Snap-tops with cleavable stoppers release cargo molecules when the stopper is removed from the pores. Nanoparticles containing catalase are taken up by cancer cells, and optical stimulation of the nanoparticles causes the catalase to activate and destroy peritoneal metastatic tumors that are almost invisible to naked eye. Moreover, the temperature-correlated afterglow signal of SPNs permits real-time temperature monitoring during photothermal cancer therapy in living mice. The structural versatility of SPNs enables a smart activatable afterglow probe with activated signal from the pore entrance. Nanovalves consisting of rotaxanes and pseudorotaxanes placed at pore entrances can trap and release molecules from the pores in response to stimuli. Both reusable and completely reversible nanovalves will be described. Activation of these nanodevices by the five types of stimuli in solution, in living cells, and in animal models will be discussed. Applications to treatments of cancers (including pancreatic and breast) and of intracellular infectious diseases (including tuberculosis and tularemia) will be presented.

Spatial and Temporal Control of Stimulation-Responsive Theranostic Nanomaterials Using Caged Functional DNA Molecules

Yi Lu; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Theranostic nanomaterials have shown potentials for molecular diagnostic tests and targeted therapeutic applications in modern medicine. To reach their full potentials for clinical applications, novel methods for spatial and temporal control of stimuli-responsive nanomaterials are required in order to elucidate detailed mechanisms of theranostic effects in vivo and to personalize the diagnostics and treatments in clinics. Toward this goal, we have been selecting, from a large DNA library of up to 10^{13} different sequences, functional DNA molecules, such as DNAzymes (DNA molecules with enzymatic activities) and DNA aptamers (DNA molecules that can bind targets selectively) that can bind a wide variety of targets, especially those small molecular biomarkers that antibodies have not been able to recognize [1]. When conjugated to nanomaterials such as gold nanoparticles, quantum dots, liposomes, iron oxide nanoparticles, upconversion nanoparticles and polymeric organic nanoparticles, these functional DNA molecules allow stimuli-responsive assembly or disassembly of these nanomaterials, resulting in target-dependent changes of not only optical and magnetic signals for diagnostics, but also controlled release of therapeutic drugs [2]. To realize the spatial and temporal control of these stimuli-responsive nanomaterials, we have added a caged group to the functional DNA molecules so that these DNA nanomaterials can be delivered into living cells, zebrafish and other animals until a decaging event at a specific location and a certain time is triggered [3]. Recent progress in this area will be presented.

Fluorescence is a perfect technique in the preparation and evaluation of supramolecules, in the light of its advantages including superior sensitivity, fast responsiveness, high signal to noise ratio. More importantly, it can be applied for in situ visualization of bioanalytes at the molecular level and monitoring complex biochemical processes in real time. Comparing to most traditional fluorophores which suffer severe photobleaching and aggregation-caused quenching (ACQ) problems, luminogens with aggregation-induced emission (AIEgens) provide a unique light-up fluorescent signal. They are nearly non-luminescent in the isolated state but emit strongly in the aggregate/clustered state. The AIE aggregates exhibit large absorptivity, robust luminosity, strong photobleaching resistance, no random blinking and excellent biocompatibility. Based on different AIEgens, various supramolecular systems have been fabricated and present fascinating applications in biosensing, imaging and therapeutics, such as biomolecular analysis, micro-environment sensing, organelle or cellular imaging, pathogen detection and killing, as well as multimodal imaging-guided therapies.

Transition Metal Mediated Bioorthogonal Catalysis with Controlled Localization and Kinetics for Nanotheranostics
Riddha Das1, Ryan Landis1, Gulen Y. Tonga2, Premskul Puangploy1, Michael Knapp1 and Vincent M. Rotello2; 1Chemistry, University of Massachusetts Amherst, Amherst, Massachusetts, United States; 2Harvard University, Boston, Massachusetts, United States.

Transition metal catalysis (TMCs) can be catalyzed in a wide variety of chemical transformations, making them potential tools for bioorthogonal catalysis. We recently demonstrated that TMCs can be encapsulated in the surface monolayer of nanoparticles (NP), generating water-soluble “nanozymes”. These nanozymes demonstrate catalysis reminiscent of enzymes but can also catalyze a variety of bioorthogonal processes. We report a rational approach to control the localization and kinetics of nanozymes by fine-tuning their surface chemistry. We demonstrated intra-extracellular catalysis by surface engineering of the nanozymes. We used membrane-penetrating cationic nanoparticles for catalysis inside and ‘stealth’ zwitterionic particles to limit catalysis to outside of cancer cells. Specific localization of nanozyme activity was demonstrated through profluorophore activation. Therapeutic efficacy was demonstrated through intra- and extracellular activation of a produg. Further, we fabricated nanozymes possessing different surface hydrophobicity to regulate their interaction with a library of profluorophore substrates. We determined that nanozyme catalysis efficiency was driven by supramolecular interactions between the nanozymes and substrates. This study of nanozyme surface engineering provides the nanozymes with specific localization and tunable catalysis reminiscent of their enzyme prototypes for imaging and drug delivery.

Enzymatic Assembling Cholesterol for Selective Cancer Therapy and Membrane Imaging
Huaimin Wang and Bing Xu; Brandeis University, Waltham, Massachusetts, United States.

Chemotherapy resistance and toxicity are major problems facing current cancer research. Here we report that enzyme responsive cholesterol conjugates effectively and selectively kill cancer cells, including platinum-resistant ovarian cancer cells. The conjugate increases the degree of noncovalent oligomerization upon enzymatic dephosphorylation in aqueous buffer. This enzymatic conversion also results in assemblies of the cholesterol conjugate inside and outside cells and leads to cell death. Mechanistic studies suggest that the formed assemblies of the conjugates aggregate extrinsic cell death receptors (e.g., DR5, CD95, or TRAILR), modulate the expression of oncoproteins (e.g., Src and Akt), disrupt the dynamics of cytoskeletons (e.g., actin filaments or microtubules), induce ER stress, and increase the production of reactive oxygen species (ROS), thus resulting in cell death and preventing acquired drug resistance. In addition, the fluorescent labeled conjugates could directly image membrane dynamics of live cells with high spatial and temporal resolution over extended time scales and areas. Being water-soluble and as the substrate of ectophosphatase, these cell compatible probes preferentially and rapidly assemble in plasma membrane, exhibit strong fluorescence, work at micromolar concentrations, and easily achieve high resolution monitoring of nanoscale heterogeneity in membranes of live cells, the release of exosomes, and the membrane dynamics of live cells. This work not only illustrates the enzyme-instructed assembly of essential biological small molecules to treat drug-resistant cancers, but also provides a facile means to investigate membrane dynamics and heterogeneity to cellular processes.

Supramolecular Polymer-Based Nanomedicine—High Therapeutic Performance and Negligible Long-Term Immunotoxicity
Guocan Yu; National Institute of Health, Bethesda, Maryland, United States.

Nanomedicines have achieved several breakthroughs in cancer treatment over the past decades, however their potential immunotoxicity are ignored, which results in serious adverse effects and greatly reduces the potential in clinical translation. Herein, we innovatively develop a theranostic supramolecular polymer using β-cyclodextrin as the host and camptothecin (CPT) as the guest linked by a glutathione-cleavable disulfide bond. The supramolecular polymerization remarkably increases the solubility of CPT by a factor of 232 and effectively inhibits its lactone ring opening in physiological environment, which is favorable for intravenous formulation and maintenance of the therapeutic efficacy. Supramolecular nanoparticles can be prepared through orthogonal self-assembly driven by π-π stacking interaction, host-guest complexation, and hydrogen bonds. The sophisticated nanomedicine constructed from the obtained supramolecular polymer can be specifically delivered to tumor sites and rapidly excreted from body after drug release, thus effectively avoiding systemic toxicity, especially long-term immunotoxicity. In vivo investigations demonstrate this supramolecular nanomedicine possesses superior anti-tumor performance and anti-metastasis capability. This pioneering example integrating the advantages of the dynamic nature of supramolecular chemistry and nanotechnology provides a promising platform for cancer theranostics.

Fluorescent Upconversion Nanoclusters for Theranostic Imaging and Photodynamic Therapy
Muthu Kumara Gnanasammandhan Jayakumar, Zhen Zhang, Xiang Zheng and Yong Zhang; National University of Singapore, Singapore, Singapore.

Fluorescent upconversion nanoparticles (UCNPs) are one of the most preferred class of nanoparticles for use in near infrared (NIR) light-based theranostics. NIR light has better tissue penetration capabilities and NIR-based imaging drastically reduces the background autofluorescence, thus becoming the ideal choice in comparison to UV/visible light which has low tissue penetration capabilities and high phototoxicity. UCNPs have the unique ability of converting NIR light to a range of UV/visible/NIR wavelengths, which could be exploited for imaging and light-based therapeutic applications. The UCNPs developed so far can only be used to perform imaging and therapy simultaneously but this is not desirable as the therapeutic process activated during imaging might cause unwanted side effects and does not offer any control over the whole process. For example, tumor imaging should be performed first to identify the location of the tumor before performing the therapeutic intervention and if the UCNPs are activated in areas other than the tumor during imaging, it would cause unwanted cell killing in normal tissues. To overcome this problem, we have designed a new UCNP-nanocluster which can be used for performing temporally separated imaging and photodynamic therapy. These nanoclusters were tested in-vitro and was shown to perform imaging and photodynamic therapy without any overlap. There was no cytotoxicity observed in cells which were used for imaging but significant cytotoxicity was observed in cells subjected to photodynamic therapy using the same nanocluster. These UCNP nanoclusters offer excellent control over theranostic applications and is foreseen to be a game-changer in this field.

Ultrasound Iron Oxide Nanoparticles for Imaging-Guided Drug Delivery
Jennifer Sherwood1, Megan Rich2, Mark Bolding2 and Yuping Bao1; 1University of Alabama, Tuscaloosa, Alabama, United States; 2The University of Alabama at Birmingham, Birmingham, Alabama, United States.

Imaging-guided drug delivery has recently attracted much attention in nanomedicine where imaging probes are used to indicate the delivery and distribution of the drugs. For such an application of nanostuctures, the blood circulation times and effective delivery and monitoring the drugs remain as major challenges in order to reduce toxicity and enhance
drug or diagnostic efficiency. In this presentation, we present a state of art approach to forming nanoclusters by crosslinking ultrasmall iron oxide nanoparticles with bovine serum albumin. This novel design not only maintains the T1 performance of the ultrasmall nanoparticles, but also significantly increases their blood circulation times from 15 minutes to over two hours. Our breast tumor model study also exhibited enhanced localization and retention of these nanoclusters at tumor sites for more than 24 hours. The ability of maintaining the T1 performance of the ultrasmall nanoparticles is significant, because previous studies have shown complete T1 loss or signal decrease upon polymer encapsulation. This design also shows great potential in encapsulating model drug molecules, which will greatly benefit the field of imaging-guided drug delivery.

**A Next Generation Theranostic Supra Molecular Nano-Platform for Sustained And Enhanced Inhibition of Cancer Stem Cells**

*Fatemeh Ostadsossein, Santosh Kumar Misra* and *Dipanjan Pan*; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Signal transducer and activator of transcription factor 3 (STAT 3) is known to be overexpressed in cancer stem cells. Poor solubility and variable drug absorption are linked to low bioavailability and decreased efficacy. Many of the drugs regulating STAT 3 expression lack aqueous solubility; hence hindering efficient bioavailability. A theranostics nanoplatform based on luminescent carbon particles decorated with cucurbit[6]uril is introduced for enhancing the solubility of niclosamide, a STAT 3 inhibitor. The host–guest chemistry between cucurbit[6]uril and niclosamide makes the delivery of the hydrophobic drug feasible while carbon nanoparticles enhance cellular internalization. Extensive physicochemical characterizations confirm successful synthesis. Subsequently, the host–guest chemistry of niclosamide and cucurbit[6]uril is studied experimentally and computationally. In vitro assessments in human breast cancer cells indicate approximately twofold enhancement in IC50 of drug. Fourier transform infrared and fluorescence imaging demonstrate efficient cellular internalization. Furthermore, the catalytic biodegradation of the nanoplatforms occur upon exposure to human myeloperoxidase in short time. In vivo studies on athymic mice with MCF 7 xenograft indicate the size of tumor in the treatment group is half of the controls after 40 d. Immunohistochemistry corroborates the downregulation of STAT 3 phosphorylation. Overall, the host–guest chemistry on nanocarbon acts as a novel arsenal for STAT 3 inhibition.

**Synthetic Biology Toolkits for Bacterial Cellulose Production**

*Sierin Lim, Meng How Tan* and *Vishnu Vadanan Sundaravadanam*; Nanyang Technological University, Singapore, Singapore; 2A*STAR Genome Institute of Singapore, Singapore, Singapore.

Bacterial cellulose is an exopolysaccharide produced by various species of bacteria, with *Gluconacetobacter xylinus* being the model organism to decipher the biosynthesis of cellulose. It has potential applications in food, pharmaceutical, and cosmetic industries due to its unique structure and mechanical property. The cellulose produced by bacteria is of high purity and crystallinity compared to those isolated from wood pulp due to the absence of lignin and hemicellulose. Despite the natural production capacity and the biogenesis knowledge, bacterial cellulose is produced in relatively low quantity. In this study, we systematically rewired the natural production cascade to enhance cellulose production capacity and the self-assembly of microfibers for the synthesis of tailor-made and customizable cellulose. *Gluconacetobacter xylinus* produces cellulose by converting UDP-glucose to cellulose through cellulose synthase located in the cell membrane. The gene encoding cellulose synthase is comprised of four subunits and is arranged in an operon. To study the metabolism of genetically modified cellulose synthase and how it affect cellulose production, we develop genetic tools and build a library of genetic parts in BioBrick formats. We have completed the construction of genetic toolkit library for the manipulation of three *Acetobacteraceae* family members that are *Gluconacetobacter xylinus* (ATCC 700178), *Gluconacetobacter hansenii* (ATCC 53582), *Komagataeibacter rheticus* (GEM). We further constructed plasmids carrying different combinations of the four cellulose synthase subunits and introduced them into the bacteria for expression to create a mutant library of synthetic host capable of producing cellulose with different capacity and property. In this study, we also examine the self-assembly mechanisms and microstructures of bacterial cellulose. Never-dried native bacterial cellulose produced from two *Acetobacteraceae* family members are disintegrated into individual fibres through TEMPO-mediated oxidation and mechanical treatment, obtaining transparent and viscous suspension. Although the main oxidant is NaClO, we find that mechanical treatment (ultrasonication) plays an important role in the disintegration process of the bacterial cellulose.
The morphology of the disintegrated fibrils are observed by SEM and the crystallinity of the disintegrated fibers are analysed by XRD. The organic functional group of the cellulose fibres are as characterized in dry state and wet condition by FTIR and RAMAN, respectively. The birefringence of the fibre suspension is also investigated under polarizing microscope. The oxidized cellulose fibres are expected to have physical interaction with metal ions. We will study this interaction in respect of forming conductive cellulose complexation. We further develop a method to synthesize bacterial cellulose hollow microparticles that are challenging to achieve using conventional method. The reformed cellulose have been shown to improve wound healing.

2:15 PM SM03.01.03
DNA-Based Attractor Patterns [Phillip J. Dorsey and Rebecca Schulman] 1,2; 1Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, Maryland, United States; 2Computer Science, Johns Hopkins University, Baltimore, Maryland, United States.

We have developed a system for fabricating and perturbing self-healing oligonucleotide-based attractor patterns in photolithographically-patterned hydrogels using ultraviolet radiation. Digital maskless photolithography combined with microfluidic handling methods provides the ability to construct soft materials of arbitrary shape at biologically relevant length scales of tens to hundreds of microns in a matter of seconds. The photoinitiator system we incorporate with this platform enables the UV-light directed initiation of photosensitive DNA-based reactions in structured hydrogels. We use this approach to first form self-healing linear and hill-shaped DNA-based patterns in poly(ethylene-glycol) diacrylate hydrogels. Undisturbed, these spatial patterns were stable over at least 24 hours. When patterns were perturbed in particular areas they reformed their original shape. The ability to grow and perturb gradients of biomolecules such as DNA may facilitate the study of cell populations in dynamic microenvironments, providing experimentalists control over where and when chemical cues are induced or inhibited at the microscale.

2:30 PM BREAK

3:30 PM SM03.01.04
Toward Utilizing Bacterial Microcompartments as a Platform for Enhanced Catalysis [Matthew D. Yates, Jefferson Plegaria, Clement Aussignargues, Sarah Glaven and Cheryl Kerfeld] 1,2, 1U.S. Naval Research Laboratory, Washington, District of Columbia, United States; 2MSU-DOE Plant Research Laboratory, Michigan State University, East Lansing, Michigan, United States; 3Physical Biosciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 4Department of Plant and Microbial Biology, University of California, Berkeley, Berkeley, California, United States.

Harnessing and engineering natural biological processes to synthesize and self-assemble highly ordered materials with nanoscale components and features is key for developing the next generation of functional biomaterials. One such nanoscale material naturally synthesized by some bacteria is a self-assembling, selectively-permeable protein shell called a bacterial microcompartment (BMC). These microcompartments are used by cells to shield sensitive metabolic reactions from the intracellular environment (e.g. oxygen sensitive CO2 fixation enzymes or enzymes that produce toxic intermediates). The selectively permeable shell consists of different protein components, most with a pore at the center, which serves to concentrate reactants and increase reaction kinetics. BMCs are an attractive platform because the components of the microcompartments (the shell proteins and/or the encapsulated proteins) can be engineered, synthesized separately, and self-assembled in the absence of a living cell, providing a great deal of design space for customization. As a proof of principle, one BMC named microcompartment shell protein (the trimeric BMC-T protein) was engineered to coordinate a FeS metal cluster at the pore, which conferred reversible redox activity to the protein in solution. Further, the FeS-modified BMC-T protein also displayed reversible redox activity when it was bound to an electrode surface, with a similar formal potential (E′ = –370 mV vs SHE) to what was obtained in solution. Further, when the protein was engineered to coordinate the FeS cluster to the opposite side of the pore, multiple redox peaks with different midpoint potentials (E′ = –460 and –340 mV vs SHE) were observed. We have also observed redox activity from an electrode-bound BMC-T protein modified to coordinate a Cu metal center at the pore, with a formal potential(s) that is also dependent on the site modified to coordinate the metal center (E′ = 200 mV [site 1], 410 and 550 mV [site 2]). These results suggest that the BMC platform is a versatile architecture that can be customized to suit various applications (e.g. sensor development, electrosynthesis, and energy storage and conversion) and represent an important step toward harnessing naturally-occurring, self-assembling, nanoscale biomaterials to perform surface bound redox chemistry in a tunable, controlled environment.

Development of Microbial Cell Factories for Production of Aromatic Chemicals and Derivatives [Akihiko Kondo] 1,2; 1Graduate School of Science, Technology and Innovation, Kobe University, Kobe, Japan; 2Center for Sustainable Resources, RIKEN, Kanagawa, Japan.

Bio-based chemicals currently receive attention as sustainable and drop-in substitutes for petroleum-based chemicals. The feedstocks used for the production of bio-based chemicals have recently expanded from edible sugars to inedible lignocellulosic biomass. The production of bio-based chemicals is a key target of the 2030 Agenda for sustainable development. In this study, we hypothesized that the development of microbial cell factories (MCFs) will significantly contribute to the achievement of the 2030 Agenda. MCFs are engineered microorganisms that can be used to produce a wide range of chemicals from renewable feedstocks. MCFs can be engineered to produce a variety of chemicals, including aromatic chemicals and derivatives. Here, we discuss the potential of MCFs for the production of aromatic chemicals and derivatives.

Keywords: Biorefinery; Lignocellulosic biomass; metabolic engineering; synthetic biology.

Accessing Novel Materials Through Biology [Sanil Chandran; Amyris, Emeryville, California, United States.

Biological systems are an important source of inspiration for the development of novel materials. The process of evolution has led to the development of a wide range of materials with unique properties. In this talk, I will discuss some of the recent advances in the field of materials science using biological systems. I will also discuss the potential applications of these materials in various fields such as electronics, biotechnology, and medicine.

4:30 PM SM03.01.07
Design of Silica Structures Using Peptides from Diatoms [Andrea Wallace and Christopher Voigt; Biological Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Development of silicon-based materials with highly organized nano- and microstructures are of increasing demand across the medical, optical, energy, and mechanical fields. Nanoscale control of silica fabrication is desirable as new functions and properties can emerge from complex structures. Current methods for controlling silica morphology often involve the use of templates or sacrificial structures, which can limit the range of possible shapes and sizes. In this talk, I will present a novel approach for designing and fabricating silica structures using peptides from diatoms as templates. The peptides are self-assembled into nanofibers, which are then used as scaffolds for silica deposition. This method allows for precise control over the morphology of the resulting silica structures, providing a new platform for the development of functional materials.
require chemical additives, extremes of temperature, pressure, or pH, and long processing times. Interestingly, biological organisms, like diatoms, naturally produce a diversity of hierarchical silica structures under ambient conditions that are difficult to obtain even through advanced synthetic methods. Here, we use the silica-mineralizing R5 peptide from the diatom *Cylindrotheca fusiformis* in combination with targeted post-translational modifications (PTMs) to rapidly synthesize silica with controlled morphology at room temperature in aqueous conditions. By screening a diverse library of modifying enzymes for activity against R5, we identified ten enzymes capable of introducing PTMs to R5 and describe a set of design rules that relate individual modifications to specific changes in silica morphology. We then use these rules to rationally design and express enzyme pathways containing multiple modifying enzymes to selectively modify R5, and demonstrate that multiple modifications create synergistic effects on silica morphology. Additionally, we show that R5 can be used in combination with synthetic and biologically produced metal nanoparticles to synthesize silica-coated core-shell nanoparticles with tunable shell thickness. This system provides a modular approach for rapidly engineering and synthesizing silica structures under ambient conditions and moves us closer to being able to synthesize complex silica structures, like those seen in nature, that will provide new functions and properties to help advance silicon-based application spaces.

**Polydopamine-Gold Nanoparticle Composite Material Synthesis by Engineered Cells**

Isaiah Weidmann and Milana C. Vasudev; University of Massachusetts Dartmouth, Dartmouth, Massachusetts, United States.

In recent years, metal nanoparticles are being used for biomedical, environmental, and industrial applications. Metallic nanoparticles, such as gold nanoparticles (AuNPs) feature prominently in plasmonics, biosensing, polydopamine and photothermal imaging. Polydopamine, which can lead to the formation of eumelanin is a biomolecule which has also gained lot of interest due to its broad absorption spectrum and has potential for optical, photo-acoustic, and biosensing applications. Formation of a biocomposite material combining such optically-active materials could lead to a tunable absorption spectrum, based on polydopamine thickness.

As the complexity of composite materials increases, the development of simple design rules become essential, and using biological building blocks is one method to achieve this. Bacterial synthesis routes offer immense potential for an efficient synthesis process, ease of functionalization, modification and repeatability. Genetically modified E Coli strains can synthesize extracellular curli nanofibers, which is an amyloid fibrous structural components present in biofilms. We have designed and assembled DNA constructs to produce curli fibers with the ability to reduce gold nanoparticles and a polydopamine-binding fusion protein. Two E. coli strains were transformed with the constructs to produce the melanin coated well-organized gold nanoparticles. Curli fibers were assembled with alternating structural curli protein, CsgA (repeat unit) segments and one of the CsgA units was conjugated to spy tag protein, while the other was conjugated to the peptide fragment (FlgA3) which reduces gold nanoparticles from the auric chloride solution. A fusion protein comprised of the spycatcher protein conjugated to the repeat unit of the Pnol17 amyloid fiber was created and the fusion lead to the formation of the gold nanoparticle-polydopamine conjugate. The goal of this study is to design and produce novel polydopamine-bound gold nanoparticles using synthetic biology approaches, to generate a preliminary model for future investigation of the feasibility and advantages of bacterially-produced tunable biocomposite materials, which could find applications in plasmonics and catalysis.

**SM03.02.01**

**Synthetic Biology for the Synthesis of Silicon-Containing Materials**

Maria J. Sanford1, 2, Chia Hung1, Maneesh Gupta1, Patrick B. Dennis3 and Matthew B. Dickerson4; Materials and Manufacturing Directorate, Air Force Research Laboratory; WPAFB, Ohio, United States; UES, Inc., Dayton, Ohio, United States.

Synthetic biology has garnered interest as a tool for the production of synthetically challenging materials. Recently, a facile bio-catalytic route to the synthesis of molecules containing carbon-silicon bonds has been reported, potentially connecting synthetic biology with the production of silicon-based materials. In this work, we report on our recent efforts towards the creation of a synthetic biology system to generate a wide range of novel, silicon containing polymers to be used as precursors for the production of robust, high-temperature materials. Ultimately, our goals are to leverage synthetic biology to create silicon containing precursor materials in an environmentally friendly, scalable manner, and to take advantage of the remarkable ability of biomolecules to self-assemble at multiple length scales to enhance the functional capabilities of the resulting high-temperature materials.

**SM03.02.02**

**Designing Diatoms—Characterization of Frustule Composition and Associated Optical Properties**

Sasha Teymorian, Joseph Labukas, James Snyder and Joshua Orlicki; U.S. Army Research Laboratory, Aberdeen Proving Gro, Maryland, United States.

Diatoms are microalgae that are particularly relevant for engineered living materials because they utilize silicon to create mineralized structures that are far more intricate and exhibit better mechanical properties than any synthetic counterpart. In this study, we seek to (1) harness the natural diversity of diatoms and (2) establish genetic control over silica morphogenesis to understand their unparalleled level of sophistication over nanotechnology. Herein, we compare the frustule composition of native strains under a variety of growth conditions, and discuss in detail implementation for strain optimization. In addition, we establish baseline optical properties and identify strains for potential applications in coatings, photonic materials and sensors. Taken together, our approach expands the understanding of accessible frustule morphologies through growth and genetic engineering.

**SM03.02.03**

**Synthetic Biology Challenges for Army Materials Applications**

Joshua A. Orlicki, James Snyder and Sasha Teymorian; Army Research Laboratory, Aberdeen Proving Ground, Maryland, United States.

The emerging field of synthetic biology provides opportunity and new capabilities for the precision synthesis, assembly, and function of architectured materials. Currently, there are significant challenges for the integration of bio-derived and bio-based technologies in the defense-oriented materials space, in which materials are expected to perform under broad operating conditions. Army platforms must reliably operate over wide temperature ranges (e.g. -40 to 75 C) and extremes in humidity. In addition, materials must exhibit the durability to be fielded for long periods of time (e.g. 5+ years) and endure strain rate deformations from low strain, high frequency vibration to high strain impact events. We anticipate a significant challenge in harnessing synthetic biology to develop materials that are effective across this environmental breadth, particularly when considering that automated/parallelized biological experiments are not aligned to traditional materials science characterization strategies that typically occur in series and require much larger scale of material. This submission will give an overview of current projects employing the tools of Synthetic Biology and highlight needs of materials in context of the Materials & Manufacturing Science Division of the Army Research Laboratory.

**SM03.02.04**

**Halogenases for Chemical Production**

Rebecca M. Raig1, 2, Drew Wagner1, 2, Wendy Goodson1 and Maneesh Gupta1; Wright-Patterson Air Force Base, Air Force Research Laboratory, Dayton, Ohio, United States; Biological and Nanoscale Technologies, UES, Inc., Dayton, Ohio, United States.

Nature has acquired a vast repertoire of catalytic functionality. As the diversity of this repertoire is perpetually expanded upon by evolution’s process of random mutation and selection, a similar method may be employed to reprogram existing enzymes for novel function. Enzymes and their engineered variants have relevance where current production routes are lacking; they have the ability to improve product yield, materials price, supply chain security and/or environmental waste accumulation. This work aims to develop platforms for generating enzyme variants in order to facilitate production of molecules with desirable economic and industrial properties. As a starting point, we are investigating the screening and selection of halogenating enzymes for use in materials production. Several classes of halogenase are being examined for the ability to install chlorine, bromine, and fluorine into carbon frameworks. Our presented work highlights a single class of enzyme, the vanadium-dependent haloperoxidase, which displays a broad substrate reactivity...
profile, stability in organic solvent, and ease of recombinant expression and purification. In addition to performing bromination and chlorination, these haloperoxidases have also been shown to perform other potentially useful reactions such as hydroxylation, sulfoxidation, and epoxidation. We hope to eventually explore the manipulation of this enzyme and its reaction conditions to direct it towards the catalysis of specific substrates and chemical transformations.

SM03.02.05 Phloroglucinol Tri-Service Effort
Vanara Varaljay, Ali Saem, Steven Blum, Carrie Drake, Chia Hung, Adam Meyer, Rebecca Mickol, Nathan Schwalm, Drew Wagner, Adam Silverman, Theresah Zu, Wendy Goodson, Katherine Germaine, Sarah Glaven, Ben Gordon, Maneesh Gupta, Michael Jewett, Julian Lucks, Matthew Lux, and Christopher Voigt;
U.S., Inc., Dayton, Ohio, United States; MIT+ Broad Institute, Cambridge, Massachusetts, United States; US Army RDECOM, Baltimore, Maryland, United States; Air Force Research Laboratory, WPAFB, Ohio, United States; American Society for Engineering Education, Washington, District of Columbia, United States; RDRL SEE-B, US Army Research Laboratory, Adelphi, Maryland, United States; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; Northwestern University, Evanston, Illinois, United States; US Navy Research Laboratory, Washington, District of Columbia, United States; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; Ginkgo Bioworks, Inc., Boston, Massachusetts, United States.

Phloroglucinol (PG) is a precursor to TATB which is an energetic chemical of interest to the DoD. PG is part of the ‘Pressure Test’ as selected by DoD stakeholders for the MIT-Broad Foundry and is a compelling test case for the Tri-Service Synthetic Biology for Military Environment (SBME) research efforts. The Tri-Service Laboratories approached the PG single ‘challenge problem’ through leveraging SBME capabilities such as strain engineering capabilities, strain banks, and rapid prototyping of paper-based sensors. The AFRL team has an aircraft and a fuel isolate library enriched for “Promonomids,” which are known to harbor PG synthesizing enzymes known as PhD. The AFRL team has designed selective PhD primers for screening Pseudomonads isolates for diverse and potentially more active PhD enzymes than found in current literature. The NRL team is taking advantage of Marinobacter CP1’s (SBME chassis) ability to accumulate significant amounts of the PG precursor malonyl-CoA. Marinobacter will be genetically engineered to produce PG through a combination of genome editing to divert carbon to malonyl-CoA and the subsequent conversion to PG through the addition of a plastid-expressed PhD. The ARL team is harnessing the robust SBME chassis Clostridium acetobutylicum to model and optimize its capability to produce significant amounts of the PG precursor malonyl-CoA with plastid-expressed PhD. ARL has determined that mixed sugar inputs yield optimal PG production. Additionally, ARL will construct a living PG sensor in soil microorganisms using ICE technology obtained from the Voigt laboratory. The ECBC team and Northwestern University collaborators have developed and optimized a paper-based, cell-free PG sensor. The paper-based PG detection system will be used in field-deployable conditions where the sensor would be triggered by PG, resulting in rapid reporting of the presence of PG. The MIT-Broad Foundry has optimized PG production in the model chassis E. coli and has built a PG genetic sensor for rapid screening. The PG Tri-Service collaborative efforts in biological and cell-free systems will result in optimized PG production and detection, invaluable for DoD and synthetic biology applications.

SM03.02.06 Protein-Based Microcapsules as Alternative Way for Ruggedization of Functional RNA-Based Sensors
Nancy Kelley-Loughnane, Irina Drachuk, Svetlana Harbaugh, and Jorge Chavez;
Air Force Research Laboratory, Materials and Manufacturing Directorate, Wright Patterson Air Force Base, Ohio, United States; UES, Inc., Dayton, Ohio, United States; Air Force Research Laboratory, 711 Human Performance Wing, Wright Patterson Air Force Base, Ohio, United States.

Conventionally, in vitro protein synthesis has been focused on a top-down approach when effective transcription/translation process relied on compartmentalization of the whole cell-free system in liposomal vesicles. In this method, having an appropriate phospholipid membrane fluidity played important role not only in the progression of protein expression, but also in mechanical stability of a very rigid osmotic system. Alternatively, protein-based vesicles prepared using bottom-up approach can solve some of the hurdles associated with liposomal vesicles. Assembled in a layered fashion, microcapsules afford tailored membrane porosity, variable DNA loading capacity and improved mechanical and chemical stability necessary for a prolonged shelf storage of RNA-based aptamers. We demonstrated that during layer-by-layer assembly, several DNA templates encoding various RNA-based aptamers and riboswitches can be immobilized in microcapsules prepared from reconstituted silk fibroin protein. Upon activation of RNA aptamers with a specific analyte, DNA templates immobilized in microcapsules were proven to be functional on transcriptional and translational levels. During incubation in a cell-free system, the rate of expression of a reporter gene was similar to the rate of expression for microcapsule-bound DNA templates, confirming that the functionality of aptamers was conserved. By increasing the loading capacity of DNA templates in microcapsules, the level of gene expression can be amplified. Further functionalization of silk shells with gold nanoparticles and antibodies will allow to expand multi-component DNA microcapsule complex design for targeted surveillance of several biomarkers. The proposed design of multifunctional protein-based microcapsules provide necessary robustness to RNA-based aptamers for their long-term storage or prolonged circulation, as microcapsule-bound DNA templates have been proven to be functional after one year storage at ambient conditions.

This research is funded by the Air Force Office of Scientific Research (AFOSR).

SM03.02.07 Gold Nanoparticle Assembled Gene Networks
Rajesh Nair, Patrick B. Dennis, Sanaz Farajollahi, Samantha Knoth, and Kathlyne Montgomery;
Air Force Research Laboratory, Dayton, Ohio, United States.

Plasmonic metal nanoparticles have interesting physiochemical properties that have been used for many applications including biosensors, cellular imaging and drug delivery. Conjugation between gold nanoparticles (AuNP) and biomolecules, proteins and nucleic acids expand these applications. Here, we applied the Polymerase Chain Reaction (PCR) to build a genetic circuit based on an oligo-conjugated AuNP foundation. Constructed gene networks are created using amplicons containing a T7 promoter followed by an open reading frame for a gene of interest and a T7 terminator. Our current focus is on optimizing PCR reaction for creating gold-conjugated gene networks as well as characterization of the AuNP-DNA complexes by Transmission Electron Microscopy (TEM) and Atomic Force Microscopy (AFM). With this approach, we plan to expand potential applications for the constructed gene networks by coupling the networks to cell free protein expression systems and exploring plasmic tunability of gene expression.

SM03.02.08 Hydrogel Encapsulated E. coli for Responsive Biomaterials
Drew Wagner, Cason Willey, Vincent Chen, Nathan Ferguson, Cheri Hampton, Chia Hung, Larry F. Drummy, Patrick B. Dennis, Wendy Goodson, Abigail Juhl, and Maneesh Gupta;
Air Force Research Laboratory, Beavercreek, Ohio, United States; UES, Inc., Dayton, Ohio, United States.

Microbial gas vesicles (GVs) are gas-filled protein microstructures encoded by biosynthetic pathways endogenous to marine bacteria and extremophiles and function to provide a way to control buoyancy by the host organism. Composed of a single layer of protein, gas vesicles are remarkable in that they exclude water from their interior despite forming in an aqueous environment. To explore materials applications of gas vesicles, we have transported a 10 gene GV operon onto an inducible expression vector and recapitulated vesicle assembly in E. coli cells. E. coli cells producing gas vesicles are further incorporated into hydrogels to create materials with tunable density that can be used to make environmentally-responsive biomaterials with variable acoustic properties. Further, we envision and are working towards altering the genetic control of the system to make GV-expression responsive to additional inducer signals and subsequently bio-print GV-expressing cells into gel-matrices to enable spatio-temporal manipulation of hydrogel properties.

SM03.02.09 Will Synthetic Acorns Grow into Biobuildings—Comparing the Coding Complexity of Natural Materials with the Software of Man-Made Systems
Joseph Riolo and Andrew J. Steckl;
University of Cincinnati, Cincinnati, Ohio, United States.

While the field of biology seeks to understand the functions and mechanisms of natural organisms, synthetic biology aims to use biological functions to engineer materials and systems. This engineering view is at the core of synthetic biology and seeks to define fundamental building blocks in nature that can be manipulated in a variety of combinations to design and produce complex systems. To illustrate this approach Ball compared the components and the level of complexity that goes into the design and manufacturing of an automobile to the process of biological cell formation – building materials (glass, metal vs nucleotides, amino acids); components (pistons, wheels vs proteins); modules (microcontroller vs genetic circuits), etc.

Barnatt asked a thought provoking question related to synthetic biology: “will synthetic acorns grow into biobuildings?” There are many aspects that need to be considered to begin to answer the question: 1. what materials that are needed for this quest; 2. what is the level of complexity involved; 3. what are associated building costs, are they
competitive. While this rhetorical question draws attention to the possibilities of synthetic biology, a rapidly growing community is exploring nearer-term applications (synthetic biochemical production, biocomputing, biosensors, etc.).

To partially answer this question we have initiated a study to characterize the complexity required to create engineered organic systems. While complexity is a relative term, computer software development can be a suitable benchmark due to similarities between instruction storing function of DNA and binary code. Further similarities between organic and software systems are the use of limited serial instruction sets (quaternary or binary) to produce arbitrarily complex outcomes when executed on deterministic systems.

The starting point is the comparison of the genome of different organisms to landmark software programming projects. The number of base pairs in the genome of organisms ranges from ~ 10 to 10 million for bacteria to ~ 1 billion for birds to a few billions for humans and other mammals. Major software projects for which some details (number of lines of code) are available have been selected for comparison, including the Hubble Space Telescope, the Mars Curiosity Rover, the Android smartphone operating system. The extent of compiled object code ranges from several hundred million to a few billion characters. The similarity between numbers of software characters in complex computer programs and base pairs in genomes, suggests that programming complex synthetic biosystems, while quite challenging and requiring a major effort, is likely to be feasible.

Biological coding provides additional functionality beyond storing of genetic information. Molecular structure and shape provide the means for reproduction of the genetic code, its transformation into amino acids and proteins, etc. This represents the storage of additional (2nd, 3rd order) valuable information that needs to be accounted in future analysis. It is important to note that genome size does not necessarily correlate with organism complexity. Interestingly, a similar case may be made for software programs, in that their size is not only related to the complexity of the system function but also on the computer language used, the period when the programming was carried out, other needs of the system, etc. Nonetheless, our preliminary evaluation indicates that the level of complexity involved in the genome of even the most sophisticated organism is comparable to large-scale man-made computer programs.

Cell-free protein synthesis (CFPS) is a promising approach for the production of biomaterials that cannot be synthesized by existing organic chemistry techniques. CFPS avoids many of the pitfalls of bacterial expression of biomaterials by allowing direct access to the chemical reaction that is taking place. Among the advantages of CFPS are increased tolerance to toxic reagents and products, facile incorporation of non-biological components such as abiotic amino-acids, the absence of cell transfection or protein purification steps, and increased yield as the CFPS system only makes the proteins it has been templated to produce. NMR monitoring of CFPS would allow us to fine-tune these systems so that they may be successfully scaled in a cost-effective manner. CFPS systems are commonly optimized via the production of green-fluorescent protein (GFP) which is spectroscopically monitored as the reaction proceeds. This approach fails in anaerobic environments since GFP chromophore maturation is oxygen dependent. Further, GFP fusions are not applicable for the production of small molecules. By utilizing radioisotope labeled substrates and various 1D and 2D techniques we expect to be able to monitor the utilization of substrates, generation of the desired products, and flux of related metabolites of various CFPS reactions. Significant differences in CFPS yield have been observed when reactions are prepared by different users and/or different cell lysates. NMR spectroscopy may be able to elucidate the mechanism behind this reaction variability. We have been able to identify metabolic differences between lysates prepared by different users. When the reactants and cell lysate used in CFPS are controlled, NMR metabolite profiles differ between users. The production of side products, such as ethanol and lactic acid, varies by user and by lysate utilized. In-situ NMR may be able to identify mechanisms for low product yield, discover undesirable metabolism pathways that are being activated, or if energy deficits are occurring.

8:30 AM *SM03.03.01  
**Synthetic Biology of Halomonas for Next Generation Industrial Biotechnology** George Guo-Qiang Chen; School of Life Sciences, Tsinghua University, Beijing, China.

Industrial biotechnology cannot compete with the petrochemical industries as it suffers from high consumptions on energy and freshwater, discontinuous processing, low product concentration and thus low product recovery cost as well as low substrate to product conversion efficiency. Therefore, to make industrial biotechnology competitive, we need develop Next Generation Industrial Biotechnology which is energy and freshwater saving and run in a continuous way instead of a batch way. Seawater based fermentation technology has been developed based on Halomonas halophaga in which is a chassis grown faster than E. coli. We have been able to assemble several multiple genes containing pathways in H. halophaga in production of various biopolymer molecules, chemicals and proteins. The growth patterns of the Halomonas spp. have been changed to influence the shapes of Halomonas spp. from short rods to long fibers, even further to large spheres, allowing more PHA accumulation and easy product recovery. The technology has been pilot tested in industrial setting (5000 L), it has been proven to be able to reduce PHA production cost at least 100%. The seawater technology should be able to improve the economic competitiveness of industrial biotechnology. We expect the technology can play an increasingly important role in the fermentation industries.

9:00 AM SM03.03.02  
**Photocatalytic Oxidation in Metal-Organic Frameworks Using E. coli Synthesized Porphyrins Ligands** Jared B. DeCoste, Marilyn Lee, Sergio Garibay and Ann Ploskonka; US Army Edgewood Chemical Biological Center, Aberdeen Proving Ground, Maryland, United States.

Utilization of various photosensitizers in metal-organic frameworks (MOFs) for photocatalytic oxidation of toxic compounds has been of recent interest. Typically these MOFs incorporate pyrene, porphyrins, or organometallic photosensitizers into the organic linker of the MOF. However, through the utilization of solvent assisted ligand incorporation (SALI), a wide variety of compounds can be post-synthetically incorporated into the 3 nm pores of NU-1000. We report here the incorporation of protoporphyrin IX produced in E. coli via the Shemin pathway into NU-1000. Various porphyrins can be produced via the Shemin pathway including coproporphyrin and uroporphyrin. Each of these porphyrins have carboxylic acid handles that can be incorporated into NU-1000 via SALI. The inclusion of these porphyrins into NU-1000 improved the rate of photocatalytic degradation of the MOF toward the chemical warfare agent simulant for sulfur mustard, 2-chloroethyl ethyl sulfide. Utilization of synthetic biology in MOF synthesis opens up new pathways that are yet to be realized through the production of novel or difficult to synthesize ligands.

9:15 AM *SM03.03.03  
**Living Architecture—Synthetic Biology for Structural Building Materials** Wil V. Srubar III; University of Colorado Boulder, Boulder, Colorado, United States.

Imagine a world where the buildings in which we live, work, and play — the walls, the roofs, the floors, the windows — are grown, maintained, and healed autonomously by living microbial communities. Imagine architects of the future that swap their sketchbooks for genetic tools that encode the architecture of a building right into the DNA of those communities. Living architecture may soon be more than a vision penned in a science fiction novel. In fact, we are closer to realizing that vision than you think, thanks to interdisciplinary teams of researchers armed with a commitment — and the synthetic biology toolkits — to make that vision a reality.
Recent advances in metabolic engineering have enabled autonomous, high-fidelity biom manufacturing of useful chemical, mineral, and polymer building blocks that can be leveraged in the design and fabrication of construction materials and living architectures at the human scale. This presentation will highlight the research efforts of a highly interdisciplinary and collaborative team at the University of Colorado Boulder that is integrating synthetic biology, microbiology, materials science, and structural engineering to design and fabricate useful minerals (e.g., aggregates for concrete production) and polymers (e.g., styrene) for materials with commercial applications to building design and construction. In one study, we demonstrate the first time that calcium carbonate (CaCO₃) mineral aggregates for mortar and concrete can be tailored by modulating the precipitation kinetics through genetic engineering of ureolytic microorganisms. We also demonstrate that useful quantities of styrene for construction material manufacture can be biologically produced via microbial engineering. In this presentation, we will also show that engineered microorganisms can be leveraged in the design of hybrid living building materials that display both biological (i.e., living, regenerative self-healing) and structural (i.e., load-bearing) function. Finally, this talk will highlight the challenges that emerge working across length scales and disciplines, as well as the grand opportunity that exists for synthetic biologists and materials engineers to work together to create never-before-imagined material solutions for critical societal problems in energy, water, and the built environment.

9:45 AM SM03.03.04
Elucidation the Mechanism of Synthetic Riboswitches by Using Cell-Free Expression Systems Nancy Kelley-Loughnane1, Svetlana Harbaugh2, Yaroslav Chushak1,2 and Jorge Chavez2; 1Air Force Research Laboratory, Materials and Manufacturing Directorate, Wright Patterson Air Force Base, Ohio, United States; 2Air Force Research Laboratory, 711 Human Performance Wing, Wright Patterson Air Force Base, Ohio, United States.

Biological systems have adapted diverse ways to control gene expression. Riboswitches are regulatory elements located in the 5′-untranslated region of mRNA that change the folded structure of the mRNA upon the binding of effector molecule and, as a consequence, alter the expression of the downstream gene. Besides the naturally evolved riboswitches that are triggered by cellular metabolites, several synthetic riboswitches have been developed that can sense and respond to non-endogenous small molecules such as theophylline, tetracycline or 2,4,6-trinitrotoluene (TNT). Majority of the synthetic riboswitches were selected and tested in the cell-based systems, usually E. coli. Cell-free protein expression systems (CFES) have several advantages for the development and testing of synthetic riboswitches including the elimination of the interaction with complex cellular networks and decoupling of transcription and translation processes. We studied the performance of theophylline-based synthetic riboswitch coupled with the sfGFP reporter gene in E.coli cellular extract and PURE cell-free systems. To monitor the mRNA dynamics a malachite green aptamer sequence was added to the 3′-untranslated region of sfGFP. Performance of the theophylline riboswitch was compared with a constitutively expressed sfGFP (control). Transcription dynamics of mRNA with riboswitch was very similar to the transcription of the control mRNA for all theophylline concentrations tested in both E. coli extract and PURE CFES. However, sfGFP expression in riboswitch construct was order of magnitude lower even at highest concentration of theophylline. This indicate that riboswitch altered the accessibility of the ribosome binding site and translation initiation rate. Dose-response curves showed similar behavior in both CFES with high micromolar to low millimolar dynamic range. The experimental effort was accompanied by computational modeling and simulations. A kinetic model of riboswitch activation was developed.

This research is funded by the Air Force Office of Scientific Research (AFOSR).

Innovations in Performance Materials Enabled by Biology Adam Safir; Zymergen, Emeryville, California, United States.

As the desire for the latest product innovations continues, the need for new materials innovation has becoming a reality. New materials development would be made easier by having access to a new palette of chemical building-blocks, and such a palette of molecules with diverse structure and functionality is already available in nature today. Through the intersection of bioengineering, synthetic chemistry and material science, we at Zymergen are working to bring such novel building blocks to bear on materials innovation. In this presentation we will review our efforts in targeted rapid prototyping of biotarget production, and the development of diverse new materials useful in a variety of advanced product sectors.

11:00 AM SM03.03.06

Melanin is a pigment ubiquitous in nature and is found in all types of living organisms. Due to its unique physicochemical properties, high biocompatibility and biostability, there has been increasing interest in the use of melanin for biotechnological, biomedical and theranostic applications. In the vast majority of prior studies, melanin has been either chemically synthesized or isolated from animals, restricting its use to small-scale applications. In this study, we engineered the fast-growing marine bacterium Vibrio natriegens to synthesize melanin by expressing a heterologous tyrosinase gene. The V. natriegens melanin demonstrated characteristic electron paramagnetic resonance signals which were enhanced upon illumination. When melanized cells were immobilized at an electrode surface and probed with diffusible mediators and electrical inputs, we observed that melanization conferred redox activities to V. natriegens. The photoprotective properties of the bacterially-produced melanin were validated by its protection of bacterial and HeLa cells from UV irradiation. Moreover, melanized bacteria were able to quickly adsorb organic compounds such as chloroquine and trimethoprim. Providing the engineered V. natriegens strain with tyrosine or tyrosine-containing peptides as precursors led to the production of melanin nanoparticles and variants with varying optical properties, suggesting that this system is tunable and could be exploited for novel materials applications. Overall, the genetic tractability, rapid division time and ease of culture using comparatively inexpensive carbon sources provides a set of attractive properties that compare favorably to current Escherichia coli production strains and warrant the further development of this chassis as microbial factory for natural products synthesis.

Furthermore, we report results demonstrating the potential of Vibrio natriegens produced melanin in chemical protective scenarios. The fabric preparation utilized microwave initiation in the presence of (3-aminopropyl)triethoxysilane to provide primary amine groups on the surface. Analysis of water vapor transport through the melanin-modified fabric indicated that the treatment should have little impact on wearer comfort. The permeation of three chemical agent simulant vapors, 2-chloroethyl ethyl sulfide (CEES), methyl vinyl ketone, and 2,4-dinitrotoluene (DNT) was measured. The most dramatic outcome was 86% reduction in the peak rate and 90% reduction in the total amount of CEES vapor transported through melanin-treated fabrics compared to untreated control. These results suggest that the adsorptive properties of the inexpensive natural polymers can be further explored and tuned using standard synthetic biology tools to produce additional application relevant compounds. Ongoing work is considering differing melanin materials and their impact when considered in this application.

11:15 AM SM03.03.07
Bacterially-Produced Melanin as Biomaterials Chia Hung1, Annika Vaia1,2, Zheng Wang1, Gary J. Vora1, Wendy Goodson3 and Maneesh Gupta1; 1Air Force Research Laboratory, Wpafb, Ohio, United States; 2UES, Inc., Dayton, Ohio, United States; 3U.S. Naval Research Laboratory, Washington, District of Columbia, United States.

Melanin, a highly-coordinated polymeric nanoparticle found in natural pigments, has many intriguing properties including protecting organisms from ultra-violet radiation, ability to sequester reactive species and metal ions, and reported electrical conductivity. Melanin particles isolated from naturally pigmented sources are biologically templated with pre-defined shapes that dictate the optical and protective properties of the melanin assemblies. The tyrosinase enzyme is known to be involved in the biosynthesis of melanin, which lends credence to the use of a synthetic biology approach to engineer tyrosinase for melanin production. In this work, Bacillus megaterium tyrosinase was engineered and expressed recombinantly in Escherichia coli. Two forms of tyrosinase fusions were designed to be secreted through the curli export system and anchored on the cell surfaces. Using these systems, small melanin nanoparticles could be produced. In addition, melanin ghosts templated by E. coli cells were synthesized and characterized. Thus the tyrosinase expression, secretion and display capability that will be presented here represents a platform capable of allowing for the production colloidal melanin nanoparticles as well as melanin functionalized surfaces. Future work will investigate tuning the optical and electrical properties of the melanin assemblies through control of size and shape of the superstructure.

11:30 AM SM03.03.08
The Design and Creation of an Oxygen Sensing Protein Kinase Regulator for Synthetic Biology Applications Sanaz FarajiDjalali1, Patrick B. Dennis1, Ruth Pachter1, Andrew
The ultimate goal of this work is to design a novel cell signaling circuits that will trigger biochemical pathways in response to the oxygenation state of their environment. For this purpose, we use PAS domains which are sensing elements found in all living organisms that respond to environmental stimuli including, light, oxygen, redox state and various metabolites. To create new oxygen sensing genetic circuits, chimeras of the heme iron binding PAS domain from the prokaryotic B. japonicum histidine kinase (FixL) are being engineered with the ability to modulate the enzymatic activity of the mammalian PAS domain containing PAS Kinase (PASK), a protein kinase involved in the control of carbon metabolism and cellular energetics. Molecular simulations, coupled with ultrafast spectroscopic techniques, are being used to support the design and testing of the chimeras. Purified chimeras are also tested for their ability to inhibit PASK kinase activity at various oxygenation states, using a newly developed, non-radiological protein kinase assay. The function of these metazoan derived signaling elements will be probed in a prokaryotic system in order to generate orthogonal signaling pathways for cellular metabolic control.
need, use of indigenous or sustainable feed stocks, and leap-ahead advances in biobased materials and technology providing smart systems providing new protection and sensing capability in operationally challenging and contested environments. With increasing complexity and control the long-term vision is to develop advanced materials imparting living function for operation in Army relevant environments-disruptive capabilities, such as self-healing, adaptation, protection & situational awareness.

The continual convergence of synthetic biology with other fields and disciplines such as additive manufacturing, lab-on-a-chip, machine learning, and multi-scale computing promises to usher in a new age of manufacturing, leading to structural and multifunctional materials. Further, as our ability to control and sustain biological systems and understanding and control of self-assembly improves, we can begin to take these advances out of the laboratory to on-demand applications. To accomplish this, key components of our approach includes the development of advanced discovery to manufacturing pipelines, bringing both an understanding of structure-function relationships and ultimately rational design principles along with tools to unlock broad ranges of hosts for access to new material sets and sustainment in military environments. Bringing together materials and application experts across the physical and engineering sciences as well as government, academia and industry will significantly advance our ability to build discovery to product pipelines, with an emphasis up front on concept of operation, manufacturability, and logistics/sustainment.

This paper will present a discussion the challenges and opportunities that this burgeoning field and snapshot of the Army’s synthetic biology program including more detailed discussion of genetic control of the biological/materials science interface.

4:15 PM SM03.04.06
Resilient Living Materials Built Through Printing Bacterial Spores
Lina M. Gonzalez and Christopher Voigt; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

A route to advanced multifunctional materials is to embed them with living cells that can perform sensing, chemical production, energy scavenging, and actuation. A challenge in realizing this potential is that the conditions for keeping cells alive are not conducive to materials processing and require a continuous source of water and nutrients. Here, we present a 3D printer that can mix material and cell streams in a novel printhead and build 3D objects (up to 2.5 cm by 1 cm by 1 cm). Hydrogels are printed using 5% agarose, which has a melting temperature (65°C) consistent with thermophilic cells, a rigid storage modulus ($G' = 6.5 \times 10^5$ Pa), exhibits shear thinning, and can be rapidly hardened upon cooling to preserve structural features. Spores of R. subtilis PY79 are printed within the material and germinate on its exterior, including spontaneously in cracks and new surfaces exposed by tears. By introducing genetically engineered bacteria, the materials can sense chemicals (IPTG, aTc, xylose, or vanillic acid) and produce biopolymers (melanin).

Further, we show that the spores are resilient to extreme environmental stresses, including desiccation, solvents (ethanol), high osmolarity (1.5 mM NaCl), 365 nm UV light, X-rays, and g-radiation (2.6 kGy). The introduction of a metabolic pathway for melanin improves resistance to 254 nm UV light and g-radiation. The construction of 3D printed materials containing spores enables the living functions to be used for applications that require long-term storage, in-field functionality, or exposure to uncertain environmental stresses.

4:30 PM SM03.04.07
A Sea Worm Jaw Protein Promotes Heme Crystallization
Zachary Reiner1, 2, Andrea Poole1, 2, Maneesh Gupta2, Chia Hung2, Wendy Goodson1 and Rajesh Naik2; 1UES Inc., Beavercreek, Ohio, United States; 2Air Force Research Laboratory, Dayton, Ohio, United States.

Hemozoin, a crystalline form of heme generated by malaria-causing parasites, is an attractive alternative to other inorganic oxidizers for energetic materials due to a higher output when combined with nano aluminum (Slocik, J. et al. Small. 2015, 5538). Developing methods to control hemozoin crystal morphology should enhance current energetic capabilities. Histidine-rich proteins have been shown to promote hemozoin crystallization with sizes smaller than those obtained from synthetic methods. Here, we identify Nvjp1, a jaw protein from sea worm, as a capable catalyst of hemozoin formation. We also compare crystals nucleated from Nvjp1 to those of known hemozoin proteins when combined with nano aluminum (Slocik, J. et al. Small. 2015, 5538).

Ultimately, the ability to generate modular nanoenergetic materials will serve present and future military needs.

*In Situ* Tissue Engineering with a Surprisingly Smart Scaffold
Buddy Ratner; Department of Bioengineering and Department of Chemical Engineering, University of Washington, Washington, Washington, United States.

Tissue engineering has been with us for over 30 years and yet, I spite of some clinical successes, it has had little impact on the day-to-day practice of clinical medicine. This has been attributed to translational issues in scale-up and production, i.e., high costs; incompletely developed technologies and regulatory concerns. The concept of *in situ* tissue engineering is attractive in that it utilizes the patient’s own cells and also the patient’s own body as the bioreactor. Sphere templated porous polymers (*STPP*, where all interconnected pores are approximately 40 microns in diameter, have been found upon implantation to be rapidly infused with macrophages which then, in about 1 month, leads to vascularized, reconstructed tissue. Larger and smaller pore size materials do not demonstrate this phenomenon. Implantation of 40 micron pore STPP in bone sites yielded bone.

Implantation in sciera yielded sclera tissue. Implantation in skin showed reconstruction of both the dermis and epidermis. Implantation in heart led to reconstruction of the heart stroma. Recent investigation of this *in situ* tissue engineering reconstruction demonstrated that major changes are occurring in RNA signals from cells in 40 micron pores, compared to cells in 80 micron pores. Also, unique cells morphologies are seen in different pore sizes. Finally, there is evidence that the macrophages may be differentiating to an endothelial-like lineage contributing to the vigorous blood vessel ingrowth. (coauthors on this work are James Bryers, Neal Beeman and Le Zhou)

11:00 AM **SM04.01.02**

Silk—From Textiles to Medical Products
David L. Kaplan; Department of Biomedical Engineering, Tufts University, Medford, Massachusetts, United States.
Silk proteins have emerged from the textile and suture worlds into a broader suite of medical utility over the past few decades. This progression started with new fundamental insights into the features of this unique protein polymer, and has subsequently evolved into new utility for these polymers in terms of clinical impact. We will review the historical, research and translational steps that have supported new medical materials and devices based on silks. We will also speculate on the future directions for this protein polymer based on the progress to date and the medical needs of the future.

11:30 AM SM04.01.03
Supramolecular Hydrogels for Prevention of Post-Operative Adhesions
Eric A. Appel; Stanford University, Stanford, California, United States.

Post-operative adhesions represent an important, unmet clinical need with costs to the U.S. healthcare system exceeding $2.5 billion annually. Adhesions form as a result of normal wound-healing processes following any type of surgery and develop after 95% of cases. In cardiac surgery, adhesions are particularly problematic during redo operations where surgeons must release pericardial adhesions from the surface of the heart before the intended procedure can begin. This process significantly lengthens operation times and introduces significant risks of hemorrhage and injury to the heart and lungs during sternal reentry and cardiac dissection. This presentation will discuss the use of a dynamically crosslinked polymer-nanoparticle (PNP) hydrogel adhesion barrier comprising hydrophobically-modified biopolymers (BPs) and biodegradable PEG-PLA nanoparticles (NPs). We demonstrate these materials to have desirable linear viscoelastic, yield-stress, and flow properties permitting simple spray delivery, robust tissue adherence, local tissue retention over the course of weeks and complete resorption within one month, as well as robust prevention of pericardial adhesion formation. We show that it is the distinct mechanical properties of these materials that dictate efficacy. Overall, this presentation will demonstrate the utility of a supramolecular hydrogel system as an effective solution for the prevention of post-operative pericardial adhesions.

11:45 AM SM04.01.04
3D Human Eye Model Using Soft and Rigid Materials
Simon Regeil, Roger Delattre and Marc Ramuz; Ecole des Mines de Saint-Etienne, Gardanne, France.

We present here the development of a physical human eye model – based on hybrid soft/rigid materials - in order to create a test bench reproducing the optical eye properties. We have developed phantom eye tissues in order to mimick the different parts like the sclera or the ciliary body as finely as possible regarding the optical properties. As a matter of fact, these parts are crucial in order to mimic human eye but often neglected in the literature. For the development of these models, we used the optical parameters (absorption and scattering coefficients and refractive index) extracted from an experimental study carried out on porcine eyes – which are close to human one. Moreover, we present a soft actuated model of the iris where the aperture ranges from 1 mm to 8 mm. Finally, all the different parts are put together to obtain a device mimicking exactly the optical properties of an eye.
This model could use to test medical imaging like diffuse optical tomography.

SESSION SM04.02: Smart Materials/Scaffolds II

Designing 3D Smart Scaffolds for Biomedical Applications Exploiting Peptide Self-Assembly
Alberto Sainani; School of Materials and Manchester Institute of Biotechnology, University of Manchester, Manchester, United Kingdom.

The use of non-covalent self-assembly to construct materials has become a prominent strategy in biomaterials science offering practical routes for the construction of increasingly functional materials. A variety of molecular building blocks can be used for this purpose, one such block that has attracted considerable attention in the last 20 years is de-novo designed peptides. Peptides offer a number of advantages to the biomaterial scientists. The library of 20 natural amino acids offers the ability to play with the intrinsic properties of the peptide such as structure, hydrophobicity, charge and functionality allowing the design of materials with a wide range of properties. Synthetic peptides are chemically fully defined and easy to purify through standard processes. Being build form natural amino acids they result usually in low toxicity and low immune response when used in-vivo and can be degraded and metabolised by the body. The β-sheet motif is of particular increasing interest as short peptides can be designed to form β-sheet rich fibres that entangle and consequently form very stable hydrogels. Through the fundamental understanding of the self-assembly and gelation processes of these peptides across length scales [Gao J. et al. Biomacromolecules 2017, 18, 826] we have been able to design hydrogels with tailored properties for a range of applications from tissue engineering [D. Kumar et al. Adv. Funct. Mat. 2017, 27, 1702424] and cell culture [Castillo-Diaz L. et al. J. of Tissue Eng. 2016, 7, 2014173146649789] to drug delivery [Tang et al. Int J Pharm 2014, 465, 427], 3D bioprinting [Raphael, B. et al., Materials Letters 2017, 190, 103. and biosensing [King P. Et al. Chem. Comm. 2016, 52, 6697].

Designing Smart Materials for Cell Modulation
Molly Stevens; Department of Materials and Department of Biengineering, Imperial College London, London, United Kingdom.

This talk will provide an overview of our recent developments in the design of smart materials for cell modulation. Bio-responsive nanomaterials are of growing importance with potential applications including drug delivery, diagnostics and tissue engineering (1) and recent examples in the design of nanostructured surfaces and elucidation of the cell-material interface will be presented [2, 3].

2:30 PM SM04.02.03
Smart Bone Mimetic Scaffolds as Cancer Testbeds
Kalpana Katti[1, 2, 3], MD Shahjahan Molla[1, 2, 3], Sumanta Kar[1, 2, 3] and Dinesh R. Katti[1, 2, 3]; 1Civil and Environmental Engineering, North Dakota State University, Fargo, North Dakota, United States; 2Center for Engineered Cancer Testbeds, North Dakota State University, Fargo, North Dakota, United States; 3Materials and Nanotechnology, Biomedical Engineering, North Dakota State University, Fargo, North Dakota, United States.

Regenerative medicine has led to many advances in tissue replacement therapies for hard and soft tissues. Besides the numerous coatings and putty-like products, tissue engineered manufactured constructs are also making headways for healing large defects. In addition, these tissue engineered constructs have a new application as testbeds for evaluating diseases. For instance breast and prostate cancer have the propensity to metastasize to bone at which point the disease is incurable. Lack of human samples at this stage of metastasis when patient is typically under hospice care and failure of animal models (since animals die before metastasis to bone) makes the humanoid test-bed a very advantageous dereve for studying cancer progression. We present a unique scaffold that uses biomimetic mineralization of hydroxyapatite inside nanocays galleries to make the hierarchical structure of human bone with a stoichiometric characteristic of new bone; a niche to which cancer cells migrate. Prostate and breast cancer cell lines are seeded on to this tissue engineered bone scaffold leading to the creation of tumoroids of cancer. We also demonstrate that this engineered test-bed duplicates the last stage of cancer metastasis as indicated by the gene expression and immunocytochemistry analysis of the tumors generated in the testbed. Metastatic and non metastatic cell lines of both prostate and breast cancer are evaluated at metastasis site indicating different and unique behaviours at bone site. Nanomechanical evaluation in conjunction with gene and protein expressions are done for cancer progression at bone site. We demonstrate that the nanomechanical evaluation can describe the progression of the disease. Thus, unique biomimetic smart scaffolds provide new opportunities to evaluate cancer metastasis.
Development of a Hybrid Hydroxyapatite-Baicalein Coating with Antibacterial Properties

Estelle Palierse1,2, Claude Jolivalt2 and Thibaud Coradin3; 1Laboratoire de Chimie de la Matière Condensée de Paris, Sorbonne Université, CNRS, Paris, France; 2Laboratoire de Réactivité de Surface, Sorbonne Université, CNRS, Paris, France.

More than 100,000 total hip replacements surgeries are performed each year in France1. Surgical site infections for these surgeries, mainly caused by the presence of microorganisms at the surface of the implant, are rare (0.5-5 % of the cases2) but can lead to serious damages such as implant failure and its removal. Currently, an efficient strategy for combating these infections is the use of systemic antibiotic prophylaxis. An alternative promising way to avoid its overuse is to use the implant as a support for the antimicrobial activity. Such a strategy allows the possibility of higher dosages near the affected site thereby improving efficiency and reducing the treatment duration and side effects3. Titanium alloy is widely used as material for body implant for its biocompatibility; nevertheless it cannot induce bone regeneration. In order to combine osseocoaudtion and local drug delivery, implants can be coated with a hydroxyapatite layer, the constituting mineral of bones, known to improve the osseointegration of implants4. The goal of this work was to develop an antibacterial coating on titanium alloy Ti6Al4V, associating a biomimetic hydroxyapatite and a natural antibacterial molecule, baicalein. This molecule is a flavonoid extracted from the root of the plant Scutellaria baicalensis, that has been used for a long time in the chinese traditional medicine for its antioxidants properties and of which the efficiency has been proved against multi resistant bacteria5. Hydroxyapatite coating was synthesized by immersion of the metal in a mineralizing solution called Simulated Body Fluid (SBF), whose ionic composition is similar to blood plasma, at physiological pH and temperature6. Hybrid materials were obtained either in a one-pot synthesis, with incorporation of baicalein in SBF, or in a two steps process consisting in the adsorption of baicalein at the surface of a pre-formed hydroxyapatite layer. Hybrid coatings were characterized by scanning electron microscopy, X-ray electron spectrometry, and both Raman and Fourier transformed infrared spectroscopies for their physico-chemical properties and for their antimicrobial activity. Finally, release of baicalein from both coatings was investigated, as well as their cytotoxicity and osteoinductivity. For purpose of comparison and understanding, a study of the molecular interaction between calcium and baicalein in solution was also performed.

3D Printing of Biomaterials for Bone Disorder—Opportunities, Challenges and Clinical Significance
Susmita Bose; Herman and Brita Lindholm Endowed Chair Professor, School of Mechanical and Materials Engineering, Washington State University, Pullman, Washington, United States.

Additive manufacturing (AM) or 3D printing (3DP) is becoming important for biomedical device fabrication, especially for patient matched implants due to lower cost and shorter lead time to manufacture. There are an estimated one million bone grafting procedures performed annually in the U.S. and a few million worldwide to repair bone defects, tumors, hip and knee replacements. Depending on the clinical need, different biomaterials are used for site specific or patient specific applications, for which different 3D printers are needed to create the biomedical device. Establishing process property relationships for different AM techniques are vital towards successful implementation of 3DP. However, additively manufactured components are still questioned for their reproducibility, machine to machine part quality variations and process specific material properties. Hard biomaterials, e.g., calcium phosphate (CaP) ceramics show significant promise towards bone implant applications, in both 3DP tissue engineering scaffolds and surface modified hip and knee replacement devices. We have used 3DP CaP scaffolds, for bone tissue engineering to control their degradation kinetics, mechanical strength, and biological properties with improved osteogenesis, angiogenesis and as drug delivery vehicle. An additional coating of polymer on both CaP scaffolds and hip / knee implant devices helped improve mechanical and biological properties while controlling the drug release kinetics. The presentation will include opportunities and challenges towards the use of 3DP or AM in developing biomedical devices.

4:00 PM SM04.03.02
Genomic DNA Functionalized 3D Printed Materials for Drug Capture
Daryl Yee1, Sankarganesh Krishnamoorthy2, Robert H. Grubbs2, Steven Hetts3 and Julia Greer1; 1Applied Physics and Materials Science, California Institute of Technology, Pasadena, California, United States; 2Chemistry, California Institute of Technology, Pasadena, California, United States; 3Radiology, University of California, San Francisco, San Francisco, California, United States.

Since the discovery of chemotherapy in the beginning of the 20th century, researchers around the world have been actively developing new and more effective chemotherapeutic agents to better treat cancer. Traditionally, chemotherapeutic agents work by interfering with cell division. However, by virtue of their mechanism of action, healthy normal cells can also be targeted and destroyed. As a result, while chemotherapy is an effective way of managing cancer, the resulting side effects limits its use. One approach currently taken to reduce these side effects is to deliver the chemotherapy drugs directly to the tumor via transarterial chemoembolization, or other similar procedures. While this has been effective in reducing systemic toxicity, more can be done to improve this. Ideally, a device that could sequester any unreacted chemotherapy agents could be installed "downstream" of the tumor prior to them entering systemic circulation. Such drug-capture materials have yet to be realized due to the difficulty in achieving materials that have the right surface chemistry and geometry for blood flow.

Working together with medical doctors, computational fluid dynamic experts, chemists, physicians and materials scientists, we report the fabrication of DNA functionalized 3D printed porous materials that can be used to trap doxorubicin, a commonly used DNA-targeting chemotherapy agent. We discuss the concept behind the device, the use of 3D printed materials as an ideal substrate, and the chemistries considered in drug binding. To achieve scalability of these devices, we developed a method of attaching cheaply available genomic DNA to these materials, a departure from commonly used synthetic DNA. The efficacy of these functionalized materials were demonstrated in PBS, where we observed a >70% reduction in doxorubicin concentration over a period of 10 minutes, highlighting the viability of this as a method of drug capture.

4:15 PM SM04.03.03
Advanced Digital Prosthetic Technology
Trevor Coward and Swati Jindal; Academic Centre of Reconstructive Science; Faculty of Dentistry, Oral & Craniofacial Sciences, King's College London, London, United Kingdom.

Digital technology has provided the maxillofacial and craniofacial team with the ability to manipulate digital images using various 3D software’s to provide additional information which can be applied to improving patient treatment outcomes. CT and MRI data can be used in conjunction with 3D printers to produce anatomical models of the skull and provide the surgeon with the advantage of planning the surgical procedure and preparing templates to act as guides during surgery to minimise tissue morbidity and reduce surgical time. Traditional methods of manufacturing maxillofacial prostheses are undertaken by hand carving the missing anatomical form in wax, and creating a mould into which pigmented silicone elastomer is placed. Over the last decade more modern technologies have been employed to manufacture anatomical face/body parts utilizing computed tomography (CT) data in conjunction with rapid prototyping (RP) techniques utilizing a hard plastic resin or thermoformed wax. However, these methods still require moulds into which a biocompatible pigmented silicone elastomer is placed.
The purpose of this presentation is to explore the development of direct printing of two component silicone elastomers in conjunction with a support structure to create complex shapes using a customized 3D printer. Ultimately, this would provide the maxillofacial prosthetist with a tool that manufactures prostheses reliably, with less emphasis placed on individual artistic interpretation. This technology has the potential to solve possible manufacturing solutions to complex shapes for both commercial and industry in addition to the current medical applications.

Method: The first step was to develop a two-component RTV silicone which was printable and had adequate properties suitable for fabrication of facial prostheses. The composition of silicone was varied to find the suitable combination with adequate strength. A 3D printer design had to be adapted to print the silicone.

Results: The base for two-component silicone was composed of 70% long, 20% medium, 10% short chain PDMS loaded with 30% filler showed optimal tear and tensile strength after printing. This newly developed two-component silicone also contained 5% cross-linker, 2.5% catalyst, 0.5% moderator and 3% thixotropic agent. The printer design and printing parameters were adapted to print the two-component silicone. Pigments were successfully printed through the printer and a hydrogel Pluronic F-127 was found to be suitable for printing colorful material for 3D printing of silicone prostheses.

Conclusions: The printing process and material have been developed to print silicone prostheses with suitable mechanical properties. The ways to incorporate colour data into printer and printing resolution need to research further.

4:30 PM SM04.03.04
Advances in Material Development and 3D Bioprinting
Hector Martinez; Cellink, Boston, Massachusetts, United States.

3D Bioprinting has gained attention in tissue engineering due to its ability to spatially control the placement of cells, biomaterials and biological molecules. The development of new hydrogel biomiks with good printability and bioactive properties has made it possible to 3D bioprint and accelerate the maturation of complex 3D tissue-like models. In this talk, we present our recent work in bioprinting and material development for 3D bioprinting and culture of healthy tissues such as skin, bone and cartilage, as well as cancer tissues for disease modelling and studies of tumor cells interaction with their microenvironment.

In addition to the biopink development we will be taking about printing thermoplastics, 4D-printing and soft robotics.

SM04.04.01
Scaffold-Mimicked Silk/Gelatin-Based Neural Microelectrode Arrays Fabricated by Aqueous-Phase Microtransfer Printing
Zhen-Ting Tang and Wei-Chen Huang; Taipei Medical University, Graduate Institute of Biomedical Materials and Tissue Engineering, Taipei, Taiwan.

Traumatic peripheral nerve injury occurs prevalently in the worldwide, which usually results in the disability of extremities. Grafting with a nerve guidance artificial conduit to guide neuron regrowth can enhance nerve regeneration. However, the commonly used nerve conduit cannot provide a spatiotemporal regulation and in-situ monitoring for localized neurons. Accordingly, in this study, neural implant device that is combined with regenerative tissue scaffolds and microelectrode arrays was developed to enhance cell growth through applying electrical stimulation and neural signals recording in a as-built tissues-mimicked micro environment ent. A new type of tissues scaffold, called Dopa-SFG in the composition of synthesized doped-modified silk fibroin and gelatin was fabricated to exhibit tissue-mimic structural and mechanical properties, adhesive ability, and phase transition under a specific temperature. The aqueous Dopa-SFG precursors can be directly transformed to a gel bulk, in turn used to transfer print a complicated microelectrode structure that was pre-fabricated on PAA-C2- sacrificial layer. Such transfer printed scaffold-based neural microelectrode array enabled conformable adhesion on a moisture-rich curvilinear surface and electrical signals transduction from the tiny microelectrode site, which is expected to provide more efficient peripheral nerve regeneration.

Results and discussion: After cooling transfer, Dopa-Silk fibroin gelatin(Dopa-SFG) is bonded to the underlying MEA. In the liquid state, Dopa-SFG dissolves the sacrificial layer of calcium ions above the MEA, and then transfers the MEA to the hydrogel through the adhesion of Dopa. Thus, an adhesive silk protein sleeve electrode having electrical stimulation and contact-guided growth and monitoring functions is produced.

Osteoinductive Thermoresponsive Conducting Hydrogels
Mayra C. Alcaraz and Jonathan Rivnay; Northwestern University, Evanston, Illinois, United States.

Regeneration of bone tissue in cases of non-union in fractures or spinal fusions present a significant medical and financial burden. Current approaches rely on scarce and undesirable allografts, new materials, or biologics, each presenting their own drawbacks and limiting efficacy. Electrical bone-growth stimulators have gained popularity with their promise of shorter recovery times; however, clinical meta analyses suggest mixed outcomes. Such invasive electrical approaches have relied on rigid wires inserted into the defect site. This approach is not ideal for regenerative engineering due to the remaining signaling and mechanical mismatch. To address this need, we turn to conducting polymers to develop a material that can fill the volume of a fracture defect site, allow for both passive and active stimulation of bone growth, and provide tissue-like characteristics. To this end, we demonstrate a thermoresponsive conducting hydrogel composite that shows differentiation of bone marrow stromal cells (BMSCs) into osteoblasts. The conductive hydrogel composite is based on a thermo-responsive hydrogel known as poly(polyethylene glycol citrate-co-N-isopropylacrylamide) (PCCN) sacrificial layer. Such transfer printed scaffold-based neural microelectrode array enabled conformable adhesion on a moisture-rich curvilinear surface and electrical signals transduction from the tiny microelectrode site, which is expected to provide more efficient peripheral nerve regeneration.

Results and discussion: After cooling transfer, Dopa-Silk fibroin gelatin(Dopa-SFG) is bonded to the underlying MEA. In the liquid state, Dopa-SFG dissolves the sacrificial layer of calcium ions above the MEA, and then transfers the MEA to the hydrogel through the adhesion of Dopa. Thus, an adhesive silk protein sleeve electrode having electrical stimulation and contact-guided growth and monitoring functions is produced.

Direct 4D Printing via Polyurethane Paint Based Composites
Jheng-Wun Su1,2,3,4, Ezgi Tekin Pulatsu1,2,3,4, Jeng-Shin Liou1,2,3,4, Jia Wang1,2,3,4,5, Lin Ng1,2,3,4,5, Michael Lin1,2,3,4,5, Hsin-Yi Tsai1,2,3,4,5, Hsin-Tzu Huang1,2,3,4,5, and Hao-Pu Liou1,2,3,4,5

In recent studies, polyurethane has shown multiple properties that make it an excellent candidate material in 4D printing. In this study, we present a simple and inexpensive additive method to print waterborne polyurethane paint based composites by adding carboxymethyl cellulose (CMC) and silicon oxide (SiO2) nanoparticles to the paint. The first function of CMC and SiO2 is to improve rheological properties of the polyurethane paint for making a printable precursor, which improves the printing resolution and enhances additive manufacturability. Second, the composite precursors improve the curing rate of the polyurethane paint without changing its inherited shape memory properties. Third, the printed composite parts show enhanced mechanical strength compared with that of the parts printed with pure polyurethane. Finally, the 3D printed polyurethane-CMC and SiO2 parts exhibit time-resolved shape transformation upon heat stimulation. To the best of our knowledge, this is the first study of using the polyurethane paint as the precursor for
SM04.04.04 Optimizing Homogeneous Thin Solid Films (HTSFs) from µL-sized Blood Droplets via Hyper-Hydrophilic Coatings (HemaDrop™) for Accurate Constitutional Analysis via IBA, XRF and XPS

Nikul Suresh1,2, Akshay K. Narayan2,2, Jyotirmoy Raychowdhury1,3, Jack M. Day4, Yu-Chien Lin3,4, Francesca J. Ark1,3, Amber A. Chou1, Shaurya Khanna1 and Karen L. Kavanagh5;1 Arizona State University, Scottsdale, Arizona, United States; 2School of Physics, University of Melbourne, Victoria, Australia; 3MicroDrop Diagnostics LLC, Phoenix, Arizona, United States; 4AcuAngle Analytics LLC, Phoenix, Arizona, United States; 5Department of Physics, American University, Washington D.C., District of Columbia, United States; 6Simon Fraser University, Burnaby, British Columbia, Canada; 7Department of Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 8SiO2 Innovates LLC, Phoenix, Arizona, United States; 9Jacobs Center for Cosmetic Surgery, Healdsburg, California, United States.

Current blood diagnostics require 2-10 milliliters (mL) of blood per test, taking hours, or days, for results. Drawing mLs of blood can induce hospital-acquired anemia (HAA) in premature infants, and in chronically, or critically ill patients. Reducing the volume drawn while increasing analysis speed and accuracy can improve healthcare, and decrease suffering and costs from infections and transfusions. Rapid results from µL blood samples can revolutionize quality and cost of care.

Theranos claimed it could analyze nanoliter (nL) blood droplets. FDAs raids triggered by inaccuracies in tests, revealed Theranos diluted nL into mL-sized vials while using standard analysis methods with errors greater than the medically acceptable threshold of 10%. However, HemaDrop™, a “hyper-hydrophilic” surface coating, can solidify micro-liter (µL)-sized blood droplets within minutes microliter-sized droplets into Homogeneous Thin Solid Films (HTSFs), without phase separation or segregation. HTSFs can be analyzed within minutes using handheld or desktop analyzers, in air or in vacuo. Blood HTSFs were tested for accuracy in measuring electrolytes (Na, K, Mg, Ca, Cl) and hematocrit (Fe) from single µL droplets. So-called “Lytes & Crit” (electrolytes & hematocrit) are often the first tests conducted in ER, ICU, NICU, OR, and hospitals, as general status depends critically on hydration (electrolytes concentration), and oxygenation (Fe hematocrit levels). These are repeated daily and sometimes every few hours.

Repeated measurements show that electrolytes and Fe in human blood are accurate within 10% using IBA, XRF, and XPS, from a few µL of blood solidified as HTSF when calibrated using commercial Balanced Saline Solution (BSS+) pre-solidified on strips coated with HemaDrop™, called DropFilmStrip™.[1-3] XRF is of particular interest because it is a desktop/handheld tool which yields within minutes compositional analysis within the medically acceptable 10% for Na, K, Mg, Ca, Cl, Fe.

Prior to IBA, XPS, and XRF analysis, congealed, uniform HTSFs are compared to conventionally Dried Blood Spots (DBS). Solidification of droplets into HTSF is observed and timed via real-time microscopic and video. In DBS, phase separation between platelets and serum yields rough, non-uniform thin solid films. But HTSFs solidified on HemaDropTM are smooth, and uniform without phase separation. Similar behavior can be seen with solidified Balanced Saline Solution (BSS) droplets. BSS congealed on HemaDropTM exhibits little crystallization and no phase separation[4] while simply dried BSS does. HTSFs of human blood, canine blood and BSS solidified via HemaDropTM coated surfaces all underwent XRF in air, XPS in 10-10 Torr vacuo, and IBA in 10-7 Torr vacuo, performed on the same set of 5 and 10 µL-sized droplets congealed into HTSFs and compared to DBS. HTSFs yield identical, reproducible 2 MeV RBS, XPS, and XRF spectra on different areas of HTSFs. C, N, O, Na, K, Ca, Mg, Cl, Fe are detected with leading edges falling within IBA resolution (<15 keV, 2-3 channels), while DBS yield leading edges spread out over 100 keV.

The damage curve method extrapolates elemental composition while accounting for possible ion damage. Four consecutive spectra are taken on each analyzed area. RBS, XPS and XRF yields are interpolated to 0-analyzing down to extract concentration limits.

IBA simulations with the software SIMNRA are fitted to the RBS spectra and matched to within 1%. Atomic compositions from sequential IBA, XPS and XRF spectra taken on different areas of HTSFs yield different results. IBA, XPS and XRF results are within 5%.[5] Relative error analysis between multiple HTSFs establishes reproducibility within 10%. Comparative analysis from these results will be discussed to show how it guides optimization of the technology.

SM04.04.05 Supercritical Ti-Based Alloys Scaffold Prepared by Fiber Metallurgy Taehyun Nam; Materials Science and Engineering, Gyeongsang National University, Jinju, Korea (the Republic of).

Ti-50.3Ni-0.7Ag and Ti-18Zr-12.5Nb-2Sn (at.%) alloys scaffolds were fabricated by sintering the alloys fibers prepared by rapid solidification method. Secondary phases such as Ti₆Ni and Ti₆Ag phases which have been observed in the bulk alloy prepared by conventional casting method were not observed in as-solidified Ti-Ni-Ag fibers. Ag content in the fibers was measured to be 0.57% much larger than that in the bulk alloy, which is beneficial to improve the antibacterial function. The two stage B2-R-B19 transition occurred and good superelasticity with superelastic recovery ratio of 93% was observed in Ti-Ni-Ag fibers. As-spun Ti-Zr-Nb-Sn alloy fibers were composed of only the β phase. Tensile tests showed that Ti-Zr-Nb-Sn as-spun alloy fibers exhibited superelastic behavior over temperature ranges between 238 K and 318 K. A large recovery strain of 4.5% for 5% pre-strain was observed at room temperature.

In order to fabricate scaffolds, the fiber segments were put into the packing chamber of graphite mold and sintered at 1173 K for Ti-Ni-Ag alloy fibers and at 1573 K for Ti-Zr-Nb-Sn alloy fibers for 60 min in high vacuum condition. The alloy scaffolds prepared by sintering the fiber segments possessed three-dimensional and interconnected pores that were structured by the bonded small fiber segments with random directions. The porosity of the scaffolds were about 80%. The compressive strength of Ti-Ni-Ag alloy scaffold was about 5.6 MPa at the strain of 4% and that of Ti-Zr-Nb-Sn alloy scaffold was about 6 MPa at the strain of 7%, similar to that of cancellous bone ranging from 2 to 20 MPa. The elastic modulus of Ti-Ni-Ag and Ti-Zr-Nb-Sn alloy scaffolds was 0.67 GPa and 0.42 GPa, respectively, which were also similar to that of cancellous bone ranging from 0.1 to 2 GPa. Supercritical strain recovery of Ti-Ni-Ag and Ti-Zr-Nb-Sn alloy scaffolds was found to be 3% and 2.5%, respectively.

SM04.04.06 Controlled Rupture of Magnetic-Sensitive Microcapsules for Selective Fluorescence off-on Detection of Trivalent Cations Bowei Du, Yu-Ting Tai and Fu-Hsiang Ko; National Chiao Tung University, Hsin-chu, Taiwan.

Microcapsules are discussed in drug delivery, biomaterial and self-healing applications for their numerous advantages[1-3]. Plenty of stimuli are used to trigger the release of core contents[4]. However, any loss of core contents prior to their stimuli will lead to weakened function of encapsulated systems. In this research, materials of magnetic-sensitive microcapsules were successfully synthesized using Fe₂O₃/polycaprolactone (PCL) to construct the shell. In our previous work, pyrene based active Schiff base probe could be formed to complexes PE-M₃⁺ (M = Fe/Cr/Al) to detect Fe³⁺, Cr³⁺ and Al³⁺ ions by its nano-aggregation induced emission enhancement (AIEE)[5]. As we known that Fe³⁺, Cr³⁺ and Al³⁺ ions are essential in the human body, Cr³⁺ plays an important role in the maintenance of an effective carbohydrates, lipid and protein metabolisms[6-7]. In addition, Cr³⁺ ion has high biological activity while diabetics can cause Cr deficiency in the body. Hence, we designed a new probe that also can perform in a magnetic field though it moves through digestive tract. In order to protect the core content and control release of encapsulated cargo that utilize microcapsules-based drug release system and high-frequency magnetic field (HFMF) to accelerate the rate of contents release. A pyrene based Schiff base derivative 2-((pyrene-1-ylmethylene)amino)ethanol (PE) was encapsulated for sensing Fe³⁺, Cr³⁺ and Al³⁺ ions to use in the fluorescence turn-on responses. Furthermore, the solvent evaporation method was used to fabricate the microcapsules using W/O emulsion. Experimental observations showed that the magnetic nanoparticles in the shell structure indicated that the shell structure was subjected to a sharp structural change when the magnetic NPs caused rapid heating when exposure to a HFMF. After the magnetic particle PCL shell was degraded in the surrounding, in the same time, Schiff base probe PE was released into environmental solution also. In particular, the activity of the “OFF-ON” fluorescent sensor was not being obviously affected by encapsulated phenomenon. As shown in experimental observation, upon the increased addition of water fraction (fw) from 0% to 80% towards PE microcapsules in CH₂CN, the UV/PL peaks at 425/413 nm were red shifted to 463/470 nm, respectively.

This encapsulated fluorescent sensor exhibited a longer shelf life and better stability compared to the original sensor. The capsules’ shell improved the thermal stability of encapsulated PE, the thermal decomposition of these microcapsules around 350 deg. Likewise, the naked eye and fluorescence turn-on sensing responses were still performed well based on the Schiff base probes and PL spectra. The magnetic field and PE microcapsules showed an “instantaneous” burst release of drug by rapid temperature raise to induce a quick melting of the PE microcapsules. Therefore, the combination of magnetic and thermal properties would be a very attractive for detection of metal ions in organisms.

Keywords: Microcapsules; Magnetic-sensitive; Fe³⁺/Cr³⁺/Al³⁺ nanorobots; PCL; Fluorescent sensor; Trivalent cations; High-frequency magnetic field (HFMF)
Articular cartilage repair poses a great challenge to the medical community due to the avascular nature and poor intrinsic healing capacity. Bone marrow derived mesenchymal stem cell (BMSC) transplantation shows great promise to prevent subsequent damage to the injured area and to reconstruct cartilage. Nevertheless, the limited regenerative abilities of the BMSC, and low survival rate and incomplete differentiation in hinder further applications. Addressing these hurdles, researchers have designed several strategies, such as 3D cell spherical and bioscaffolds that mimic the natural tissue microenvironment to deliver physical and soluble cues. However, several pertinent impediments hinder advances in stem cell transplantation, including poor integration of cell-cell interaction and cell-ECM interaction into single system, and the diffusional limit of approximately 150-200 μm restricts the mass transportation of nutrients and growth factors.

To this end, we report a novel biodegradable MnO$_2$/gelatin nanomaterial to induce BMSC assembling and to control the chondrogenic differentiation of assembled BMSC in a highly selective and efficient way. Further, as a proof-of-concept demonstration, we utilized MnO$_2$-nanofiber as both cell-adhesion substrate and a chondrogenic inducer-delivery carrier with enhance stem cell differentiation in vitro and in vivo. Specifically, our novel nanoreinforced cell hydrogels have several advantages: (i) unique topographical properties to better mimic native cartilage microenvironment; (ii) integration of cell-cell interaction and cell-ECM interaction; (iii) highly efficient growth factor loading and spatiotemporal release capacity; (iv) highly stretchable and injectability; and (v) innovative magnetic resonance imaging (MRI) property. Our nanoreinforced cell assembling method shows great therapeutic potential for advanced stem cell transplantation and cartilage regeneration.

Effect of Photo-Initiators on Polymerisation of Thiol-ene Clickable Gelatin Bioinks

Kai-Hung Yang$^1$, Gabriella Lindberg$^2$, Roger Narayan$^1$, Khoon Lim$^2$ and Tim Woodfield$^2$; $^1$North Carolina State University, Raleigh, New Jersey, United States; $^2$University of Otago, Christchurch, New Zealand.

Bioprinted scaffolds with physico-mechanical properties mimicking the native extracellular matrix (ECM) environment holds great potential for successful regenerative medical treatments and/or 3D models of cellular behaviors. Recent advances highlight alkylated gelatin (GelAGE) as a versatile hydrogel platform for both lithography-based and extrusion-based biofabrication with highly tailorable properties. This material is further known to be susceptible to photo-crosslinking with both UV- and Visible-light based photoinitiator systems. It is, however, unknown how these different photoinitiator systems affect long-term mechanical and rheological properties of GelAGE for the fabrication of tissue constructs with clinical relevant sized since UV light is known to be harmful for cells.

This study therefore aimed to study the polymerisation of GelAGE with UV (Irgacure 2959) and visible light (LAP, Ru/SPS) photoinitiators and concentrations suitable for lithography-based and extrusion-based printing applications based on resulting physico-mechanical and rheological properties. Gelatin was reacted with 12 mmol of allyl glycidyl ether (AGE) and 2 mmol NaOH per gram of gelatin at 65°C for 1h followed by dialysis, lyophilisation and NMR characterization. Hydrogel constructs were photo-polymerised (30mW/cm$^2$, 3min, 20wt.-% GelAGE) with linear dithiothreitol (DTT) at 1:1.5–1:6 AGE:SH molar ratios and different photoinitiators using either visible-light (450nm, 0.05wt% Lithium phenyl-2,4,6-trimethylbenzoylphosphinate; LAP or 0.2-1mM ruthenium; Ru and 2-10mM sodium persulfate) or UV-light (365nm, 0.05wt% Irgacure 2959) for 15min. Depth of cure, shape retention, viscosity, compressive modulus, mass loss, and mass swelling ratio were further characterized. Mechanical properties of photoinitiator systems was further studied as a function of time for hydrogels crosslinked with Ru/SPS and LAP. GelAGE was successfully synthesized (DodM:42) and fabricated through 10mm large constructs. Compared with Ru/SPS and Irgacure 2959, hydrogels with LAP demonstrated a higher degree of cure, shape-fidelity and homogenous polymerisation. Depth of cure was independent of DTT concentration (10.58-10.84mm), unlike hydrogels with Ru/SPS or Irgacure 2959. Better shape retention was also observed for LAP samples post swelling, the one with 1:1.5 AGE:SH molar ratio (partially dissolved, height drop to 6.32nm). GelAGE with UV photoinitiator (Irgacure 2959) resulted in lowest depth of cure and worst shape fidelity. The viscosity was observed to increase both with time of curing and dependent on the DTT concentration (0min = 10$^2$ Pa s, 15min = 3x10$^3$ Pa s for 1:1.5 AGE:SH molar ratio, 0min = 10$^2$ Pa s, 15min =1.7x10$^2$ Pa s for 1:6 AGE:SH molar ratio) which could be used to extend the fabrication window for extrusion-based bioprinting. The mechanical strength of Ru/SPS polymerised GelAGE constructs was further shown to be time-dependent (0min = 8.2 kPa, 10mm = 34 kPa, 30min = no hydrogel formation) and tailorable with different ratio of Ru:SPS and weight percent of GelAGE. Further replenish of SPS resulted in stiffer close to original value at t=0. Mass loss and swelling ratio were observed to be time-dependent as well. The time-dependent relationship of mechanical properties observed could be a powerful tool to achieve seamless mechanical gradients in biofabricated constructs by either bypassing processing for a short term or replenish SPS at certain time point.

In conclusion, GelAGE with LAP initiated polymerization offers a thiol-ene clickable biocompatible hydrogel platform that can be applied to fabricate clinical relevant sized tissue constructs with high fidelity and shape retention. In addition, the Ru/SPS system can provide a wide range of stiffness and gradient stiffness formation while the viscosity can be adjusted by varying DTT concentration to fit extrusion-based printing. All these results support the use of visible light photoinitiators but rather than UV photoinitiator.

Bioprinted 3D Hybrid Nasal Cartilage with Integrated Functional Olfaction

Yasamin Aliasrnof$^{1,2}$, Manu S. Mannoor$^1$ and Su Ryon Shin$^1$; $^1$Mechanical Engineering, Stevens Institute of Technology, Hoboken, New Jersey, United States; $^2$Medicine, Harvard Medical School, Cambridge, Massachusetts, United States.

Recent advances in microfabrication and biomaterials techniques have opened new doors to regenerate and recapitulate human organs in vitro with adequate levels of functionality required for regenerative medicine and drug development. Such advancements have enabled simultaneous targeting of the two challenges in nasal reconstruction surgeries: (i) high precision and personalized reconstruction of the nasal cartilage implants, (ii) retention of the olfactory epithelium and odor perception. The new hybrid nasal organ can be equipped with remarkable capabilities such as augmented odor detection and new levels of olfactory perception. Herein, we present precise reconstruction of the nasal cartilage using chondrocyte cell-laden photo-cross-linkable biomaterials as boneink and multi-material 3D bioprinting technique to fabricate a 3D cartilage tissue construct with tunable stiffness. In addition, by embedding vasculature in the macro-scale printed construct, we have also demonstrated the competence of our system in providing macro-scale viability and improved recapitulation of the cell behavior in 3D cartilage tissue construct. The engineered nasal cartilage tissue construct has been fully integrated with an electrochemical biosensing system to bring functional olfactory sensation. Functionalized with a variety of protein-ligand binding forms, including peptide-bacteria, antibody-virus, and peptide-chemicals, the developed nasal construct is capable of tunable selectivity towards specific airway disease biomarkers, explosives and toxins. With confirmed biocompatibility in integration with viable cartilage-like tissue, the proposed hybrid organ can lay the ground for creation of functional cellular biologic interfaces and humanoid cyborgs.

Design New Material Interface with Neurons for Neuron Stimulation and Regeneration

Chen Yang; Boston University, Boston, Massachusetts, United States.

Access and adoption of advanced prosthetics for children has been limited due to a variety of factors including: high costs, limited insurance coverage options, challenges in adaptation and training leading to high rejection rates, and limitations in technology or performance. These factors have driven prescribers to limit prescriptions of advanced prosthetics for children with congenital amputations, which occurs in approximately 5 out of 10,000 live births. Significant progress is needed to advance the field not only in the technology be developed, but also in the overarching training and feedback provided to the patients. In this study we discuss new techniques that have been integrated to advance the design in wearable neuroprosthetics, and a gamified, visual approach to training in the pediatric environment.

This work has demonstrated the effectiveness of using electromyographic (EMG) actuation in gamified simulations to train the actuation of multiple hand position gestures in a virtual environment. This type of training leverages real time visual feedback to user inputs, in this case muscle flexure with varied magnitude and time dependent patterns. This provides a stronger link between the intentionality capture (input) and the assigned thresholds and patterns required to activate the multiple states (outputs). This is implemented as a game that simulates the control of the prosthetic and translates the EMG input into functional game mechanics, providing meaningful feedback in form of gameplay. Initial studies have focused on testing the signal actuation repeatability to target specific multi-point magnitude set thresholds, and have shown promising results.

The role of additive manufacturing in medical devices has been developing both in practice and in the regulatory framework. The FDA’s new non-binding best practices have been key towards standardizing process flow and ensuring repeatable. The device developed in this study has been produced using 3D printed acrylonitrile butadiene styrene (ABS) plastic, via fused deposition modeling (FDM), including a dissolvable acrylic copolymer to allow for complex internal channels. Interlocking parts are created to interface with mechanical components including: fasteners, springs, and cabling. The advantages of this type of manufacturing allow for rapid prototyping, custom sizing for short run manufacturing, and the ability to grow modular parts that can be used to resize the antebrachial and brachial segments. These parts have demonstrated exceptional strength to weight ratios and durability. Print orientation, orienting the fiber deposition direction in context with the part and applied mechanical loads, is critical to achieving durability.

To achieve quantifiable outcomes, including arm system performance and the influence on patient’s quality of life, a clinical trial protocol for assessment has been developed in conjunction with Oregon Health & Science University (OHSU) and the University of Central Florida (UCF). This protocol includes assessment data points four times across the course of the one year study. Occupational therapists from OHSU will support the evaluation and provide valuable insight as to when multi-gesture hand states are appropriate to “unlock” for the patient. This novel development of technology and clinical translation is critical to advancing the accessibility of advances prosthetics for pediatrics. The use of additive manufacturing has enabled significantly lower costs, rapid prototyping, and advanced customization critical to improving clinical outcomes and experience.

9:30 AM SM04.05.04
Implantable devices and scaffolds with new functions interfacing with neural systems enables new techniques to fire and reconnect neurons. Specifically, we will report our recent progresses on a fiber based photoacoustic converters for successful in vitro and in vivo neuro stimulation and a biocompatible silk-based nanoladder scaffolds for facilitating neuron functional connection after injuries. In the first application, we design and develop a miniaturized fiber with diameters ranging between 500 microns to 1 millimeter composed of two layers: a diffusion layer and a expansion layer with nanocomposites to produce high intensity and controlled frequency of localized ultrasound when excited with nanosecond laser light. In vitro and in vivo neuron stimulation was successfully achieved with a laser duration of 20 milisecond. Neural stimulation in motor cortex of intact awake mouse brains confirmed the stimulation was localized with a high spatial resolution of 500 microns and not through direct auditory stimulation. In the second application, we design and demonstrate a silk-based scaffold composed of micron size fibers and nanoscale protrusions to direct axon growth along a predefined direction and facilitate neuron functional reconnection in vitro and in vivo.

Perineural invasion (PNI) is the neoplastic invasion of nerves. However, the mechanisms underlying its pathogenesis remain largely unknown. In this study, we created a hydrogel biochip to mimic a nerve tissue microenvironment for investigating the interaction between schwann cells and cancer cells. A new type of conductive tissue scaffold was developed via conjugating gelatin with poly(3,4-ethylenedioxythiophene (PEDOT), within which a naturally occurring polymer, melanin was incorporated to improve electrical properties. The resultant composite exhibited porous 3D structure with elastic conductivity and high chemical stability. The existence of Melanin and PEDOT was analyzed by FTIR confirming the bonding. Through SEM image we observed 300 nm spherical Melanin nanoparticles and PEDOT polymer both embedded in the hydrogel pore walls. The analysis of physicochemical characteristics indicated the electrical and mechanical properties increases as melanin and PEDOT incorporate with hydrogel. Furthermore, the in vitro biodegradation of compound showed a decreasing current as the conductive materials increases. At last we use the compound to create a hydrogel-based Electrode texture by transferprinting technique. As a result, a degradeable nerve-mimicking biochip was formed to investigate Perineural invasion.

9:45 AM SM04.05.04
Ultra compliant Gelatin-Based Conductive Microelectrodes Applied Fore Mimicking Neuro Microenvironment of Perineural Invasion

Yue-Xain Lin and Wei-Chen Huang; Taipei Medical University, Taipei City, Taiwan.

Implantable devices and scaffolds with new functions interfacing with neural systems enables new techniques to fire and reconnect neurons. Specifically, we will report our recent progresses on a fiber based photoacoustic converters for successful in vitro and in vivo neuro stimulation and a biocompatible silk-based nanoladder scaffolds for facilitating neuron functional connection after injuries. In the first application, we design and develop a miniaturized fiber with diameters ranging between 500 microns to 1 millimeter composed of two layers: a diffusion layer and a expansion layer with nanocomposites to produce high intensity and controlled frequency of localized ultrasound when excited with nanosecond laser light. In vitro and in vivo neuron stimulation was successfully achieved with a laser duration of 20 milisecond. Neural stimulation in motor cortex of intact awake mouse brains confirmed the stimulation was localized with a high spatial resolution of 500 microns and not through direct auditory stimulation. Two Photon Polymerization-Based Additive Manufacturing of Microstructured Medical Devices

Roger Narayan; North Carolina State University, Raleigh, North Carolina, United States.

Laser-based additive manufacturing techniques such as two photon polymerization, matrix assisted pulsed laser evaporation-direct write, and laser induced forward transfer have been used over the past two decades to create surfaces with small-scale features for medical applications. For example, the two photon polymerization technique involves use of femtosecond laser (e.g., a titanium:sapphire laser) pulses for selective polymerization within highly localized regions of a photosensitive resin. Polymerization and hardening occur at sites within the photosensitive resin where the excitation threshold of the photoinitiator is exceeded. Polymerization of microscale and sub-microscale features is possible since the two photon absorption exhibits a nonlinear relationship with the incident light intensity. Two photon polymerization has been used to prepare structures with sub-microscale features out of photosensitive acrylate-based polymers, zirconium oxide hybrid materials, and organogelated ceramic materials. Several types of medically-relevant structures, such as scaffolds for tissue engineering and medical devices, have been prepared using two photon polymerization. For example, we have used two photon polymerization to prepare small-scale lancet-shaped devices known as microneedles for transdermal delivery of pharmacologic agents or transdermal sampling of body fluids. Efforts to optimize the two photon polymerization processing procedures and postprocessing procedures for medical applications will be considered. In addition, selection of an appropriate photoinitiator for use in medical applications will be considered. The biological and functional evaluation of two photon polymerization-created medical devices and scaffolds for tissue engineering will be described. Necessary steps in the development of two photon polymerization as a commercially viable manufacturing method will be described.

11:00 AM **SM04.05.06
3D Printable Bouncing Hybrids for Cartilage Regeneration

Julian Jones; Imperial College London, London, United Kingdom.

Orthopedic surgeons need devices that can replace the articular surface of cartilage, then regenerate the cartilage to replace the device, all while recruiting cells from the underlying bone marrow. Such devices do not yet available, but they could be, using our new hybrid biomaterials. Hybrids have nanoscale co-networks of inorganic glass and organic components, e.g. sol-gel silica and biodegradable polymers. We now have hybrids that can “bounce” and self-heal. The hybrids are ideal for 3-D printing inks, which can yield bespoke scaffold architectures. Osteochondral devices can now be 3D printed that stimulate articular cartilage production and also provide the bearing surface with tribology similar to native cartilage.
Bone implants are frequently used to treat osteoarthritis and reconstruct large bony defects. The aging population as well as increasing numbers of obese patients will enhance the future need for orthopedic implants. Although the use of these implants in total joint replacements has become one of the most successful procedures in medical practice, two major challenges remain: implant-associated infection and implant longevity. As a result, the bar for proper functioning implants has been raised: implants should ideally prevent infection by bacteria that are increasingly resistant to antibiotics as well as induce and support sustained tissue integration between implant and surrounding bone tissue to secure implant longevity. Both requirements can be fulfilled by bone implants with multifunctional surfaces that we have synthesized through a combination of rational design, selective laser melting (SLM) and plasma electrolytic oxidation (PEO) in the presence of metallic nanoparticles (NPs).

Additive manufacturing has boosted new research areas in which the functionalities of biomaterials do not depend on the material properties but are direct consequences of the topology and can therefore be rationally designed. This has enabled the synthesis of highly porous biomaterials that closely mimic the mechanical properties of native bone. Furthermore, geometrical features such as porosity, pore size and curvature can be rationally designed to promote tissue integration. However, porous biomaterials are at risk for infection as they may have surface areas up to several orders of magnitude larger than solid biomaterials. Therefore, it is essential to biofunctionalize the surface such that not only bone regeneration is improved yet simultaneously infection is prevented.

Here, we present the synthesis and characterization of multifunctional titanium bone implants. We designed long porous implants that were synthesized from medical grade Ti-6Al-4V powder by SLM resulting in porous implants with a 4 times enlarged surface area compared to solid implants. Subsequently, the implant surface was biofunctionalized by PEO using an electrolyte consisting of Ca/P species and Ag, Cu and/or Zn NPs. PEO is very suitable for highly porous structures as it generates a homogeneous oxide layer in which the NPs become entrapped, thereby preventing nanotoxicity. Following biofunctionalization, biomaterial surface morphology was analyzed by scanning electron microscopy, chemical analysis by energy dispersive X-ray spectroscopy, phase composition by X-ray diffraction and ion release kinetics by inductively coupled plasma optical emission spectroscopy. Antibacterial testing was performed against methicillin-resistant *Staphylococcus aureus* (MRSA), a pathogen commonly involved in implant-associated infection. We determined the antibacterial leaching activity in a Kirby-Bauer assay and quantified bactericidal activity in vitro as well as in an ex vivo murine infection model. Subsequently, through live/dead staining, metabolic assays and measurement of alkaline phosphatase activity the cytotoxicity and osteogenic differentiation of human mesenchymal stem cells (hMSC) were analyzed.

PEO biofunctionalization of the porous titanium implants resulted in a micro/nano-porous TiO$_2$ surface layer that contained hydroxyapatite. The immobilized NPs in the surface generated the release of Ag, Cu and/or Zn ions for at least 28 days resulting in strong antibacterial leaching activity and prevention of bacterial adhesion in vitro and ex vivo, with AgNPs demonstrating the largest antibacterial activity. The biofunctionalized surfaces did not induce cytotoxicity and improved the metabolic activity of hMSC. Altogether, the biofunctionalized porous titanium implants presented here are suitable candidates for further preclinical development to prevent implant-associated infection and improve implant longevity.
induced one particular cellular orientation as the fibroblasts followed and oriented along the capillary long-axis while the flat plate-like regions of the prosthesis, which initiates the foreign body response of the patient’s immune system leading to inflammatory bone loss. Bone loss may also be the result of stress shielding, caused by the mechanical mismatch of the bone-implant interface. With the introduction of a metallic implant, the physiological loading condition of the bone changes, since most of the load is carried by the implant. According to Wolff’s Law, this will cause bone to adapt itself by reducing its volume in places it is no longer needed. Biomaterial optimization is therefore inevitable, when working towards the next generation of life-lasting implants.

The emerging concept of metamaterials offers a promising route to the development of such implant biomaterials with unique combinations of mechanical (e.g. Negative Poisson’s Ratio (NPR)), mass-and fluid-transport (e.g. diffusivity and permeability) and biological properties (e.g. tissue regeneration performance). The topology of these so-called meta-biomaterials, may be rationally designed to exhibit unprecedented properties for tissue regeneration and sustained mechanical support. The tremendous developments in metal additive manufacturing have allowed us to fabricate these highly complex micro-architectures, including triply periodic minimal surfaces and hybrid combinations of auxetic and conventional meta-biomaterials.

Unlike conventional meta-biomaterials, auxetic meta-biomaterials have a negative Poisson’s ratio and expand laterally in response to axial stretch. A recent study has proven their importance within the field of orthopedics, where a rational distribution of negative (auxetic) and positive Poisson’s ratios was used to improve implant-bone contact and potentially implant longevity in the femoral component (i.e. hip stem) of a Total Hip Replacement (THR). Since the hip stem is repeatedly loaded under bending, the lateral side of a conventional implant will be retracting from the bone under tensile loading. The bone-implant interface is not only more susceptible to failure when subjected to tension, but the implant’s retraction also reduces bone-implant contact and allows wear particles to enter the bone-implant interface space. Laterally applying an auxetic meta-biomaterial therefore resulted in compression on both of the implant’s contact lines with the surrounding bone, decreasing the chance of bone-implant interface failure and stimulating osseointegration.

In this work, we characterize the mechanical properties of additively manufactured, titanium auxetic lattices, based on the re-entrant hexagonal honeycomb. The mechanical properties of auxetic meta-biomaterials are inherited from the auxetic property of Poisson’s ratio, which is got to be a value of 0.75 through slight hindrances. The limit micro-architecture of Laser Melting (SLM) process was explored to synthesize structures with optimal bone-ingrowth properties. Their architecture was therefore evaluated using micro-CT, while its quasistatic and fatigue properties were assessed in a compression test. The Poisson’s ratio was experimentally determined using Digital Image Correlation (DIC), based on the movement of a randomly applied speckle pattern. With this comprehensive library of mechanical and morphological properties, we hope to contribute to the adoption of auxetic lattices within the field of orthopedics, as an ideal substitute for bone in life-lasting implants.

We will report a throughput electrical biosensing system to rapid assess the human health and environmental toxicity of nanoscale materials to find the kinetics of nanotoxicity at cellular level. In this project, we developed a unique biosensing system for analyzing nanotoxicity assays of gold, silver, cadmium oxide and carbon nanotubes nanomaterials. An array formatted electrical impedance sensing system was utilized to kinetically analyze the cytotoxicity of different sizes as well as different concentrations of the materials by measuring the resistance of each electrode as the cells attach simultaneously and in real-time, a critical feature in the monitoring of cytotoxicity. To further enhance our results, each electrode was deposited with a gold salt in order to improve the reproducibility of each electrode in monitoring the cell attachment. An electrical impedance measuring biosensor to perform cytotoxicity assays on human lung fibroblasts and rainbow trout gill epithelial cells is made. Several metallic nanoparticles, carbon nanotubes and graphene

We will report a throughput electrical biosensing system to rapid assess the human health and environmental toxicity of nanoscale materials to find the kinetics of nanotoxicity at cellular level. In this project, we developed a unique biosensing system for analyzing nanotoxicity assays of gold, silver, cadmium oxide and carbon nanotubes nanomaterials. An array formatted electrical impedance sensing system was utilized to kinetically analyze the cytotoxicity of different sizes as well as different concentrations of the materials by measuring the resistance of each electrode as the cells attach simultaneously and in real-time, a critical feature in the monitoring of cytotoxicity. To further enhance our results, each electrode was deposited with a gold salt in order to improve the reproducibility of each electrode in monitoring the cell attachment. An electrical impedance measuring biosensor to perform cytotoxicity assays on human lung fibroblasts and rainbow trout gill epithelial cells is made. Several metallic nanoparticles, carbon nanotubes and graphene
nanosheets are tested. This method provides shorter run times, easier performance and more precise results. By measuring the impedance change when cells attach to the electrodes on the biosensing chip, real time kinetic effects of toxicity of the various materials are recorded. The biological and physical characterization of nanotoxic effects of engineered nanomaterials using the biosensing chip will also provide an alternative approach for setting standards for assessing toxicities of other nanomaterials. This system was able to provide a more rapid, efficient and straightforward method of measurement compared to the current method of incorporating the nanoparticles into a cell culture directly.

Surface plasmon resonance (SPR) is a quantum electromagnetic phenomenon arising from the interaction of light with free electrons at a metal-dielectric interface. At a specific angle or wavelength of light, the photons energy is transferred to the excitation of the free electrons oscillation on the surface. The change in the refractive index (RI) is influenced by the analyte concentration in the medium in contact with the metal surface. SPR has been widely used for the detection of gaseous, liquid, or solid samples. In this study, the use of a novel SPR module (PhotonicSys SPR H5) was tested for the detection of the stroke biomarker N-terminal pro-brain natriuretic peptide (NT-proBNP). NT-proBNP is secreted from the heart in response to increase in diastolic pressure of the heart. NT-proBNP is proven to be a good biomarker for stroke diagnosis, with sensitivity >90% and specificity >80%. However, there is still a need for a new diagnostics technique, mainly addressing assay specificity and set up. The PhotonicSys SPR H5 system, is a miniature fast and portable system, which can be easily integrated with other instruments and used in the field; therefore, it is attractive as a point-of-care sensor. The novelty in the technology is that the SPR substrates and the reading methodology. The system provides self-referenced measurement to compensate for drifts and provide a stable measurement. NT-proBNP detection was tested with two different types of SPR substrates having different top interacting surfaces (Au and SiO2), in water, buffer and plasma samples. In addition, specific detection was done by bondied anti-NT-proBNP antibody onto the SPR substrate. NT-proBNP was detected in a range of clinically relevant concentrations for stroke, from 0.1ng/ml to 80ng/ml. The sensor demonstrated a clinically relevant limit-of-detection (LOD) of 0.1ng/ml. In the case of silicon oxide substrate, the RI showed an increasing pattern with increasing concentrations. However, in the case of the metal substrate (Au-Ag), the RI showed a decreasing pattern with increasing concentrations. More detailed explanation for the difference in the two patterns will be given by examining further the interaction of NT-proBNP with each surface.

Porous, Ultrasoft, Magnetically-Stimulated Membranes for Biomimicry and Biosensors via 3D Printer Scaffolding

We will report how porous, elastic, and biocompatible membranes can be made by combining sheets from soft dendritic colloids (SDCs) with a magnetically-responsive, 3D printed silicone scaffold. The resulting multilayer structures could be used as tissue matrix surrogate scaffolds in magnetically-actuated cyclic strain bioreactors. SDCs are a new class of polymer aerogel material characterized by a branched corona of nanofibers spread out in all directions. They are produced in a scalable polyelectrolyte precipitation process under intensive shear. Their fractal, hierarchical structure enables remarkable adhesion and networking properties, mimicking the contact splitting effect seen in gecko leg adhesion. We show that SDC nonwovens composed of a thermoplastic polyurethane can be fabricated into porous, nonwoven membranes with morphological features similar to that of the branched, fibrous architectures comprising physiological tissues such as lung tissue. The SDC membranes are ultrasoft, with controllable moduli of physiological softness that can mimic both soft, healthy tissue and stiffer, diseased tissues characterized by stiffened fibers resulting from pathologies such as cystic fibrosis. These SDC membranes, combined with a new method of 3D printing of magnetically-responsive silicone mesh scaffolds, allow modulated, cyclic actuation of the material to predetermined strain values. The inclusion of these ultrasoft, porous membranes in a magnetically-actuated bioreactor setup will allow their facile, untethered, long-term actuation during cell growth to determine the effects of the scaffold’s mechanical properties on cell proliferation and viability in vitro for toxicological and human performance evaluations.
Thermotropic, hydrophobic liquid crystal elastomers have significant advantages of facile patterning, a variety of available monomers, and well-studied elastomer chemistries. These patternable elastomers can undergo high amounts of actuation strain, but these strains are typically not realized below 100-200 C, as determined by the liquid crystalline phase transition. To lower this actuation temperature to near body temperature, we use a 2-click thiol-acrylate/thiol-ene chemistry to copolymerize mesogens with isotropic monomers, which can shift the transition temperature and resulting actuation temperature from 105 C to 28 C. This control of phase behavior enables liquid crystal elastomers which can morph in response to contact with skin or warm tap water. Additionally, these low-temperature elastomers can be 3D printed, allowing structural freedom which is unfeasible in many other liquid crystal elastomer chemistries.

Alternatively, we can synthesize gels which respond to aqueous stimuli, such as pH, by building hydrogels from chromonic liquid crystals. We have synthesized the first hydrogel from chromonic liquid crystals which can be orderted through surface alignment and copolymerized with responsive monomers. By controlling the crosslink density of the gel with non-polymerizable chromonic precursors, we can polymerize gels ranging from ~10 kPa to ~300 kPa. The modulus of the gel is ~2x stiffer along the axis of molecular alignment, which guides anisotropic actuation in response to temperature and pH. This control over crosslink density not only allows for control over the magnitude of shape change but also allows us to synthesize gels similar to soft tissues with anisotropic mechanical properties.

With these strategies, we have taken steps towards the use of liquid crystalline polymers in biological applications. Both liquid crystal elastomers and liquid crystal gels have been used as substrates for mammalian cell culture to confirm the biocompatibility of these materials. By controlling the molecular orientation of these ordered gels and elastomers, we can potentially affect cellular behavior both statically by anisotropic modulus and dynamically by temperature-based or pH-based actuation.

**Metabolite-Responsive Peptide Nanostructures**
Rain Ulijn1,2; Advanced Science Research Center, City University of New York, New York, New York, United States;
Department of Chemistry, Hunter College, New York, New York, United States.

Ligating systems derive their functions from the dynamic interactions of multiple components, they operate away from equilibrium, and rely on the continuous consumption of high energy metabolites (predominantly ATP) to sustain their existence. This differentiates living systems from synthetic materials, which are mostly static, simple in composition, and they do not consume energy to support their function. The active and multi-component properties of living matter gives rise to structures with rapid-response, selective and context-dependent dynamic functions that are currently not accessible to synthetic materials. The talk will cover our recent progress in the use of peptide ensembles to produce shape changing, metabolite consuming nanostructures. We will discuss: (i) our discovery approaches used to identify peptide ensembles which recognize metabolites, including ATP, (ii) the development of peptide ensembles with conformation-induced reactivity and (iii) the integration of modular functions of assembly, catalysis and metabolite recognition to form active materials.

**Nucleopeptide Assemblies Selectively Sequester ATP in Cancer Cells and Target Cell Nucleolus**
Huaimin Wang and Bing Xu; Brandeis University, Waltham, Massachusetts, United States.

Based on the recent near atomic structures of the PYRIN domain of ASC in the protein filament of inflamasomes, we rationally designed nucleopeptides to form supramolecular assemblies selectively sequester ATP in live cells and capable of delivery into cell nucleoli. We developed assemblies of nucleopeptides that selectively sequester ATP over ADP. Counteracting enzymes interconvert ATP and ADP to modulate the nanostructures formed by the nucleopeptides and the nucleotides. The nucleopeptides, sequestering ATP effectively in cells, slow down efflux pumps in multidrug resistant cancer cells, thus boosting the efficacy of doxorubicin, an anticancer drug. As the first example of assemblies of nucleopeptides that interact with ATP and disrupt intracellular ATP dynamics, this work illustrates the use of supramolecular assemblies to interact with small and essential biological molecules for controlling cell behavior. Moreover, the nucleopeptides accumulate preferentially at cell nucleolus, demonstrating the potential for nucleolus delivery for therapeutic benefits.

**STINGel—A Biomaterial-Based Drug Delivery Vehicle for Enhanced Cancer Immunotherapy**
David G. Leach1, Jeffrey Hartgerink1, Neeraja Dharmaraj2 and Simon Young2; Department of Chemistry, Rice University, Houston, Texas, United States; Department of Oral & Maxillofacial Surgery, University of Texas Health Science Center at Houston, Houston, Texas, United States.

Modern cancer treatment relies on the discovery and use of potent drug molecules, yet many drug therapies suffer from inefficient or unoptimized delivery methods, resulting in poor on-target efficacy and significant off-target effects. Our work focuses on the development of novel, biomaterial-based drug delivery vehicles that can be used to enhance the efficacy of existing therapies and treat challenging diseases such as cancer. Recent advancements in the field of immunotherapy have yielded encouraging results for the treatment of advanced cancers. For example, cyclic dinucleotides (CDNs) are a powerful new class of immunotherapy drugs known as STING (Stimulator of Interferon Genes) agonists, currently in clinical trials. However, previous studies of CDNs in murine cancer models have required multiple high dose injections, and improve survival only in relatively nonaggressive tumor models. Therefore, we are working to improve the efficacy of CDN immunotherapy by developing a novel biomaterial strategy we call “STINGel.” This was done through the use of Multidomain peptides (MDP) carrier vehicles, which can self-assemble into networks of nanofoamers that result in injectable hydrogels. Standard MDP hydrogels are biocompatible and can be loaded with various bioactive factors, facilitating cell growth in vitro and displaying complete cellular infiltration in vivo. This project studies the development of a delivery material to improve the efficacy of STING agonist anti-cancer immunotherapy, taking advantage of the charged domains of a lysine-based MDP hydrogel to achieve extended and localized drug release. STINGel has been shown to dramatically improve tumor survival over immunotherapy alone in a challenging murine cancer model, resulting in 6-fold higher survival after only a single intratumoral injection of CDN-loaded hydrogel. Continuing work seeks to develop second-generation delivery materials by synthesizing and studying new MDPs with different charge chemistries, and by characterizing their effects on drug release kinetics, immune response, and final tumor treatment efficacy. This project’s goals are to develop various new delivery biomaterials and better drug treatment methods, which will ultimately be translatable to the clinic.

### 11:30 AM *SM05.01.04*
**Self-Assembling Multidomain Peptide Nanofibers for Immunotherapy, Wound Healing and Other Biomedical Applications**
Jeffrey Hartgerink; Rice University, Houston, Texas, United States.

Multidomain Peptides (MDPs) are a class of self-assembling peptides which can form a nanofibrous gel under the proper environmental conditions which can be selected from...
cues such as pH and ionic strength. These hydrogels have convenient handling properties which allow them to be easily aspirated and subsequently delivered by syringe, even through exceptionally narrow-bore needles. Depending on the application, these hydrogel can be used loaded with small molecule drugs, proteins, cells or a combination of all these. However, the nanofibrous hydrogel can also be used unloaded where we have found that free of any bioactive agents it is rapidly infiltrated with cells in vivo and remodeled into highly vascularized tissue. One of the great advantages of MDPs are the ease with which they can be modified and tailored to a particular application. Over the past decade we have prepared over one hundred variants on this sequence and can now describe with confidence peptides that will assemble under acidic, basic and neutral pH, with or without complimentary salts and, most recently with and without charge on the nanofibers themselves. In this presentation I will discuss our general design criteria for self-assembling MDPs. I will also describe recent results related to their use in the treatment of a model of diabetic ulcers with and without bacterial infection. In this work we find that the innate regenerative ability of the hydrogel dramatically accelerates wound healing over a negative control as well as over a commercially available, and clinically prescribed, hydrogel. In a separate study I will describe the use of the MDP hydrogel as a small molecular delivery agent and compare it to commercially available hydrogels such as collagen, alginate, Matrigel and hyaluronic acid. Applying MDPs in a model of cancer immunotherapy we deliver a cyclic dinucleotide to dramatically improve the efficacy of this STING agonist in a challenging model of head and neck cancer.

Supramolecular Peptide Immunotherapies—Effect of Material Structure on Immune Phenotype Yaoying Wu, Sean Kelly, Lucas Shores and Joel Collier; Duke University, Durham, North Carolina, United States.

Supramolecular peptide immunotherapies are receiving interest in a range of settings, from infectious diseases to cancer to chronic inflammation. One of the chief advantages of these materials is that their modular construction makes it possible, in principle, to adjust the strength and phenotype of the immune responses raised in different settings. Immune phenotype can be controlled grossly by the co-delivery of adjuvanting molecules, but here we sought to determine how fine differences in the nanostructures of supramolecular peptide materials also influence the strength and character of the immune responses raised. In this talk, the effect of various nanostructural aspects of supramolecular peptide materials, including size, stability, surface charge, and epitope content will be discussed. This work compared multiple self-assembling peptide systems, including beta-sheet fibrillizing peptides and alpha-helical fibrillizing systems that could be engineered to form assemblies of varying size. In mice, smaller assemblies were more capable of cross-presentation to stimulate CD8+ T-cell responses than larger assemblies, and the helical system generated stronger antibody responses for poor B-cell epitopes, likely because these materials contained T-cell epitopes within their assembly domains. In sublingual vaccination (under the tongue), peptides and peptide assemblies were found to be generally non-immunogenic, even when delivered with sublingual adjuvants; however, the addition of oligoethylene glycol moieties to the materials enabled them to elicit surprisingly strong immune responses. The necessity of achieving a carefully controlled strength and phenotype of immune response will be highlighted in the context of active immunotherapies against inflammatory cytokines such as TNF and IL-17, for which these materials continue to be in active development.

2:00 PM Session SM05.02: Molecular Mechanism of Alzheimer's Disease—Towards Prevention and Cure

Zoya Leonenko1,2,3, 1Department of Biology, University of Waterloo, Waterloo, Ontario, Canada; 2Department of Physics and Astronomy, University of Waterloo, Waterloo, Ontario, Canada; 3Waterloo Institute for Nanotechnology, University of Waterloo, Waterloo, Ontario, Canada.

Alzheimer’s disease (AD) is a neurodegenerative disease characterized by dementia and memory loss for which no cure or prevention is available. Amyloid toxicity is a result of the non-specific interaction of toxic amyloid oligomers with the plasma membrane. We studied amyloid aggregation and interaction of amyloid beta (1-42) peptide with lipid membrane using atomic force microscopy (AFM), Kelvin probe force microscopy and surface Plasmon resonance (SPR). Using AFM-based atomic force force spectroscopy (AFS) we measured the binding forces between two single amyloid peptide molecules. We demonstrated that lipid membrane plays an active role in amyloid binding and toxicity: changes in membrane composition and properties increase amyloid binding and toxicity. Effect of lipid composition, the presence of cholesterol and melatonin are discussed. We discovered that membrane cholesterol creates nanoscale electrostatic domains which induce preferential binding of amyloid peptide, while membrane melatonin reduces amyloid-membrane interactions, protecting the membrane from amyloid attack. Using AFS we find that novel pseudo-peptide inhibitors SG effectively prevent amyloid-amyloid binding on a single molecule level and thus can potentially prevent amyloid toxicity. These findings contribute to better understanding molecular mechanism of Alzheimer's disease and aid into developments of novel strategies for cure and prevention of AD.

2:15 PM  Session SM05.02: Multidomain Peptide Hydrogel Accelerates Healing of Full-Thickness Wounds in Diabetic Mice

Nicole Carrejo, Amanda Moore, Tania Lopez Silva, David G. Leach, I-Che Li, Douglas Walker and Jeffrey Hartgerink; Rice University, Houston, Texas, United States.

Diabetes Mellitus is one of the most common metabolic disorders in the world, representing a significant health problem and economic issue. Approximately 15% of diabetic patients develop chronic wounds in their lower extremities due to complicating symptoms. Wounds in diabetic patients have relatively longer healing periods than normal wounds. Specifically, diabetic wounds exhibit delayed wound closure, prolonged inflammation, and are often infected with bacteria. The gold standard of treatment for diabetic patients with chronic wounds consists of debridement of the wound, infection control, offloading of weight, and patient education. Despite these efforts, chronic wounds frequently lead to amputation, an outcome that strongly motivates the development of new treatments. One approach to address these issues is to load cells, growth factors, or other biomolecules into scaffold materials to control release kinetics and achieve treatment localization. The difficulty here is the complex interplay between delivery material, diffusing soluble agents, and loaded cells. The wound healing process consists of a delicate sequential cascade of cell types and growth factors, and deviation from the proper sequence can adversely affect the
Many disease processes are driven by “undruggable” protein-protein interactions (PPIs) inside cells. In cancer, for example, tumor suppressor proteins are often inactivated by upregulation of their protein binding partners. Despite the promise of therapeutic peptides for disrupting PPIs, their delivery to and into cells remains a major obstacle to clinical translation. Peptides amphiphiles (PAs), a peptide conjugated to a hydrophobic tail, are one tool for facilitating intracellular peptide delivery. PAs self-assemble into micellar nanoparticles, protect peptides during delivery to diseased cells, and facilitate cell-uptake of peptides that would otherwise not be internalized. However, after internalization, PAs remain trapped in endosomes, which prevents them from reaching their cytoplasmic targets and reduces therapeutic efficacy. To facilitate their intracellular delivery, we have designed cleavable PAs to release therapeutic peptides after internalization and have explored strategies to facilitate their endosomal escape. We have explored this delivery system in two PPI systems frequently hijacked by cancer cells: the guardian of the genome (i.e. p53) and the gatekeepers of apoptosis (i.e. the BCL-2 family of proteins).

4:00 PM SM05.02.06
Self-Assembling Prodrugs Honggang Cui; Johns Hopkins University, Baltimore, Maryland, United States.

Covalent modification of a therapeutic agent represents an effective means to improve the drug’s pharmacokinetic profile for enhanced therapeutic outcomes. Incorporating the concept of molecular assembly into the prodrug design provides a new dimension for tailored synthesis of supramolecular medicine to address specific clinical needs. This self-assembling prodrug strategy uniquely and specifically exploits the self-assembling potential of therapeutic agents to achieve improved treatment efficacy. In this presentation, I will detail our rational design of monodisperse, amphiphilic anticancer drugs—which we term drug amphiphiles (DAs)—that can spontaneously associate into discrete, stable supramolecular nanostructures with a 100% drug loading. Our results suggest that formation of nanostructures provides protection for both the drug and the biodegradable linker from the external environment and offers a mechanism for controlled release.

4:15 PM SM05.02.07
Programmed Cell Death Instructed by Membrane-Interacting Supramolecular Assemblies Shantanu Sur1, Samuel Stupp2, Charlotte H. Chan3, Darren Sipes4 and Arielle Stoian1; 1Clarkson University, Potsdam, New York, United States; 2Northwestern University, Chicago, Illinois, United States.

The balance between charge and intermolecular hydrogen bonding is considered critical in determining the cellular effects of self-assembled peptide amphiphile (PA) materials. These two parameters have been tuned to induce cell membrane disruption, promote neuronal development, and amplify response to growth factors. To conjugate an alkyl tail at the C-terminus of the peptide in the PA, a lysine residue is commonly used as a linker. In this work, we show that the orientation of this lysine relative to the peptide chain and the alkyl tail plays an important role in determining PA’s ability to induce programmed cell death. When the alkyl tail is conjugated to the side chain amine of lysine linker, the resulting PA induced oncotic type of programmed death on cervical cancer cells, evidenced by loss of mitochondrial membrane potential, decrease in intracellular ATP level, and formation of giant blebs. Cell viability was rescued when the lysine orientation was reversed (the alkyl tail was attached to the primary amine) even though the nanostructure retained very similar morphology. Further investigation suggests that the oncosis could be triggered by an alteration in the cell membrane properties resulting from sequestration of cholesterol by membrane-associated PA nanofibers. Our results demonstrate how a subtle difference in the molecular design can be utilized to tailor the assembled nanostructure to elicit specific cell response.

4:30 PM SM05.02.08
Instructed-Assembly for Cell Morphogenesis and Mitochondrial Delivery Huiimin Wang, Hongjian He, Zhaoqianqi Feng and Bing Xu; Brandeis University, Waltham, Massachusetts, United States.

Context-dependent signaling, as a ubiquitous phenomenon in nature, is a dynamic molecular process at nano- and microscales, but how to mimic its essence using non-covalent synthesis in cellular environment has yet to be developed. Here we discuss two examples of instructed-assembly (iA) of a supramolecular phosphoglycopeptide (sPGP) as context-dependent signals for morphogenesis of cells; (2) enzymatic morphology/phase transition of isopeptides effectively delivery cargos to mitochondria in a cell selective manner. In the first case, while enzymes (i.e., ectophosphatasases) on cancer cells catalyze the formation of the filaments of the sPGP to result in cell death, damping the enzyme activity induces 3D cell spheroids. Similarly, relying on the ratio of stromal and cancer cells in a co-culture to modulate the expression of the ectophosphatase, the iA process enables cell spheroids. The spheroids act as a mimic of tumor microenvironment for drug screening. In the second case, consisting of DYKDDDDK (Flag, a substrate of enterokinase (ENTK)) as the branch and a phenylalanine rich short peptide as the backbone, the isopeptides (Mito-Flag) form micelles, which, upon the cleavage of the Flag catalyzed by ENTK, turn into a gel made of nanofibers. Entering cells mainly via clathrin mediated endocytosis, the micelles interact with the mitochondria having ENTK and high membrane potential. The mitochondrial ENTK cleaves the Flag of the isopeptides, thus turning the micelles to nanoparticles on the mitochondria. Mixing the Mito-Flags and cargos (drug molecules, proteins, and genes) allows the selective delivery of the cargos into mitochondria of cancer cells. These results provides a new way to control cell fates and to target organelles for biomedicine.
SESSION SM05.03: Poster Session: Supramolecular Biomaterials for Regenerative Medicine and Drug Delivery
Session Chairs: Eric Appel, Honggang Cui, Patricia Dankers and Matthew Webber
Tuesday Afternoon, April 23, 2019
5:00 PM - 7:00 PM
PCC North, 300 Level, Exhibit Hall C-E

SM05.03.01
A Lipid Raft Modified Multifunctional Nano Gene Delivery System in Brain Targeting
Wei Wang1, Jianping Wang1, Qilong Wang1, Xia Cao1,2, Ximing Xu1 and Jiangnan Yu1
1 School of Pharmacy, Jiangsu University, Zhenjiang, China1, 2 Renal, Harvard medical school, Cambridge, Massachusetts, United States.

Glioma has become an extremely hazardous intracranial malignant tumor due to its high degree of malignancy and invasive growth, and there is no efficient way for therapy. Lipid rafts (LR) was discovered in the study of the biological membrane structure of a niche structure with special functions, and which could be an effective target for the antitumor agent in numerous malignancies. Here, we report a multi-functional nano-gene delivery system (MNDs), which wrapped carbon quantum dots and DNA in blood cell membrane and modified with lipid rafts sourced from U251 cells. The morphology of MNDS is characterized by SEM, TEM, and DLS, which showed that the modified MNDS had coated with lipid raft, and spherical size is around 100 nm. Compared with normal fibroblast, the results of in vitro had confirmed that LR modified MNDS could effectively target to U251. Besides, the modified MNDS can validly target brain sites after tail vein injection, which means the MNDS could successfully penetrate the blood-brain-barrier (BBB) in vivo. This new delivery system could potentially provide a new tragic for glioma differentiation, which could a new method for the therapy of cerebral disease therapy.

SM05.03.02
Coassembly of Enantiomeric Peptides Inside Mitochondria for Cancer Therapy
Ja-Hyoung Ryu; UNIST, Ulsan, Korea (the Republic of).

Homochiral assembly of amphiphilic peptides consisting either D- or L-enantiomers inside the living cells are emerging as an attractive strategy for different biological implications including therapeutic. However, less attention is given for the heterochiral assembly of peptides consisting both D- and L-isomers. Homochiral assembly containing both D- and L-isomers (racemates) could create wonders in their biological impact since the assembly of racemates often results in altered properties compared with enantiomers such as faster kinetics, higher mechanical strength and enzymatic stability. In here, we have monitored altered morphological and biological properties of a short peptide amphiphile, Mito-FF upon their co-assembly with mirror pair, Mito-ff. Mito-FF is an intra mitochondrial self-assembling peptide amphiphile, which induce cancer cell apoptosis followed by mitochondrial damage upon co-assembly inside mitochondrial fibrillation. Mito-FF upon co-assembly with Mito-ff induced thick fibrous bundle of diameter upto 100 nm, while enantiomers form fiber of diameter – 10 nm. The co-administration of Mito-FF and Mito-ff in the cell induced drastic mitochondrial disruption than enantiomers both in vitro and in vivo as a result of intra mitochondrial racemic co-assembly to form thicker Mito-rae fibrous bundles.

SM05.03.03
Receptor-Targeting Protein Nanocarriers for Potential Chemotherapy of Non-Muscle-Invasive Bladder Cancer
Ja Zhang, Mullapudi Sneha Sree, Juwita Rahmat, Ratha Mahendran, En-Tang Kang, Edmund Chiong and Koos Gee Nee; National University of Singapore, Singapore, Singapore.

Bladder cancer is the costliest cancer to treat, requiring long-term follow-up and repeat interventions, because almost 70% of patients with non-muscle-invasive disease will develop tumor recurrence, and about 25% will progress to the muscle invasive stage. One of the major shortcomings associated with current intravesical chemotherapy is the short residence time of the drug in the bladder since much of it is lost upon the first voiding of urine. Our research focus is on the development of protein drug nanocarriers in the form of albumin molecules (~6 nm) and nanoparticles (~100 nm) that can target and be readily taken in by tumor cells via targeting receptors that are highly expressed on bladder cancer cells. Peptides that target fibroblast growth receptor 3 (FGFR3), epidermal growth factor receptor (EGFR) and CD47 on human bladder tumor cells were designed and the uptake of these peptides by bladder cancer cells was investigated. The uptake of the peptide targeting CD47 was the highest followed by those targeting EGFR and FGFR3. Thus, our subsequent drug delivery study centered on protein nanocarriers conjugated with the CD47-targeting peptide, and loaded with drugs commonly used for non-muscle invasive bladder cancer therapy. Our in vitro experiments showed that within the exposure time expected for intravesical therapy (2 h), the killing of bladder cancer cells treated with these receptor-targeting drug-loaded nanocarriers was significantly enhanced (drug IC50 reduced by a factor of ~3 to >10) compared to the free drug or the drug-loaded non-functionalized nanocarriers. Thus, CD47-targeting drug-loaded protein nanocarriers are a promising candidate for intravesical chemotherapy against non-muscle-invasive bladder cancer.

SM05.03.04
Polymer Nanoparticle-Based Combination Therapy for the Treatment of Multi-Drug Resistant Bacteria and Biofilm Infections
Akash Gupta, Jessa Makabenta, Cheng-Hsuan Li, Ryan Landis, Friederike Schlüter and Vincent M. Rotello; University of Massachusetts Amherst, Amherst, Massachusetts, United States.

The emergence of drug-resistance among pathogenic bacteria constitutes one of the paramount challenges to the human health worldwide. This threat is further exacerbated by biofilm-associated infections that are even more challenging to treat. Conventional antibiotic-therapies are ineffective due to their inability to penetrate biofilm matrix coupled with the rapidly growing number of antibiotic-resistant strains. Host-defence peptide mimicking synthetic polymeric have emerged as promising novel antimicrobials that can disrupt the microbial membrane and readily penetrate biofilm matrix. However, their lack of specificity towards mammalian hosts limits their widespread therapeutic application. Here, we report synergistic antimicrobial therapy using engineered polymeric nanoparticles with colistin antibiotic for combating MDR bacterial and biofilm infections. We observed an 8-16-fold decrease in antibiotic dosage in presence of polymeric nanoparticles to combat planktonic cells and eradicate pre-formed biofilms of multiple MDR species. The synergy observed on planktonic bacteria was attributed to the ability of NPs at (sub-lethal concentrations) to create small pores on bacterial membrane that increased influx of antibiotics inside the microbes. Moreover, antibiotic accumulation inside biofilms increased by ~3.5 times in presence of NPs, resulting in a synergistic effect to kill the constituent microbes. Overall, this strategy demonstrates the ability of polymeric NPs to minimize the side-effects caused by high doses of ‘lethal’ antibiotics while simultaneously rejuvenating the antibiotics rendered ineffective due to development of drug-resistance in bacteria.

SM05.03.05
Spatially Controlled Bioorthogonal Catalysis for Imaging and Drug Delivery
Riddha Das, Akash Gupta, Ryan Landis, Golen Y. Tonga and Vincent M. Rotello; University of Massachusetts Amherst, Amherst, Massachusetts, United States.

Bioorthogonal transformation of prodrugs and profluorophores using transition metal catalysts (TMC) offers a promising strategy for imaging and therapeutic applications. However, maintaining activity and controlling the localization of TMCs make their use in biomedical applications challenging. Here we report the engineering of nanoparticles of gold nanoparticles (AuNPs) with encapsulated TMCs (nanozymes) to provide specific intra- and extracellular localization. We used membrane-penetrating cationic nanoparticles for catalysis inside and ‘stealth’ zwitterionic particles to limit catalysis to outside of mammalian cells. Specific localization of nanozyme activity was demonstrated through bioorthogonal activation of profluorophores inside biofilms demonstrating potential for early detection of biofilm-associated infections. Taken together, these studies demonstrate a new level of spatial control for TMC-mediated bioorthogonal catalysis for diagnostic and therapeutic purposes.

SM05.03.06
Nerve/Osteoblast/Endothelium Multicellular System Based on Ultralong Hydroxyapatite Nanowires/Cellulose Multifunctional Biological Paper Promotes Bone Regeneration
Feng Liu; Crystal Materials Institute, Shandong University, Jinan, China.

Large segmental bone defect is a common clinical disease, which frequently leads to lifelong disability and seriously affect the quality of life of patients. Clinical transplantation of some bioactive scaffold materials has been applied to the treatment of bone defect. However, it remained a big challenge due to safety and efficacy concerns as well as the prohibitive cost. In general, severe bone injury is always accompanied by vascular injury and nerve injury, which still is a serious clinical challenge. Therefore, the new strategy is
not only to design a simple acellular biological scaffold, but also to construct a multicellular system to induce cell proliferation and differentiation, which can significantly accelerate tissue regeneration. As a bone component, hydroxyapatite is a common bioactive material, which is often applied in the repair of bone defects. Herein, we synthesized ultralong hydroxyapatite nanowires (>100 μm) and then prepared hydroxyapatite-cellulose flexible multifunctional biopaper. Growth factor bone morphogenetic protein (2-BMP-2) and nerve growth factor (NGF) were loaded in different areas of the paper. Adipose derived stem cells, endothelial cells and neural stem cells were seeded on different areas by cell printing technology. Along with the long-term release of growth factors, the induced cells were successfully differentiated into osteoblasts and nerve cells, which significantly promoted bone repair. This method provides a promising strategy for bone regeneration and bone tissue construction in vitro.

SM05.03.07
Jet Printing Organic Cocrystals from the Vapor Phase Siddharth Borsadia and Max Shtein; Materials Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States.

Nearly half of newly discovered active pharmaceutical ingredients (APIs) suffer from poor dissolution in water. After finding a successful “hit” using high throughput screening methodologies, many promising APIs must undergo subsequent chemical modification to improve the dissolution behavior. Pharmaceutical cocrystals are of growing interest as a means of controlling the release of an active pharmaceutical ingredient (API) without modifying its molecular structure. Pharmaceutical cocrystals are typically defined as a combination of two organic compounds in solid form, held together by hydrogen bonds and simple stochiometries (e.g., 1:1, 1:2, etc. molar ratios) of API and coformer. By choosing an appropriate coformer, the dissolution behavior of the API (i.e. its concentration over time) can be controlled and even enhanced significantly over the pure form and can have many functional advantages. Current methods of creating pharmaceutical cocrystals, however, are limited by the necessity for a liquid solvent during synthesis, required post-processing, and compatible delivery methods. We have developed a novel, solvent-free method for synthesizing organic cocrystals. The method, organic vapor cocrystalization (OVCC), involves subliming the API and coformer into a carrier gas, followed by jetting the gas mixture onto a temperature-controlled substrate, where the organic materials condense to form the cocrystal film. As proof of concept, we demonstrate for the first time the synthesis of the cocrystal system of caffeine and succinic acid, whose isolation has not been previously obtained by conventional methods. X-ray diffraction and differential scanning calorimetry are used to confirm the presence of the cocrystal phase, while scanning electron microscope studies show that the cocrystal forms an elongated morphology comprised of long needles, whose length and orientation depend on process parameters. Because a liquid solvent is not needed, OVCC opens the door to new cocrystal systems and printing applications. The new OVCC process enables excellent process control and automation, and automation is highly scalable for the manufacturability of cocrystal products.

SM05.03.08
Encapsulation of Flavonoids and Triterpenoids Extracted from Cranberries in Peptide-Based Spheres Yasaman Hamedani, Catherine Neto, Milana Vasudev and Elvira Lou E. Evangelisti; University of Massachusetts Dartmouth, Dartmouth, Massachusetts, United States.

Nanoscale technologies and its applications in medicine for disease diagnosis, treatment and prevention, has gained considerable attention during the past decade. Nanomaterials have been widely used in drug delivery systems as nanotubes, nanomachines, nanofibers and nanomembranes since they can mimic or alter biological processes. Nanospheres have been widely investigated as transport vehicles due to the ease and efficiency of uptake in the cells. Peptide-based carriers are a promising candidate for drug delivery due to ease of synthesis via self-assembly, biocompatibility, biodegradability, and tuneable chemical structures. Such peptide-based nanospheres have the potential to be targeted for a specific organ as well as increasing the half-life in systemic circulation, enhancing bioavailability, improved retention time of the therapeutic molecules and intracellular penetration. In this study, the fabrication of peptide-based nanospheres by electrospinning technique have been demonstrated, and their potential as carriers for targeted delivery of cranberry extracted flavonoids such as proanthocyanidins, and triterpenoids such as quercetin and urso acid have been evaluated. For this purpose, triphenylalanine nanospheres containing the drugs have been fabricated using a coaxial electrospinning set-up. Probiotic bacteria such as L. acidophilus, L. casei and Akkermansia were also encapsulated in such micro-carriers to improve their viability in the gut and intestinal tract. The effect of encapsulation of bacteria in stimuli-responsive peptide-based carriers, which can assist with on-demand release and the co-encapsulation of proanthocyanidins and triterpenoids was studied to understand their influence on bacterial cell survivability. The self-assembly and secondary structure of the fabricated tripeptide spheres have been analyzed through SEM, FTIR, Raman and CD analysis. The morphology and chemical structure of drug and bacteria enclosed carriers have also been characterized. The nanospheres carriers have then been modified to be targeted specifically for colon cancer. The efficiency of the carriers was analyzed by observing the release behavior of each of the drugs with and without post crosslinking treatment. The extent of their delivery to cells and their influence on reduction in tumor cell proliferation has been analyzed. 

SM05.03.09
Fluorophilic-Lipophilic-Hydrophilic Poly-2-Oxazolines Block Copolymers as MRI Contrast Agents—From Synthesis to Self-Assembly Sergey Filipov1,2, Leonid Kabervo1, Bart Verbraeken1 and Richard Hoogenboom1; 1Harvard University, Cambridge, Massachusetts, United States; 2Institute of Macromolecular Chemistry, Prague, Czechia; 1Department of Organic and Macromolecular Chemistry, Ghent University, Ghent, Belgium.

This work focused on the synthesis and self-assembly of triphilic poly(2-oxazoline) triblock copolymers with high fluorine content towards our future aim of developing poly(2-oxazoline) MRI contrast agents. A highly fluorinated 2-substituted-2-oxazoline monomer, namely 2-(1H,1H,2H,2H-perfluorooctyl)-2-oxazoline was synthesized using the Grignard reaction. The polymerization kinetics of the synthesized monomer was studied and it was used for the preparation of triblock copolymers with hydrophilic 2-methyl-2-oxazoline, hydrophobic 2-ethyl-2-oxazoline and fluorophilic blocks by Cationic Ring-Opening Polymerization yielding polymer with low relatively dispersity (1.2-1.4). The presence of the blocks with the different nature in one copolymer structure facilitated self-assembly of the copolymers in water and dimethylsulfoxide as observed by dynamic light scattering, rytension transmission electron microscopy, and small-angle neutron scattering. The nanoparticle morphology is strongly influenced by the order and length of each block and the nature of solvent, leading to nanoparticles with core-shell structure as confirmed by small angle neutron scattering. The reported poly(2-oxazoline) block copolymers with high fluorine content have high potential for future development of MRI contrast agents.

SM05.03.10
A Bioinspired Platform to Deliver Neurotrophins to the Central Nervous System for Neural Regeneration Duo Xu and Yunfeng Lu; University of California, Los Angeles, Los Angeles, California, United States.

The central nervous system (CNS) plays a central role in the control of sensory and motor functions, and the disruption of its barriers can result in severe and debilitating neurological disorders. Neurotrophins are promising therapeutic agents for neural regeneration in the damaged CNS. However, their penetration across the blood–brain barrier remains a formidable challenge, representing a bottleneck for brain and spinal cord therapy. We developed a nanocapsule–based delivery system that enables intravenously injected nerve growth factor (NGF) to enter the CNS in healthy mice and non-human primate. The encapsulation of NGF is achieved by in situ polymerization, which grows a thin layer of polymer around individual NGF molecules, forming NGF nanocapsules. These nanocapsules can efficiently penetrate the blood–brain barrier and enter the CNS after intravenous administration via the endogenous neurotransmitter transport pathway. In pathological conditions, the delivery of NGF enables neural regeneration, tissue remodeling, and functional recovery in mice with spinal cord injury. This technology can be utilized to deliver other neurotrophins and growth factors to the CNS, opening a new avenue for tissue engineering and the treatment of CNS disorders and neurodegenerative diseases.

SM05.03.11
Supramolecular Polymeric Chemotherapy Based on cucurbit[7]uril-PEG Copolymer Hao Chen1, Yueyue Chen2, Han Wu1, Jiang-Fei Xu1, Zhiwei Sun1, Zhiwei Sun1, Xu Zhang3, Tianyi University, Beijing, China; 2Capital Medical University, Beijing, China.

For combining the advantages of supramolecular chemotherapy and polymer therapeutics, we developed a new strategy of supramolecular polymeric chemotherapy based on a water-soluble polymer (poly-CB[7]), with cucurbit[7]uril (CB[7]) embedded in its PEG backbone. A supramolecular polymeric complex was fabricated from poly-CB[7] and oxaliplatin, a typical anticancer drug, and displayed lower cytotoxicity to normal cells than oxaliplatin. In addition, the cytotoxicity of the oxaliplatin could be restored through competitive replacement of oxaliplatin from CB[7] cavity by spermine, which is overexpressed in the microenvironment of cancer cells. Interestingly, compared with pristine
oxaliplatin, the supramolecular polymeric complex showed higher cytotoxicity to cancer cells. The enhanced cytotoxicity may result from a combined effect of the release of oxaliplatin and the decrease of sperm in the microenvironment, as sperm is essential for cell growth and proliferation. Besides, the supramolecular polymeric complex also prevailed the pristine oxaliplatin on the long circulation performance in vivo. Therefore, by the interplay of polymer chemistry and supramolecular chemistry, the fusion of stability and adaptivity could be achieved, which may open new horizons for supramolecular chemotherapy.

SM05.03.12
pH-Induced Charge-Reversal Amphiphile with Cancer Cell-Selective Membrane-Disrupting Activity Yincheng Chang, Jiang-Fei Xu and Xi Zhang; Tsinghua University, Beijing, China.

Supramolecular chemotherapy aims to employ supramolecular chemistry to reduce cytotoxicity of cancer chemotherapy agents. To this end, a charge-reversal amphiphile exhibiting charge conversion from negative to positive induced by pH is designed. It selectively kills cancer cells through cell membrane disruption. This amphiphile comprising an alkyl chain and anionic headgroup of acid-labile β-carboxylic amide (C16N-DCA) was prepared. In the microenvironment of normal cells with pH 7.4, the negatively charged C16N-DCA exhibited considerably reduced cytotoxicity. However, in the acidic microenvironment of cancer cells with pH 6.5-6.8, the headgroup charge of C16N-DCA changed from negative to positive under hydrolysis of the acid-labile amide group. As a result, the generated cationic amphiphile displayed significant killing of cancer cells by disrupting their cell membranes. This strategy of supramolecular chemotherapy with concise design represents a new route of chemotherapy for anticancer strategies.

SM05.03.13
Multifunctional β-Cyclodextrin Macrocrosslinker-Based Self-Healable Hydrogels Showing High Mechanical Strength, Enhanced Stability and pH Responsiveness for Drug Delivery Daham Jeong, Chul-gu Kim, Yohan Kim, Seonmok Kim and Seunho Jung; Department of Bioscience and Biotechnology, Konkuk University, Seoul, Korea (the Republic of).

A novel multifunctional β-cyclodextrin macrocrosslinker-based self-healable hydrogel is developed by crosslinking β-cyclodextrin oligomer allyl ether (C[βCD–OM]AE), a β-cyclodextrin oligomer with allyl groups and quaternary ammonium groups formed from chlorohydrin and another epoxide, with adnamously guest units and acryl acid moieties. The covalent bonds between the allyl groups and hydrogel backbones are designed to increase the stability of supramolecular hydrogels without losing their self-repairing attribute by introducing a macrocrosslinker concept. This new hydrogel shows a trebling in the storage modulus and a high tensile strain up to 1590%. The tensile strength of the C[βCD–OM]AE@Ad hydrogel is more than double that of the monomeric βC hydrogel without cationic groups. The volume magnitude of the C[βCD–OM]AE@Ad hydrogel can be stably changed by swelling, and it can be expanded more than eight times on a shift in the pH from 1.2 to 7.4. In addition, the hydrogel shows good cytocompatibility. The C[βCD–OM]AE@Ad hydrogel also showed ibuprofen sustained-release property depending on the pH. This multifunctional βCD macrocrosslinker-based self-healable hydrogel designed to combine chemical links, the host–guest interactions of macrocrosslinkers, and electrostatic attractions could provide good stability, improved mechanical strength, and beneficial self-healing performances for further applications in a wide variety of fields, including biomedicine.

SM05.03.14
Aggar -Serin Blend Antioxidant Hydrogel Dressing for Chronic Wounds Suhela I. Tyeb1, Nitesh Kumar2, Ashok Kumar1 and Vivek Verma1; 1Biological Sciences and Bioengineering, Indian Institute of Technology Kanpur, Kanpur, India; 2Materials Science and Engineering, Indian Institute of Technology Kanpur, Kanpur, India.

Chronic wounds are difficult to heal and results in morbidity and economic burden on the patient. Hallmark of these wounds are prolonged inflammatory phase, poor collagen production, hampered angiogenesis, upregulation in reactive oxygen species (ROS) and matrix metalloproteases. In order to achieve good healing, it is desirable to address as many of the aforementioned issues as possible. Aggar-based hydrogels show the potential application as wound dressings owing to their high moisture retention, cytocompatibility, ease of fabrication, availability of raw materials and cost effectiveness. However, they do not exhibit substantial antioxidant property and enhancement in collagen production that are required in wound dressing materials for chronic wounds.

In this work, flexible agar-based hydrogel films were fabricated via solvent casting method. These films were incorporated with sericin protein to enhance the antioxidant property of dressing materials. These films showed an improvement in antioxidant property and collagen production that are required in wound dressing materials for chronic wounds.

Electrospinning is a versatile technique for producing composite micro-/nano-fibers from various functional materials. The properties of electrospray nanofiber membranes provide many versatile elements that can be excellent resources for biomedical applications, such as drug delivery, tissue engineering and wound healing. In addition, coaxial electrospinning produces core/sheath fibers that provides even more advanced features, such as (a) independent combination of two or more functional materials; (b) encapsulating functional molecules and their controlled release; (c) protection of incorporated drugs from the outer environment. In the initial stages of applying electrospinning fibers in the biomedical area, core/sheath fibers enabled the incorporation of two separate polymers into a single fiber in order to combine good mechanical properties from synthetic polymers and cell biocompatibility from biomaterials. In the past decade, coaxial electrospinning has become one of most popular techniques for developing novel drug delivery vehicles, enabling the controlled and sustained release of the drug from the fiber core. Moreover, multiple drugs can be individually incorporated into either the core or sheath layers (or both layers) enabling synergistic effect from two or more different drugs.

Moving beyond sustained release, “on-demand” release triggered by external stimuli has emerged recently. In this report, we present on-demand triggered release using stimuli-responsive materials, such as self-immolative polymer (SIP) and pH-responsive Eudragit polymers. We also introduce bio-responsive SMART nanofiber membranes for developing non-hormonal contraceptive devices. For triggered release by external stimuli, we have produced nanofibers with SIP in the sheath encapsulating core materials. In the absence of stimulus, no drug release is observed, whereas abrupt core release was observed upon SIP depolymerization is triggered by external stimuli. Controlled multi-pH response has also been demonstrated using core/sheath fibers made of two different Eudragit polymers. Core-sheath fibers made of Eudragit L 100 (EL100) core and Eudragit S 100 (ES100) sheath provide three-phase responses depending on environmental pH within physiological range. At pH < 5, no release was observed from either core or sheath layer. At pH within 5-6 range, while release from the sheath is minimal, the controlled release from the core can be obtained by adjusting the sheath thickness. For pH > 6, all core and sheath materials are quickly released. This three-phase responses within physiological range is very useful for targeted drug delivery in because the environment in human organs has different pH values. For all cases, due to the high surface-to-volume ratio of nanofiber membranes, their response rates to external stimuli or environmental pH is much quicker (> 25 x) than that of the cast film equivalent. Finally, we will introduce bio-responsive nanofiber devices for the contraceptive application without using any hormonal agent. The fiber device is made of HPMC and Carbopol 974P composite polymers. HPMC provides a mucoadhesive and highly viscous hydrogel network and Carbopol polymers provide the pH buffering capacity with high viscosity. Upon contact with seminal fluid (pH ~ 8), HPMC/Carbopol nanofiber membranes convert into hydrogel, providing a physical barrier by swelling, with a low pH value of ~4, which acts as a spermicidal agent. This non-hormonal bio-responsive contraceptive device is highly attractive for women’s health, providing excellent spermicidal performance without affecting user’s hormonal conditions.

Adorption Kinetics of Methylene Blue in Biocompatible Hydrogels for Drug Delivery Systems

Lucas Ribeiro, Renata Lang Sala and Emerson Rodrigues de Camargo; Chemistry, Federal University of Sao Carlos, Sao Carlos, Brazil.

The study of biomaterials based on injectable hydrogels has increased over the past years due to their potential medical application in non-invasive treatments for tissue engineering and drug delivery systems. These hydrogels can be adjusted to deliver drugs in vivo for long periods without activating the immune system. Thromsensitive hydrogels, as poly[N-vinylcaprolactam] (PNVCL), when heated above a determined temperature (called lower critical solution temperature, LCST) change from a state where the chains are swollen in an aqueous medium (by hydrophilic interactions) to a state in which they self-aggregate by predominant hydrophobic interactions [1]. In this transition, hydrogen bonds between the polymer chains and the water molecules break and the hydrogel aggregates expelling these molecules, creating a phase separation. By understanding the physicochemical aspects of the swelling-collapse transition, it is possible to evaluate the suitability of PNVCL as smart delivery systems [2]. PNVCL is biocompatible, facilitating its use as a biomaterial. In this way, PNVCL was synthesized by radical polymerization in the presence of azobisobutyronitrile (AIBN) initiator, dimethyl sulfoxide (DMSO) as solvent, for 4 h at 70 °C and N2 atmosphere. The hydrogel was purified using dialysis membrane to remove DMSO and monomers unreacted. The LCST and energies involved during the swollen to aggregate states were calculated from the analysis of a PNVCL aqueous suspension (1% m/v) by UV-vis spectrophotometry. The material changes from a transparent system to opaque when heated, allowing to be studied by its transmittance in different temperatures. The polymers synthesized showed a LCST of 33.6 °C, which results in the gel formation in the body temperature. The calculated enthalpy and entropy changes during the phase transition were 6000 kJ mol-1 and 20 kJ K-1 mol-1, respectively. The FTIR spectrum of PNVCL showed bands relatives to the functional groups C=O (1617 cm-1), C-H (2930 cm-1) and water adsorbed by the amide cyclic group (3300 cm-1). For applications as a drug delivery system, the hydrogels capacity to adsorb drugs was evaluated by varying the concentration of Methylene blue-MB (5, 10, 25, 50, 100 e 200 ppm). In this study, methylene blue was used as a model for hydrophobic drugs, which are usually difficult to be released in a controlled manner by hydrogels with a typical hydrophilic character. The advantage of PNVCL comes from its amphiphilicity, which hydrophobic groups interact with the medium and the hydrophobic chains agglomerated above LCST interact with the drug. PNVCL suspensions (5% m/v) in the presence of MB were heated at 37 °C for 5 min, centrifuged and the supernatant was measured by UV-vis spectrophotometry. Two adsorption mechanisms were tested: Langmuir and Freundlich. The best model fitted was Freundlich, which can be used to describe non-ideal systems with heterogeneous surface. The amount of dye adsorbed varying the PNVCL concentration (5,10 and 20% m/v) was also studied. The adsorption of 50 ppm MB was up to 40% and increased linearly with polymer concentration. Thereby, PNVCL can be a suitable injectable delivery system for hydrophobic drugs with different concentrations.

Mesoporous Nanoparticles for Drug Delivery Applications

Shahjahan K. Chowdury1, SeungHyun Park1, Yong-il Park1 and Won Hyung Ryu2; 1Department of Advanced Material Science and Engineering, Kumoh National Institute of Technology, Gyeongbuk, Korea (the Republic of); 2School of Mechanical Engineering, Yonsei University, Seoul, Korea (the Republic of).

Recently, there have been increasing interests in mesoporous silica especially in the field of controlled drug delivery. It is increasingly important to control the degree of bioactivity and rate of bigradation of such mesoporous silica. In this study, mesoporous silica nanorods were obtained by filling the precursor sol derived from tetraethyloxysilicate(TEOS) into the columnar pores (20 nm – 200 nm) of anodic aluminum oxide (AAO) substrate, and their drug-performance were investigated. In addition, in order to use in intracranial drug delivery system, paramagnetic mesoporous nanoparticles having SPION (superparamagnetic iron oxide nanoparticle) cores were also fabricated by coating SPION nanoparticles with the same silica precursor sol which was used for the fabrication of the mesoporous silica nanorods. The porosity and biodegradation kinetics of the fabricated mesoporous nanorods and magnetic nanoparticles were analyzed using SEM, TEM, XRD, FTIR. The performance of the mesoporous silica nanorods as drug delivery carrier and intraocular drug delivery efficiency of the fabricated magnetic nanoparticles were evaluated.
Highly Functionalised Water-Soluble Fullerene Derivatives—Cage Size Affects Hierarchical Self-Assembled Structures

The natural extracellular matrix (ECM) is a highly dynamic, supramolecular structure composed of various bioactive molecules held together by specific interactions. The ECM directly interacts with cells and dictates cell behavior to a large extent. Our goal is to synthetically mimic this intricate natural system using supramolecular materials based on hydrogen bonding units. The dynamics of the supramolecular system is shown to be important in the presentation of bioactive epitopes to cells. By design, highly dynamic supramolecular fibrous particles decorated with cell adhesive RGD motifs were made and studied in solution. It was shown that these soluble particles interact with the cell surface, and that the dynamics of bioactive presentation is dependent on the method of supramolecular incorporation. Transient networks and hydrogels composed of similar molecules were shown to have slowed down dynamics, compared to the particles in solution. These hydrogels, when formulated in the right way, were able to enhance cell viability and adhesion. When highly robust solid materials were made using the same supramolecular motif, cell adhesion and migration could be tuned. However, the ECM displays a plethora of bioactive peptide signals. Therefore, a high throughput screening approach was taken using a design of experiments set up, to investigate a library of natural ECM proteins as coatings, and a synthetic library of ECM peptides supramolecularly incorporated as additives in the base material. It was found that the several sequences and/or combinations outperformed others, showing the importance of the high throughput screening approach. The proposal that both the dynamics and presentation of bioactive sequence determines cell behavior is currently being investigated. In this way we aim to make steps towards the design of a synthetic ECM analogue.

Dissipative Supramolecular Materials with a Tunable Lifetime

Most biological materials exist in non-equilibrium states driven by the irreversible consumption of high-energy molecules like ATP or GTP. These energy-dissipating structures display a plethora of bioactive peptide signals. Therefore, a high throughput screening approach was taken using a design of experiments set up, to investigate a library of natural ECM proteins as coatings, and a synthetic library of ECM peptides supramolecularly incorporated as additives in the base material. It was found that the several sequences and/or combinations outperformed others, showing the importance of the high throughput screening approach. The proposal that both the dynamics and presentation of bioactive sequence determines cell behavior is currently being investigated. In this way we aim to make steps towards the design of a synthetic ECM analogue.

Dissipative Supramolecular Materials with a Tunable Lifetime

Most biological materials exist in non-equilibrium states driven by the irreversible consumption of high-energy molecules like ATP or GTP. These energy-dissipating structures are governed by the kinetics of energy dissipation. They are thus endowed with unique properties which include spatiotemporal control over their presence, the ability to repair damage or the ability to form higher-order structures driven by reaction-diffusion fronts. Most of these properties would be desirable in human-made materials.

We and others have thus set out to explore the use of dissipative self-assembly for the use of supramolecular (bio)-materials.[1-7] In this work, we will design criteria for dissipative supramolecular materials. I will focus on our recently described system and its application as a vehicle that can control cellular uptake, or deliver drugs.

Macromolecular Therapeutics

Multi-drug resistant diseases are one of the biggest challenges society is facing in the domain of healthcare. Contraction of a multi-drug resistant disease, whether through a microbial infection or the loss of chemotherapeutic effectiveness, results in an extremely poor patient prognosis given the severely limited treatment options. The rapid resistance development in microbes, for instance, has completely eviscerated the current antimicrobial drug pipeline. The resistance development of a variety of cancer cell lines has rendered treatment with a single therapeutic agent completely ineffective. Instead, chemotherapeutic treatments must rely on a bevy of chemotherapeutic agents and chemosensitizers to achieve remission, most often at the cost of the patient’s well-being, owing to significant toxicity.

Traditional, small-molecule drug therapy usually targets highly specific cellular processes or interactions, enabling resistance development through simple mutations in the pathogen’s genome. In contrast, macromolecular therapeutics consist of polymeric assemblies that exhibit selective but non-specific interactions with the pathogen, making resistance development extremely difficult. In fact, macromolecular therapeutic agents developed at IBM have shown no resistance development in the treatment of bacteria and viruses, in preliminary in vitro studies. Additionally, these agents have been found to be highly effective against drug-resistant bacteria and cancer cell lines, while maintaining very low toxicity towards healthy cells. Given these impressive features, macromolecular therapeutics hold significant promise for disease treatment.

SESSION SM05.06: Supramolecular Hydrogels

Glioblastoma multiforme (GBM) is the most common primary cancer in adults and one of the most aggressive cancers with extremely poor survival statistics owing to high rates of disease recurrence. GBM infiltrates the brain tissue diffusely making complete surgical excision impossible. Current standard of care involves surgical resection of the tumour, concomitant radiotherapy and alkylating chemotherapy, followed by adjuvant chemotherapy. Chemotherapeutic choices are limited on account of most drugs’ poor propensity to cross the blood brain barrier. Systematic treatment with unspecified concentrations of chemotherapy is ineffective and risks adverse side effects. A localised and sustained delivery for various therapeutic applications including diabetes, vaccine development, immunotherapy, and CRISPR-Cas based gene editing. In this talk, I will discuss the design, synthesis, biological studies, and biomedical applications of our new vectors.

3:30 PM *SM05.06.01
Overcoming the Blood-Brain Barrier—Post-Resection Drug Delivery to Glioblastoma Multiforme Using Supramolecular Hydrogels

Zhibin Guan; University of California, Irvine, Irvine, California, United States.

Various RNAs, such as siRNA, microRNA, and mRNA, play pivotal roles in biological functions and have gained increasing importance for therapeutic applications. However, the lack of safe and efficient delivery vehicles remains the major challenge to RNA-based therapeutics. Our lab designs both small molecule and polymer-based molecular carriers for safe and efficient delivery of both short and long RNAs into cells. Using natural building blocks such as amino acids, we have developed dendronized bolaamphiphiles and polypeptides that are biocompatible, biodegradable, and highly efficient for RNA delivery. Our systematic investigation into structure–property relationships revealed important correlations between molecular design, self-assembled nanostructure, and biological activity. Through collaborations with biomedical researchers, we further investigate RNA delivery for various therapeutic applications including diabetes, vaccine development, immunotherapy, and CRISPR-Cas based gene editing. In this talk, I will discuss the design, synthesis, and the biological and biomedicinal applications of our new vectors.

Through dynamic supramolecular recognition, it is possible to create materials rationally designed beginning at the molecular level with specific, dynamic, and tunable non-covalent interactions. Certain benefits to this approach are precise control of composition, improved routes for targeting drugs, and new strategies to create materials that respond to a variety of stimuli with concomitant changes in their properties. The modularity of supramolecular interactions also facilitates opportunities to combine multiple payloads within a single delivery platform, as well as a route to the facile incorporation of specific targeting motifs that enable recognition in complex biological milieu. Using macrocyclic host-guest recognition, dynamic and tunable heterodinumeric interactions enable precise control over the properties and availability of small molecule and protein drugs. This includes the ability to design new materials with affinity-directed dynamics, stimuli-responsive properties, or user-directed changes in mechanical properties. Furthermore, the ability to precisely tune affinity leads to a spectrum of different dynamics in topologically identical materials, as well as facilitating recognition even in complex or contaminated environments. By leveraging this affinity axis, a new route to precisely target therapies may also be achieved. We are very excited about this approach to creating new functional biomaterials through engineered supramolecular interactions, and will highlight these advances across several material platforms.

The "printing," or layer-by-layer extrusion, of cell-laden hydrogels results in the fabrication of 3D tissue-like structures. These fabricated tissues have potential applications in regenerative medicine and as in vitro tissue prototypes for drug screening. Bioinks for 3D bioprinting of synthetic tissues must fulfill three criteria: they must have rheological properties appropriate for extrusion printing, they must be cyto-compatible during the printing process, and they must include biological cues to control cell behavior after printing. Here we report on a recently developed family of bioinks that meet these requirements and can be further customized to achieve a range of mechanical properties. These hydrogel-based bioinks are produced from blends of engineered recombinant proteins and peptide-modified, naturally occurring biopolymers such as alginate. These materials undergo two-stages of crosslinking: (i) weak, peptide-based, supra-molecular assembly to homogeneously encapsulate cells in a shear-thinning hydrogel within the ink cartridge and (ii) stimuli-responsive crosslinking post-printing to rapidly stabilize the construct. Benefits of this two-stage crosslinking strategy include the prevention of cell sedimentation within the ink cartridge, mechanical shielding of the cell membrane from damaging extrusion forces during printing, rapid post-print self-assembly within an aqueous bath that prevents cell dehydration, and fine-tuning of the printed scaffold mechanical properties for optimal cell-matrix interactions. We demonstrate that tuning of the hydrogel material properties can be used to identify bioinks suitable as scaffolds for the large-scale expansion of neural stem cells.

10:15 AM *SM05.07.03 Materials Science for Regenerative Biology Samuel Stupp; Northwestern University, Evanston, Illinois, United States.

One of the grand challenges for science in this century is to create strategies to regenerate parts of the human body in order to achieve longer “healthspans.” Materials science has a central role to play in this quest, which is both a highly desired and critical societal outcome given shifting demographics. The ultimate role, but not the only one, of materials in regenerative biology is to act as a bioactive medium with finite half-life that traffics signals in dynamic fashion. This in fact imitates the function of extracellular matrices as tissues develop or repair after injury, and requires molecular design of soft materials to directly activate signaling pathways via cell receptors or protein signals such as growth factors. This lecture will describe a broad platform of supramolecular biomaterials built with a toolbox of peptides, peptide amphiphiles, glycans, and nucleic acids that exhibit various forms of dynamic bioactivity toward neural or musculoskeletal cells. In one example it is possible to switch biological signals on and off through external cues, and in another one there is capacity in the material to adapt to the living structure for optimal signaling. In a third example an unprecedented soft material that exhibits reversible self-assembly of superstructures is found to modulate the phenotype of cells involved in tissue repair.

10:45 AM *SM05.07.04 Kidney Organoid Encapsulation in Static vs Dynamic Cross-Linked Supramolecular Hydrogels for Organoid Growth Floer A. Ruiter, Thomas Geuens, Shahzad Hafeez, Antonio Feliciano, Clemens A. van Blitterswijk, Vanessa LaPointe and Matthew Baker; MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht University, Maastricht, Netherlands.

Induced pluripotent stem cells (iPSCs) differentiated to a mixture of kidney cell types are observed to rearrange into kidney nephron-like structures when aggregated, spotted and cultured in a media/air interface. Although kidney like structures were observed, organoid growth is limited. No further growth or rearrangement was observed after 18 days in a media/air interface cell culture. Moreover, preliminary results within our group showed overexpression of extracellular matrix (ECM) proteins, which is due to a fibrosis reaction. Here we hypothesized a possible need for a 3D environment, which mimics the in vivo surrounding matrix of the developing kidney in the fetus. Hence, the use of supramolecular hydrogels.

Conventional supramolecular hydrogel cross-linking methods mostly rely on static covalent chemistry, such as thiol-ene chemistry. Although these hydrogels show similarities to the in vivo ECM structural characteristics, they do not mimic the dynamic behavior of the natural ECM. Cells within the natural ECM are constantly stimulated by physical and chemical cues, which change over time. For example, the repair of injured tissue occurs in multiple stages. Initial provisional matrix deposition is at the injured tissue side where matrix modification restores the tissue. However, small difference in environment cues can result in excessive secretion of collagen by the cells, which subsequently results in fibrosis or scar tissue. The dynamic cues and interactions of matrix composition, biochemical molecules and matrix mechanics all play a significant role to the cellular behavior and induced pathways to healthy or diseased tissues. Therefore, there is a need for scientists to design the hydrogel that mimics this dynamic behavior beside static structural composition.

New dynamic visco-elastic cross-linked supramolecular hydrogels of reversible covalent chemistry offer a novel approach to mimic the natural dynamic ECM behavior. Within our lab we observed a significant different in hydrogel stiffness, stress relaxation time and self-healing characteristics with different cross-linkers. This shows the possibility of tuning these materials for the desired dynamic behavior for the required cellular response.

Here we encapsulated the formed kidney organoids in the design reversible covalent chemistry cross-linked supramolecular hydrogels. Organoid cell arrangement, ECM expression, proliferation, and metabolic response were investigated in these designed hydrogels. These results were compared with to the encapsulation of organoids in a conventional thiol-ene static covalent cross-linked hydrogel.

11:00 AM SM05.07.05 Covalent-Supramolecular Polymer Hybrids for Cartilage Repair Jacob A. Lewis1, Mark McClendon1, Brett Nemke2, Yan Lu1, Mark Markel2 and Samuel Stupp3, 1; 1Department of Biomedical Engineering, Northwestern University, Evanston, Illinois, United States; 2School of Veterinary Medicine, University of Wisconsin–Madison, Madison, Wisconsin, United States; 3Simpson Querrey Institute, Northwestern University, Chicago, Illinois, United States; 4Department of Materials Science and Department of Chemistry, Northwestern University, Evanston, Illinois, United States.

Articular cartilage lacks the intrinsic ability to regenerate following injury or disease. Biomaterials scaffolds can improve cartilage healing by supporting cell infiltration and guiding new matrix deposition, yet these materials must withstand dynamic shear in the articulating joint. Transforming growth factor β-1 (TGFβ-1) binding peptide amphiphile (PA) matrices have been shown to improve cartilage healing in a lapine model; however, these materials lacked the mechanical integrity necessary for use in load-bearing large-animal joints. To improve material retention, we developed a PA-hyaluronic acid (HA) hybrid material, which improved the mechanical toughness of scaffolds. Combining these two materials formed a biocompatible gel with a highly porous microstructure containing bundled supramolecular polymers. Because of its improved mechanical properties, the material was well retained in shallow osteochondral defects in the load-bearing knee condyle. Four weeks following implantation, joints treated with TGFβ-1 loaded scaffolds revealed an improved level of tissue infiltration and integration with surrounding cartilage relative to control defects treated with only the growth factor alone. The observed improvements early in the healing process suggest the possible use of these covalent-supramolecular polymer hybrids as scaffolds for cartilage repair.

11:15 AM SM05.07.06 Evaluating and Designing BTA Supramolecular Hydrogels for Viscoelastic 3D Cell Culture Shahzad Hafeez1, Nicholas M. Matsumoto2, René P. Lafeur2, Egbert W. Meijer2 and Matthew Baker2; 1Department of Complex Tissue Regeneration (CTR), MERLN Institute, Maastricht University, Maastricht, Netherlands; 2Institute of Complex Molecular Systems (ICMS), Eindhoven University of Technology, Eindhoven, Te Netherlands, Eindhoven, Netherlands.

The extracellular matrix (ECM) is the non-cellular component present within all tissues and provides essential biological and mechanical cues required for tissue growth. Traditional synthetic covalent hydrogels (a network of hydrophilic polymers) have been investigated for 3D cell culture and probing cell-matrix interactions as they mimic the
mechanics of soft tissues and support cell adhesion. However, these hydrogels are elastic and lack the viscoelasticity found in native ECM and soft tissues and can only allow tissue formation via degradation, since they are built from covalent bonds. To overcome these limitations, hydrogels with reversible crosslinks are developed which could respond to cell stresses by rapidly breaking and reforming the bonds while maintaining uniform biophysical properties.

In our lab, we are working with 1,3,5-benzenetricarboxamide (BTA) supramolecular hydrogels. BTA molecules stack over each other through 3-fold hydrogen bonding and hydrophobic interactions to form long self-assembled BTA fibres, resulting in the hydrogel. BTAs are of interest for us owing to their cell-relevant timescales, protein-like fibrous structures and the ease of adjusting viscoelastic properties by controlling interactions at the molecular level. In addition, these gels exhibit injectability, showing a potential for bioprinting, and can serve as a platform for the generation of spatiotemporal dynamic co-cultures.

For cell viability, cultured cells within gels were stained with calcinein-AM and ethidium homodimer-1 and imaged using fluorescence microscopy. Minimal cytotoxicity was observed over 7 days. To be more quantitative, an absorbance-based LDH and CyQUANT assays were carried out. LDH assay showed approximately 10% dead cells and results are comparable to algin control sample, CaCl₂ crosslinked. The CyQUANT assay showed that cell number fairly stayed constant and gels did not enhance the proliferation. Interestingly, chondrocytes aggregation within gels were observed over time which was visualized with actin and nuclei staining. Currently, cell culture experiments are being carried out to investigate cartilage matrix formation by chondrocytes within BTAs hydrogels with varying viscoelastic timescales.

Furthermore, to expand the current BTA hydrogelator library (with different architectures) work was carried out towards desymmetrization of BTAs; a penta-fluorophenol BTA synthon (BTE-F,Ph) has been synthesized and desymmetrized using hexylamine as a model reaction. This work enables the creation of a small library of hydrogels with varying dynamicity and viscoelasticity that can help in developing a better understanding of cell-ECM interactions and directing cell fate.

11:30 AM *SM05.07.07
From Dynamically Crosslinked Hydrogels to Tunable Bioinks for 3D-Printed Tissue Engineering Constructs Matthew Baker, MERLN, Maastricht University, Maastricht, Netherlands.

Statically crosslinked hydrogels poorly recapitulate the complex and responsive behavior of a cell’s native extra cellular matrix (ECM). Cells have a difficult time growing, migrating, and fusing to form tissue within a densely crosslinked covalent hydrogel, yet covalently crosslinked hydrogels are the most widely used material for 3D printing of cell laden hydrogels (bioinks). Consequently, in order to create more complex and biomimetic 3D tissue engineering constructs, there is a noticeable need for the creation and use of dynamically crosslinked hydrogels within biofabrication and 3D printing.

Recently, our lab has developed both supramolecular and dynamic covalently crosslinked hydrogels which show high cell viability upon encapsulation, tunable network dynamics and mechanical properties, and exhibit self-healing, injectability, and 3D printability. In this talk, I will mainly focus on the dynamic covalent crosslinked hydrogels based on imine type crosslinking. These imine cross links are dynamic under physiologic conditions, resulting in appreciable on/off rates depending on the molecular structure of the crosslinker. Furthermore, these hydrogels are easily functionalized with biological cues using oxime ligation strategies. Several cell types (HDF, ATDC5, pancreatic islets) show good cell viability within these hydrogels. We observe noticeable changes in cellular function (proliferation, morphology, etc.) depending on the dynamics of the hydrogel formulation, enabling the matching of network dynamics with the desired cellular response. These hydrogel formulations also show good 3D printability, allowing the creation of spatially defined cell-laden constructs with enhanced function (as compared to other covalent bioinks).

These developed hydrogels represent new classes of dynamic bioinks for 3D printing and the construction or large tissue engineering constructs. The ability to fabricate appreciable size and spatially defined objects with biomimetic network dynamics enables the creation of complex multicellular constructs that can facilitate inter-cellular communication. Current efforts in the lab are focused on using these dynamically remodelable networks to study the interactions of cells and migration through reversible networks in complex geometries.
Hydrogel Inks for 3D Printing: Eugenia Kumacheva; Chemistry, University of Toronto, Toronto, Ontario, Canada.

Man-made nanofibrillar hydrogels have recently emerged as a new class of bionimetic materials that reproduce the filamentous nature and properties of in-vivo extracellular matrices, act as scaffolds for three-dimensional cell culture and tissue engineering, and offer interesting properties in actuation and soft robotics. Our group has developed new “inks” for 3D printing of hydrogels that are derived from cellulose nanocrystals and different types of polymers. These inks offer a number of useful properties, including their shear thinning behavior, the biocompatibility of the resulting hydrogels and the capability to fine-tune hydrogel composition, structure and physical properties in a throughput manner.

11:30 AM *SM06.01.03
Optically Camouflaged Microgel In Water—Prescribed Pattern Transformation in Swelling and Thermochromic Effects
Nicholas Fang and Xinhao Li; Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Amazing capabilities of structural coloration and camouflage in marine animals such as cephalopod has inspired intensive study of smart materials and functional coatings. How do we gain control over optical and acoustic response using such soft and switchable microstructure of hydrogel? In this talk, we will present some simple analytical model that outline the design strategies of these transparent microgels. Our model suggest that inhomogeneous stress develops as the gel swells under mechanical constraints, which gives rise to spontaneous buckling instability without an external force. We will also demonstrate a new type of thermochromic coating using co-polymerized pNIPAm–AEMA hydrogel microparticles. The light blocking mechanism is clearly elucidated by applying Mie scattering theory, which predicts the scattering efficiency in a broad solar spectrum. The cross-link density and size of the microgel particles are manipulated to deliver prominent performance in both modulating solar thermal and visible light spectrum, which is unachievable by any thermochromic counterparts. We further discuss the potential applications agile and transparent actuators and robots formed hydrogel in water.

1:30 PM *SM06.02.01
Jamming and Rheology of Microgels—The Role of Particle Architecture
Maddalena Mattioli, Sarah Goujard and Michel Cloitre; ESPCI Paris, Paris, France.

At high concentration, microgels form glassy materials which behave as weak elastic solids at rest but yield and flow at high stresses. These materials are basic components of viscoelastic formulations used as high-performance coatings, solid inks, ceramic pastes, textured food, and personal care products. Synthetic chemistry offers a panel of strategies to tune the internal architecture of microgels and their interactions, which involve elastic repulsion and attractions of different origins. An important question concerns the relation between the particle elasticity, the phase diagram, the nature of the liquid to solid transition, and the macroscopic rheology [1].

Microgel elasticity can be tuned by varying the crosslink density, which appears to be one of the key parameters that determine the phase diagram and the rheology of microgel suspensions. Highly crosslinked microgels exhibit well-defined glass and jamming transitions and cross from liquids to entropic glasses and jammed glasses when the volume fraction is increased [2]. In the jammed glass regime, the flow properties exhibit universal properties. The macroscopic rheology is well described by a micromechanical model where microgels are described as purely elastic particles interacting under the combined action of elastic repulsive forces and viscous drag forces [3]. Weakly crosslinked microgels behave very differently. They solidify above a well defined volume fraction but the glass and jamming transitions can no longer be disentangled. Yielding is now time dependent and the flow curves exhibit distinct scaling properties.

These behaviors are representative of two universality classes of soft particles where the flow properties are controlled by the dynamics of the elastic cages formed by interlocked neighboring particles and the viscoelastic deformation of individual particles, respectively.

Searching for Universal Features of Soft Deformable Colloids—A Comparison of the Rheology of Dense Microgel and Star Polymer Suspensions
Leo Gury, Michel Cloitre and Dimitri Vlassopoulos; 1 FORTH, Crete, Greece; 2 ESPCI, Paris, France.

Dense microgel suspensions have both been shown to exhibit a thermal glass-to-jammed glass transition, characterized by large yield stress and linear dependence of plateau modulus on concentration, as well as other fine differences in flow curves [1]. There appears a consensus suggesting that shape adjustment in the highly concentrated regime is at the origin of jamming [3]. On the other hand, hairy particles represent a distinct class of soft colloids, being essentially the counterpart of microgels, with the additional feature (and degree of freedom) being their dangling arms [4]. Hence, a natural question that emerges concerns the role of internal microstructure on the dynamic properties of soft colloids and in particular the possible glass to jamming transition at high concentrations. Here, we address this challenge by systematically investigating highly concentrated suspensions of well-characterized microgels and multimer star polymers. Whereas both types of particles are able to shrink and deform under the action of osmotic pressure, star polymers can also interpret their arms and, moreover, can be investigated throughout the entire concentration regime up to the dry melt state. We show that the difference in the internal particle microstructure is reflected in distinct rheological signatures of these soft colloids. We focus on linear and nonlinear rheological shear measurements and analysis with additional support from dynamic light scattering, and attempt at providing a generic guidelines for tuning the flow properties of soft colloids via knowledge of their microstructure. Subtle differences in flow curves and associated velocity profiles are critically discussed and linked to the different features that dictate particle softness. We show that these distinct universality classes of soft colloids possess flow properties with generic features which can be tailored at molecular level.

Passive Microrheology Analysis of Sol-Gel Processes by Diffusing Wave Spectroscopy
Matt Vanden Eynden, Roland Ramsch, Giovanni Brambilla, Pascal Bru and Gerard Meunier; 1 Formulaction, Inc., Worthington, Ohio, United States; 2 Formulaction, Toulouse, France.

Passive microrheology is a powerful tool to study gels and their formation. Passive microrheology consists of using micron sized particles to measure the local deformation of a sample resulting from the thermal energy, the Brownian motion. Our technique is based on Diffusing Wave Spectroscopy, which is a multiple backscattering technique using a CCD camera to correlate the fluctuation of the backscattered light to the motion of the particles. By mathematical processing of the signal, the motion of the particles can be related to the viscoelastic properties of the sample, as particle speed and particle displacement are directly related to viscosity and elasticity. This work will give an overview of possible applications, with a focus on the Sol-Gel processes. Indeed, various functional and customized materials are prepared for a wide range of applications by the Sol-Gel process, and precise microrheological characterization could benefit to the optimization of preparation and properties of such materials properties. This work will show, how Rheolaser
have used the Q-tensor approach for nematic liquid crystalline systems and found conditions for formation of highly ordered phases where orientation order parameter approaches similar shape transformation was observed. Surprisingly the highly cross-linked hollow microgels under applying the uniaxial strain to the system could form liquid crystal phases. Uniaxial deformation of the simulation box with continuous microgels leads to reordering of the microgels. At the same time homogeneous deswelling, volume reduction and self-shape of the microgels is close to the Wigner-Seitz cell of the fcc-structure and two-fold compression still keeps the fcc ordering. Quite different behavior is observed for the case degree. Uniform compression of the simulation box with continuous microgels beyond the overlap regime leads to their compression with further shape transformation. Ultimate and hollow microgels (with cavity) subjected to uniform compression (concentration) and uniaxial deformations (one- or two-dimensional solvent evaporation). We have and deswelling mechanisms of microgels of different architectures and cross-linking density in overcrowded conditions. We propose computer simulations of regular (continuous) the soft particles upon concentration and crystallization? We can imagine that in addition to the spatial ordering, the shape and volume transformations of the microgels can occur transformations. It is well known that concentration of solid colloidal particles in suspensions can lead to their phase separation and/or crystallization. The latter means that the Polymeric microgels are soft colloidal particles highly sensitive to variation of environmental conditions (e.g. temperature, pH, etc.) leading to the volume and shape transformations. It is generally accepted that concentration of solid colloidal particles in suspensions can lead to their phase separation and/or crystallization. The latter means that the Polymeric microgels are soft colloidal particles highly sensitive to variation of environmental conditions (e.g. temperature, pH, etc.) leading to the volume and shape transformations. It is well-known that concentration of solid colloidal particles in suspensions can lead to their phase separation and/or crystallization. The latter means that the particles are spatially-ordered in the solution forming face-centered cubic (FCC) or hexagonal close-packed (HCP) structures. The natural question arises: What is going on with the soft particles upon concentration and crystallization? We can imagine that in addition to the spatial ordering, the shape and volume transformations of the microgels can occur upon concentration. In the current work we give a detailed description of the structure and dynamics of concentrated suspensions of soft microgels. We explore the deformation and deswelling mechanisms of microgels of different architectures and cross-linking density in overcrowded conditions. We propose computer simulations of regular (continuous) and hollow microgels (with cavity) subjected to uniform compression (concentration) and uniaxial deformations (one- or two-dimensional solvent evaporation). We have demonstrated that final structure of the microgels and their ordering strongly depends on the cross-linking density, relative size of the cavity (hollow microgels) and compression degree. Uniform compression of the simulation box with continuous microgels beyond the overlap regime leads to their compression with further shape transformation. Ultimate shape of the microgels is close to the Wigner-Seitz cell of the fcc-structure and two-fold compression keeps the fcc-structure ordering. Quite different behavior is observed for the case of the hollow microgels. The uniform compression leads to the spontaneous buckling of the microgels and cavity collapse. This is accompanied by breaking of the fcc-structure ordering. Uniaxial deformation of the simulation box with continuous microgels leads to reordering of the microgels. At the same time homogeneous deswelling, volume reduction and self-similar shape transformation was observed. Surprisingly the highly cross-linked hollow microgels under applying the uniaxial strain to the system could form liquid crystalline phases. Selected strain direction provides overall uniaxial deformation of the hollow microgels in such a way that they form disk-like objects which exhibit liquid crystalline behavior. We have used the Q-tensor approach for nematic liquid crystalline systems and found conditions for formation of highly ordered phases where orientation order parameter approaches
Increasing the particle density of a suspension of microgel colloids above the point of random-close packing, must involve deformations of the particle to accommodate the increase in volume fraction. By contrast to the isotropic osmotic deswelling of soft particles, the particle-particle contacts give rise to a non-homogeneous pressure, raising the question if these deformations occur through homogeneous deswelling or by the formation of facets. Here we aim to answer this question through a combination of imaging of individual microgels in dense packings and a simple model to describe the balance between shape versus volume changes. We find a transition from shape changes at low pressures to volume changes at high pressures, which can be explained qualitatively with our model. Whereas contact mechanics govern at low pressures giving rise to facets, osmotic effects govern at higher pressures, which leads to a more homogeneous deswelling. Our results show that both types of deformation play a large role in highly concentrated microgel suspensions and thus must be taken into account to arrive at an accurate description of the structure, dynamics and mechanics of concentrated suspensions of soft spheres.

SM06.03.03 Coarse-Grained Models for Predicting Microstructure of Crosslinked Gels

Eric Jankowski, Mike Henry, Carla E. Reynolds and Stephen Thomas; Materials Science and Engineering, Boise State University, Boise, Idaho, United States; The Boeing Company, St. Louis, Missouri, United States; The University of Tennessee.

Predicting gelation in polymer systems is difficult because of the long-time dynamics and complex components that characterize them. In this work we perform coarse-grained molecular dynamics simulations of reacting epoxies to access longer times and relevant volumes for observing up to 100nm features, gelation, and glass transitions. Here we focus on calculations that connect nanostructure to transition temperatures. We demonstrate that gelation and glass transitions depend on the degree of cure in epoxy systems, and quantify the degree to which coarse-grained models are predictive of experiments. We find that these coarse-grained models are quantitatively predictive of glass and gelation transitions for simple epoxy thermosets. Using GPU-accelerated simulations we demonstrate the potential for using coarse-grained models of polymer gels to provide a window into how processing protocols can be used to tailor the structure and properties of gels synthesized by crosslinking.

References
Magnetic microgels are colloidal particles consisting of a crosslinked polymer network with embedded magnetic particles [1,2]. The presence of magnetic particles inside the microgels is advantageous for many applications because in this case, magnetic microgels and their properties can be controlled by means of applied magnetic fields. However, magnetic microgels exhibit interesting behaviour even in the absence of an external magnetic field. In addition, the zero-field case provides a benchmark for understanding any changes in structural or magnetic properties when the field is applied. In this contribution, we focus on studying the properties of both single magnetic microgel particles and their suspensions by means of computer simulations in the zero-field case. We exploit our previously developed coarse-grained model for creating homogeneously and heterogeneously crosslinked microgels with a randomized internal architecture of the polymer network and incorporate ferromagnetic dipolar particles in a random manner [3]. Heterogeneous microgels have a distinct homogeneously crosslinked core and a shell. We examine microgels with different fractions of crosslinked monomers and content of magnetic particles in order to find out how these parameters influence the structural and magnetic properties of both homo- and heterogeneous magnetic microgels. Having the insight into single particle properties, we study microgel suspensions in order to understand what is the typical self-assembly scenario for magnetic microgels and how this scenario changes depending on magnetic content and density of the studied system.

SM06.03.05 Light and Temperature Dual Responsive Microgels Based on Spiropyran and N-Vinylcaprolactam Chaolei Hu1,2, Wenjing Xu1,2 and Andrij Pich1,2, Functional and Interactive Polymers, Institute of Technical and Macromolecular Chemistry, RWTH Aachen University, Aachen, Germany; 2DWI-Leibniz Institute for Interactive Materials e.V., Aachen, Germany.

Light and temperature dual responsive microgels system based on spiropyran modified poly (N-vinylcaprolactam)-vinylamine copolymer was designed and built up. The novel and applicable microgels synthesis route involved first preparing spiropyran modified poly (N-vinylcaprolactam)-vinylamine copolymer via RAFT polymerization, hydrolysis and coupling, and then being crosslinked to microgels through W/O mini-emulsion. Light and temperature responsiveness of the synthesized microgels were investigated. The UV-vis spectrum demonstrated the reversible light-responsive behavior of microgels in aqueous solution, which comes from the spiropyran photosomerization under different irradiation. DLS results show that the microgels swell in darkness due to the-equilibrated gel particles feature spiropyran molecules in the polar, merocyanine form. After irradiation of visible light, the particle size becomes smaller because spiropyran changes to the relatively nonpolar, closed spiro form. DLS results also show the spiropyran modified microgels have temperature responsiveness: the microgels undergo a volume phase transition in water from a swollen state to a collapsed state with increasing temperature and the VPTT decreases corresponding the non spiropyran modified microgels due to the hydrophobic spiropyran units.

SM06.03.06 Fed-Batch, Temperature-Programmed Synthesis of µm-Sized Microgels—Closing the Size Gap Between Batch and Microfluidic Synthesis Agnieszka N. Ksiazkiewicz1,2, Wenjing Xu1,2 and Andrij Pich1,2, Functional and Interactive Polymers, Institute of Technical and Macromolecular Chemistry, RWTH Aachen University, Aachen, Germany; 2DWI-Leibniz Institute for Interactive Materials e.V., Aachen, Germany.

Microgels or nanogels are cross-linked polymer networks that can respond to environmental change like temperature or pH. When triggered, they collapse or swell in solvents, while preserving their 3D structure. Micron-sized microgels can have plenty of interesting applications in crystallization studies, microlensing or mimicking cells. Microgels with the size above 10 µm can be synthesized using microfluidics [1]. However, very low yields and specific equipment requirements lead to high demand on synthesis of microgels via dispersion polymerization approaches. Moreover, the typical size of gels synthesized using standard batch polymerization reactions is in nanometer scale. Thus, particles ranging from 1 to 10 µm are hardly accessible, and means to obtain them need further investigation. Micron-sized poly(N-isopropylacrylamide) (pNIPAm) microgels have been obtained previously [2]; however, known toxicity and suspected cancerogenicity of pNIPAm disqualifies the usage of these gels in medical applications.

In contrast to pNIPAm, poly(N-Vinylcaprolactam) (pVCL) is non-toxic and biocompatible [3], making it a great candidate in medical and biomaterial fields. Here, for the first time, we have synthesized temperature-responsive pVCL microgels with large diameter (1-5 µm) via aqueous, surfactant-free precipitation polymerization. The size control was achieved by employing programmed temperature ramp during the nucleation stage of polymerization. In this work, the influence of various parameters such as monomer, cross-linker and initiator concentration, rate of temperature ramp, start and end temperature as well as dosing of the reagents was investigated. We were able to obtain microgels in different size ranges, depending on parameters altered.

SM06.03.07 Ultrahigh-Throughput Production of Monodisperse and Multifunctional Janus Microgels via In-Air Microfluidics Claas W. Visser, Ton Kamperman, Vasileios Trikalitis, Detlef Lohse and Marcel Karperien; University of Twente, Enschede, Netherlands.

Microfluidic chips can reproducibly generate large numbers of complex droplets and particles, but have a low throughput that blocks their industrial use. Furthermore, the resulting particles cannot be readily used as building blocks for solid (meta)materials, as they are contained by a liquid phase. Here we address these limitations by ejecting a train of droplets into the air and manipulating their properties by impact of a second liquid jet. The surface tension of the jet was reduced, so that it encapsulates the droplet by Marangoni spreading. Subsequent on-the-fly manipulations, including solidification and controlled deformation, enable fabrication of monodisperse emulsions, particles, and fibers with diameters of 20 to 300 µm at rates that are 10 to 100 times higher than usual microfluidic methods. Deposition of the partly-solidified droplets onto a solid substrate enables one-step manufacture of three-dimensional (3D) multiscale materials. For example, we demonstrate an artificial pancreatic tissue in which each solidified droplet forms a controlled micro-environment for MN6-cells that maintain their capacity to proliferate and produce insulin. In-air microfluidics, as we name this approach, enables fabrication of controlled multi-material particles and capsules at industrially relevant rates (up to 3 ml/minute/ nozzle). I will present recent results including the fabrication of multifunctional Janus particles for enzymatic cascade reactions, and sketch how In-air microfluidics may contribute to one-step fabrication of multi-scale materials with controlled mechanical, biological, or thermal properties.
rigid nanoparticles, flexible macromolecules, micelles or vesicles. When swollen, they are soft and have a fuzzy surface with dangling chains and the presence of cross-links provides structural integrity - in contrast to linear and (hyper-) branched polymers. Finally, microgels reveal interface activity without being amphiphilic. Due their properties, microgels can be used to tune the colloid-to-polymer transition.

We will discuss properties of microgels of different architecture (e.g. ultra-low crosslinked, hollow, multi-shell) both in aqueous solution and at interfaces. These microgels respond to various stimuli as, e.g. temperature and pH, and enable uptake and release applications. The structure of microgels and complexes with guest species are investigated by means of scattering methods, especially exploiting the technique of contrast variation in small angle neutron scattering. The experimental results are be compared to computer simulations. In addition, superresolved fluorescence microscopy is employed.

Microgel adsorb to fluid and rigid interfaces surfaces and their response to external stimuli allows preparing responsive emulsions and coatings which can be used in biocatalysis and as sensors. Interfaceal properties are probed via compression isotherms as well as by scanning force and fluorescence microscopy.

9:00 AM *SM06.04.02 Dynamics of PNIPAM Microgels at Liquid Interfaces Valérie Ravaine1, Véronique Schmitt2, Joris Sprakel1, Louis Keal3 and Cecile Monteux4; 1ENSCPB, Bordeaux, France; 2Wageningen University, Wageningen, Netherlands; 3CRPP, Bordeaux, France; 4ESPCI, Paris, France.

We investigate the drainage dynamics of thin liquid foam films containing PNIPAM microgels suspensions with two cross-linking densities (1.5 % or 5% mol BIS) and at two microgel concentrations (0.1 and 1% wt). For this purpose we use a thin film pressure balance apparatus that can apply a controlled and sudden hydrostatic pressure on the film and record the subsequent film thinning as a function of time. Once the film thickness has reached a stationary value, we test the adhesion between the interfaces of the film by reducing the pressure and measuring the angle between the film and the meniscus. This angle increases on reduction of pressure for adhesive films, which resist the separation of their interfaces. Non-adhesive films separate easily, and the meniscus angle stays constant. At low microgel concentration, the more densely cross-linked microgels (5% mol BIS) tend to drain into more adhesive films than the more loosely cross-linked particles (1.5% mol BIS). The adhesion results from particles that bridges the two air-water interfaces constituting the film, i.e. particles being shared between both interfaces of the films. In those cases, the film, which is initially stabilized by a bilayer of microgel particles rearrange to a state where the particles are shared by them. These results are discussed and compared with previous studies at low concentration of microgels, which have shown that emulsions stabilized with densely crosslinked microgels are more adhesive and less resistant to mechanical stresses than those obtained with lower cross-linking densities. In addition micron-scale depleted zones with no microgels are observed in the films stabilized with the 5% mol BIS particles, which eventually lead to the rupture of the film. At 1% wt, the films drain slowly, are not adhesive and have the thickness of a bilayer of microgels while at 0.1% wt, the films have the thickness of a monolayer of microgels, are adhesive and show bridging. From the thin liquid foam film thicknesses we extract a rough estimation of the radii of adsorbed particles in the thick-films before applying the pressure. Our results are consistent with particles being adsorbed in a spread conformation for the 0.1% wt sample and in a compressed conformation for the 1% wt sample. In line with previous studies on emulsions, we conclude that a larger surface coverage may reduce rearrangements, thus preventing bridging.

9:30 AM SM06.04.03 Microgels at Liquid-Liquid Interfaces—Comparing Experiments with a Realistic Model Fabrizio Camerin1,2; 1Dipartimento di Scienze di Base e Applicate per l'Ingegneria, Sapienza University of Rome, Roma, Italy; 2Institute for Complex Systems, National Research Council, Roma, Italy.

A distinctive feature of microgel particles is that of being soft colloids with an internal polymeric architecture. At liquid interfaces, in particular, they deform and flatten significantly due to the balance between surface activity and internal elasticity. For this reason, recent experimental studies have shown that they are a valuable choice to stabilize smart emulsions in contrast to common rigid colloids [1, 2]. Despite the clear potential this system could bring, a detailed theoretical understanding of the phenomenon is still lacking. In fact, commonly accepted models in which the internal structure is neglected or diamond-like, where polymer chains have a fixed length, are not able to reproduce this behavior, especially by the fact that the corona would not flatten out. Conversely, we have now provided a realistic model that reproduces in silico the polymeric network of PNIPAM microgels [3], even in the presence of an explicit solvent [4].

By placing the microgel at liquid-liquid interfaces, we can now directly compare the morphology of the microgels resulting from simulations with in-situ cryo-electron microscopy measurements and AFM imaging after Langmuir-Blodgett depositions [5]. The correct modelling of the internal degrees of freedom allows for a qualitative comparison with the experimental outcomes and to report a consistent trend as a function of the fraction of crosslinkers. By varying the parameters of the monomer-solvent potential, we are able to selectively tune the surface tension, as expected for different combinations of solvent at the interface. This opens up the possibility to evaluate single-particle elastic properties and effective interactions among microgels, that can be used to predict macroscopic behavior. These are also essential to develop predictive power for the use of microgels in a broad range of applications.

10:15 AM *SM06.05.01 Microgel Morphology Resolved by Mesoscale Computer Simulations Roland G. Winkler; Theoretical Soft Matter and Biophysics, Institute for Advanced Simulation, Forschungszentrum Juelich GmbH, Juelich, Germany.

The structural properties of microgels adapt to external stimuli by swelling or shrinking in response to changes in temperature, pH, ionic strength of the solution, or solvent composition [1]. This renders them ideal candidates for a broad range of applications including encapsulation for drug delivery, sensing, and food additives. The possibility to change the microgel composition during the synthesis opens an avenue for novel applications. An example is the synthesis of core–shell microgels, which are typically comprised of polymers with distinctly different properties, e.g., their hydrophobicity, which allows for the control of the microgel morphology, and opens an avenue for novel applications [2].
Here, we present results of hybrid simulations combining the multiparticle collision dynamics method [3] for the fluid with molecular dynamics simulations for the microgel to systematically characterize the morphologies of core–shell microgels [2]. With increasing hydrophobic interaction of the shell polymers, we observe drastic morphological changes of the microgel from a core-shell structure to an inverted microgel, where the core is turned to the outside, or a microgel with a patchy surface of core polymers directly exposed to the environment. A phase diagram is established of the various morphologies.

Moreover, the morphologies of a microgel are analyzed during collapse from a swollen soft, deformable networks with a fuzzy surface to a colloid with homogeneous density and a sharp surface, which is achieved by solvent exchange [1]. Time-resolved small-angle x-ray scattering experiments and computer simulations unambiguously reveal a two-stage process: In a first, very fast process, collapsed clusters form at the periphery, leading to an intermediate, hollowish core-shell structure that slowly transforms to a globule. This structural evolution is independent of the type of stimulus and thus applies to instantaneous transitions as in a temperature jump or to slower stimuli that rely on the uptake of active molecules from and/or exchange with the environment. The fast transitions of size and shape provide unique opportunities for various applications as, for example, in uptake and release, catalysis, or sensing.

template. As the hydrogel is a water-swollen network of hydrophilic polymers, the microgel matrix is highly permeable to small molecules while being impermeable to the macromolecules larger than its limiting mesh size. Moreover, as the average mesh size is controllable by adjusting the molecular weight of gel-forming monomers, the cut-off threshold of permeation is tunable. Taking advantages of the hydrogel for SERS analysis, we microfluidically prepare monodisperse microgels containing metal nanoparticles. The microgels exclude adhesive macromolecules while allowing infusion of small target molecules to the surface of metal nanoparticles. Therefore, Raman intensity for the target is tunable. Taking advantages of the hydrogel for SERS analysis, we microfluidically prepare monodisperse microgels containing metal nanoparticles. The microgels exclude adhesive macromolecules while allowing infusion of small target molecules to the surface of metal nanoparticles.
characterized by high network inhomogeneity due to polymer chain bundling, which accelerates the network collapse. We probe the effect of crosslink density on the volume transition and show that its decrease leads to a sharper volume phase transition near the critical point. Finally, we examine the bulk modulus of compressed microgel suspensions at different packing fractions and solvent conditions. We evaluate the degree of particle-particle penetration to establish its relation to the micromechanics of compressed microgel suspensions.

4:30 PM SM06.07.03Towards High Throughput Microfluidic Devices Alexander Jans and Alexander J. Kuehne; DWI-Leibniz Institute for Interactive Materials, Aachen, Germany.

Droplet based microfluidic is a versatile tool to generate confined volumes in form of an emulsion. In contrast to bulk emulsification techniques, microfluidics produces highly uniform droplets, which act as templates for chemical reactions. Microfluidic emulsification has been used in particular to create functional and soft colloidal structures. In the microfluidic drop-maker, these particles are generated consecutively one-after-the-other and the yield over time is low with a single drop-maker.

To overcome this challenge, several approaches were taken by parallelizing in ladder- or tree- type structures using PDMS based systems and soft-lithography, resulting in large footprint devices with large dead volumes. We could show that by producing microfluidic devices by rapid prototyping we can stack drop-makers on top of each other and minimize the device footprint and overall channel length. Furthermore, such 3D printed microfluidic devices enable new design strategies, which are impossible to obtain using common soft-lithographic approaches. To showcase the freedom of design in 3D prototyped devices we designed a helical channel structure device where all drop-makers disperse into a single continuous channel. This design leads to significantly increased droplet concentrations of the dispersed phase. Compared to individual drop-makers the volume fraction of droplets is up to 300% higher. Double emulsions have also received a high interest in biomedical applications because of their potential to produce monodisperse capsules and facile loading protocols with diameters on the micrometer scale. Classical (glass capillary and PDMS) devices lack durability and required surface modification while parallelization strategies remain complicated. We present a new system based on a 3D printed device that utilizes the advantages of rapid prototyping to produce double emulsions in three or more parallelized channel geometries for high throughput reaction containers for polymer and microgel capsules.

4:45 PM SM06.07.04Strategies to Realize Precise Macroscopic Supramolecular Assembly Mengjiao Cheng; Beijing University of Chemical Technology, Beijing, China.

Macroscopic supramolecular assembly (MSA) investigates multivalent interactions between building blocks larger than 10 micrometer and modified with numerous interactive motifs. MSA has provided a platform for fundamental understanding of various interfacial phenomena such as underwater adhesion, self-healing etc. Because large interactive interfaces of macroscopic building blocks have induced more kinetic possibilities, the assembled structures are normally poorly-ordered, which is not favorable for practical applications. To address the problem of macroscopic self-assembly processes being insensitive to errors and having poorly aligned assemblies, we have proposed two strategies for precise self-assembly by (1) pre-orientation of building blocks or (2) post-method of self-correction. The first strategy applies long ranged forces (capillary forces, magnetic forces) by anisotropic surface modification of the building blocks and may ameliorate the precision to some degree. However, the essence of insensitivity to errors still leads to some defects. Therefore, we used the second strategy of self-correction to realize precise MSA: through suitable control over the disassembly kinetics, the poorly and precisely aligned structures could be self-identified and selectively disassembled the poorly aligned structures, which led to re-assembly of the building blocks; after cyclic iteration of disassembly and re-assembly, we could achieve precise MSA of all interactive pairs.

References
we demonstrate a number of new effects. The microgels can serve as compatibilizers of immiscible molecules.\textsuperscript{1,2} In particular, we demonstrate that two initially immiscible liquids, A and B (oil and water), can partially or fully be mixed within the microgel adsorbed at their interface. If the incompatibility of the liquids is relatively low, they form a homogeneous mixture outside the whole microgel particle being segregated outside. As the incompatibility grows, separation into two (micro)phases within the microgel occurs. We demonstrate this effect for homopolymer\textsuperscript{1,2} and amphiphilic\textsuperscript{1} (AB-copolymer) microgels.

Adsorption of the microgels on a solid surface leads to their flattening: the shape of the microgel is determined by a balance between the gain in the energy of adsorbed monomer units and the penalty in the elastic free energy of the subchains subjected to lateral stretching. Despite a strong interaction with the surface, the adsorbed microgels are able to swell and collapse in response to environmental changes (pH and temperature) varying the size on the surface. We have demonstrated a peculiar behavior of the microgels adsorbed on a patterned surface (planar surface with cylindrical holes or pores).\textsuperscript{4} It turns out that a microgel can enter and exit a narrow cylindrical pore under external stimuli leading to collapse and swelling of the microgel. Attractive interactions between the microgel and the pore surface stimulate the microgel entering upon its collapse. The entering is driven by a gain in the surface energy: the area of the microgel-pore contacts is maximized within the pore. Swelling of the microgel within the pore of a finite size is thermodynamically favorable if the pore thickness exceeds a certain threshold value. Otherwise, the swelling leads to the microgel exit. The physical reason for this is a gain in the elastic free energy of the subchains which are less stretched outside the pore. We systematically study swelling and collapse of the microgel within the pore. Both longitudinal size and radial concentration profiles are calculated for different strength of the beads with each other and the pore surface. We predict an intra-microgel “phase” coexistence leading to the formation of a dense adsorbed layer near the pore surface and highly swollen central part of the microgel. Furthermore, the permeation of nanoparticles, whose size is smaller than the mesh-size of the microgels was simulated under different swelling and adsorption degrees. It is demonstrated that the microgel can slow down and completely stop the permeation of nanoparticles through the pore.

Pickering Emulsions Stabilized by Microgels—Link Between Microgel Adsorption at Model Interfaces and Emulsion Properties Marie-Charlotte Tatry\textsuperscript{1, 2, 3}, Véronique Schmitt\textsuperscript{1} and Valérie Ravaïne\textsuperscript{1, 2, 3};\textsuperscript{1} Centre de Recherche Paul Pascal, Centre National de la Recherche Scientifique, PESSAC, France;\textsuperscript{2} Institut des Sciences Moléculaires (Nysa), Centre National de la Recherche Scientifique, PESSAC, France;\textsuperscript{3} University of Bordeaux, PESSAC, France.

Microgels are soft and deformable colloidal particles which can be swollen by a solvent and adsorbed at liquid interfaces. The well-known poly(N-isopropylacrylamide) (pNIPAM) microgels are thermo-sensitive and exhibit a volume contraction when the temperature is raised above the volume phase transition temperature (VPTT). These particles have shown high potential as Pickering emulsions stabilizers: emulsions could be stable at temperatures below the VPTT and be destabilized on-demand above it \cite{1}. Understanding microgel adsorption at model interfaces gives better insight into the link between microgels conformation, mechanical properties of the interface and properties of the resulting emulsions \cite{2, 3}.

In this work, we highlight the role of structural parameters such as the cross-linking density i.e. the microgel deformability, their size or the presence of charges through the use of pH sensitive groups or in-situ (pH, electrolyte concentrations). For that, a systematic approach is adopted using two complementary methods: the spontaneous adsorption and the forced compression. Both equilibrium and kinetics studies are conducted: by the pendant drop method, we examine the microgel interfacial properties, measuring the dynamic surface pressure, tension and the dilational visco-elasticity \cite{4}. By the Langmuir film technique, the conformations and packing of microgels as a function of surface pressure could be discussed \cite{3}.

Moreover, microgels deformation and adsorption at the liquid interface have consequences on emulsion macroscopic properties (stability, flocculation, etc.). Despite the complexity of comparison, spontaneous adsorption of microgels at model interfaces can be correlated with the microgels conformation in emulsions or foam films in which microgels are locked into various conformations and with the emulsions properties. Taking into account the kinetics of adsorption at the interface and processing conditions, we could control emulsification pathways from high energy methods to microfluidics.

Finally, on the basis of this knowledge, we show how the concept can be extended to new designed microgels that are responsive to other (bio)-stimuli such as glucose \cite{5}.

Macroscopic Supramolecular Assembly and Its Applications Feng Shi; College of Materials Science and Engineering, Beijing University of Chemical Technology, Beijing, China.

Macroscopic supramolecular assembly (MSA) is a recent progress in supramolecular chemistry regarding assembly events between building blocks larger than ten micrometer. Researches on this topic have provided both a deep fundamental understanding of interface-interface molecular recognition in a multivalent manner and a novel methodology for the fabrication of supramolecular materials. To address the problems of “what kind of building blocks could achieve macroscopic assembly?”, we have established a general design rule of MSA that assembly probability decreases with the increasing elastic modulus of building blocks. Moreover, we have proposed the concept of “flexible spacing coating” to achieve MSA of rigid materials. To promote the practical applications of MSA, we have fabricated biocompatible 3D structures with targeted chemical modification, which provide a novel strategy to address the current challenges in fabricating complex 3D tissue scaffolds with localized protein for further cell differentiation.

Simulating the Response of Liquid Crystalline Elastomer Microposts to Light James T. Waters\textsuperscript{1}, Joanna Aizenberg\textsuperscript{2} and Anna Balazs\textsuperscript{1};\textsuperscript{1} University of Pittsburgh, Pittsburgh, Pennsylvania, United States;\textsuperscript{2} Harvard University, Cambridge, Massachusetts, United States.

Liquid crystalline elastomers (LCEs) represent a realizable physical system that can exhibit a large, non-linear response to an environmental stimulus. By adding light-sensitive
moieties to the mesogens responsible for liquid crystalline order, one can create elastomers that will change shape in response to ultraviolet light. This provides a basis for a “write once, read many times” (WORM) memory. Information is encoded in an array of LCE microposts through a magnetic field during cross-linking, and then read out by introducing a light source. The system will return to its initial state upon removal of the stimulus, allowing the reading process to be repeated without altering the system. We developed a finite element simulation code to study components of such a system. Using our simulation method, we can predict the micropost deflection as a function of the preset nematic director and the incident angle of the light. We make comparisons to available experimental results and describe new findings that reveal how light can be used to regulate the structure of an array of multiple, interacting LCE microposts. These studies point to new ways of utilizing the LCE arrays for technological applications.

2D Binary Microgel Alloys for Soft Nanotemplating Miguel Angel Fernandez Rodriguez, Maria-Nefeli Antonopoulou, Fabio Grillo, Dominic Gerber and Lucio Isa; Interfaces, Soft Matter and Assembly, Department of Materials, ETH-Zurich, Zurich, Switzerland.

2D binary colloidal alloys are useful structures as colloidal models and for nanofabrication applications. Up to now, only close-packed binary colloidal assemblies on a substrate have been reported. We instead report a versatile sequential deposition method using differently sized PNIPAM based microgels. We are able to produce complex assemblies with decoupled density gradients for the two particles and with fine control over the interparticle distance. The delicate interplay between capillary attraction and steric repulsion at an oil-water interface allows obtaining a broad range of crystalline microstructures. After deposition on a silicon wafer, such assemblies can be further used as masks for wet etching to obtain Vertically Aligned Nanowires (VA-NWs) with applications in photonics, cell transfection or superhydrophobic surfaces. We synthesized microgels and used a Langmuir trough to deposit the microgels from the water/hexane interface onto silicon substrates. In order to get the binary assemblies, sequential depositions of the microgels of different sizes were performed. This protocol allows the independent control of the interparticle distance for each particle type, e.g. achieving a gradient of interparticle distance for the small microgels while the big microgels are kept at a fixed interparticle distance. Moreover, through the fine-tuning on the microgel architecture and of the deposition parameters, square lattices can be obtained thanks to a fine balance between capillary quadrupolar attraction and steric repulsion at the water/hexane interface. AFM images were taken to characterize the transferred assemblies and HF wet etching enabled producing VA-NWs using the binary colloidal assembly as masks for metal-assisted chemical etching. Such VA-NWs have interesting optical properties, ranging from iridescence to structured colors and wavelength modulation, depending on the geometry of the VA-NWs, which we characterized with reflectivity measurements and compared to simulations.

11:30 AM SM06.09.04
Field-Induced Reconfigurable Assembly of Spherical Ionic Microgels into Crystals and Microtubules Brittita Joseph Bonifaç1, 2 and Peter Schurtenberger1; Physical Chemistry, Department of Chemistry, Lund University, Lund, Sweden; 2Centre for Nanoscience and Nanotechnology, Sathyabama Institute of Science and Technology, Chennai, India.

Electric field induced assembly or field-directed self-assembly is a very attractive path towards the creation of 3D ordered structures. Previous experiments with soft ionic microgels (5 mol% cross-link density) have indeed revealed the existence of different fluid and ordered and amorphous solid phases as a function of effective volume fraction and field strength [1]. Moreover, they provided evidence for a novel field-induced phase transition scenario with multiple path-dependent routes for phase-transition kinetics, and the existence of long lived metastable crystal states that were thought to be due to the ability of these particles to partially interpenetrate and form long-lived entangled states [1,2]. Here we now use ionic microgels in order to investigate the importance of particle softness on the resulting field-induced state diagram. The ionic microgels used in the study are made up of poly(N-isopropylacrylamide)-co-acrylic acid (PNIPAM-co-AAc). The more densely crosslinked particles (10 mol%) at low particle concentrations and at low field strengths (at 0.5 and 0.6kV/cm) form a fluid string phase. As the field strength is further increased, the particles assemble into islands of small body-centered tetragonal (BCT) crystals co-existing with a gas phase. These results are consistent with the field measurements on moderately crosslinked microgels [1,2]. At higher field strengths however, the BCT sheets fold and adopt a regular tubular structure reminiscent of a single-walled microtubule. The tubular assembly can be reconfigured by switching ON/OFF the field. While ellipsoidal particles (polystyrene core, PNIPAM-co-AAc shell) polarized in an external electric field were observed to associate into well-defined tubular structures [4], no comparable self-assembly processes have been reported for hard or soft spherical particles so far. Here we present a systematic study of the field-induced self-assembly of ionic microgels as a function of crosslink density, particle concentration, field strength, and discuss the underlying phase transition kinetics and pathways for the various liquid-solid and solid-solid transitions present.

Soft Material Programming Through the Spatiotemporal Release of Oligonucleotides Moshe Rubanov, Phillip J. Dorsey, Dominic Scalise, Wenyu Wang and Rebecca Schulman; Johns Hopkins University, Baltimore, Maryland, United States.

The programmable spatiotemporal release of molecular outputs is a prerequisite for creating new classes of stimuli responsive biomaterials capable of executing sensing and computational programs. Here we demonstrate the ability to fabricate heterogeneous micromaterials that implement sequentially activated molecular cascades with programmed timescales of activation and release from a hydrogel. These materials use DNA-based strand-displacement to direct the sequential release of short oligonucleotides from spatial domains. Maskless photolithography enables the spatial sequestration of acrylate-modified short oligonucleotides for local hybridization reactions within hydrogels at sizes of tens of microns. To control temporal release, we used a toehold mediated DNA strand displacement reaction cascade that allows for the controlled release of oligonucleotides at 8-hour intervals. This system could be used to direct chemo-mechanical actuation within soft-robots or as a local chemical clock to sequentially coordinate movement. The programmed release of DNA oligonucleotides from hydrogel substrates enables the scalable development of DNA-based reaction-diffusion systems that regulate the availability of oligonucleotides at different points in space and time.

SESSION SM06.10: Towards New Applications of Colloidal Gels II
Session Chairs: Michel Cloitre and Shin-Hyun Kim
Thursday Afternoon, April 25, 2019
PCC North, 200 Level, Room 228 A

1:30 PM *SM06.10.01
Why Microgels are Ideally Suited to Improve the Performance of Next Generation Solar Cells Brian Saunders; School of Materials, University of Manchester, Manchester, United Kingdom.

Microgels are well-known swellable colloidal gel particles that have been studied for more than 80 years. They have excellent colloidal stability in their swollen (micрогel) state due to their inherently low effective Hamaker constant and this is augmented by steric and electrostatic repulsion. Microgels also have excellent synthetic versatility which enables water- or organic-swelling microgels to be synthesised in a scalable manner (to the multi-tonne scale). In less than a decade the power conversion efficiency of solution processable perovskite solar cells (PSCs) has, remarkably, increased from a few percent to greater than 23%. This incredible rate of efficiency increase is unprecedented in the history of solar cell research. PSCs are remarkably tolerant to additives and are scalable to, potentially, multi-megawatt deployment scale at low cost. In this discussion an overview of our recent work using microgels as additives to improve the performance of PSCs is discussed. Polystyrene microgels enable lower concentrations of expensive conjugated polymers to be used for the hole-transport matrix part of PSCs and also improve the stability[1]. Poly[N-vinylformamide] microgels enable micropatterning of the perovskite capping layer of PSCs to produce an unexpected disordered inverse opal morphology which improved the efficiency compared to control devices[2]. Recent results obtained using microgels in other parts of the solar cells to enhance PSC performance will also be presented. Because microgels and PSC technologies can be combined in a variety of ways to give performance benefits and both are potentially low cost this hybridisation of old and new technologies has a bright future.
Stable, inexpensive and high-performance CO2 separation membranes are of significant interest as a key materials to sequester CO2 from exhaust gases of fire plants. In order to achieve the membranes procedure to create defectless CO2 permeable membranes which thickness is smaller than micrometer scale have to be developed. We have reported that temperature responsive hydrogel-particles containing amine groups can reversibly absorb large amount of CO2 in response to the temperature dependent phase transition of hydrogels (JACS, 134, 18177, 2012. Angew. Chem. 53, 2654, 2014). In this presentation, we report that ultrathin hydrogel membranes of thickness below 100 nm can easily be prepared by deposition of the microgel particles on the top of porous films. The membranes showed CO2 selective permeability against nonacidic gases such as N2.

Mussel Adhesion Needs a Battery

Herbert Waite; MRL, University of California, Santa Barbara, Santa Barbara, California, United States.

The wet adhesion of mussels, although incompletely understood, has inspired numerous translational studies seeking to capture its strength, toughness and versatility. Given the Dopa-rich interfacial proteins in mussel adhesion, most translations depend on adopting Dopa or catechol functionalities for a variety of synthetic backbone chemistries. Although notable short-term successes have been reported, a robust and durable adhesive formulation based on catechol or Dopa has yet to emerge. The reason for this is fairly obvious: catechols including Dopa are prone to oxidation. Although oxidation products such as quinones have some use in promoting cohesion as cross-linking agents, they have poor adhesion on most surfaces. Despite the very oxidizing influence of seawater, catechol-mediated mussel adhesion does not succumb to this limitation. Indeed, adhesive plaque interfaces remain reducing after months of service in the sea. Current evidence supports that mfp-5 with >25 mole % Dopa deposited as a 10-20 nm thick film is the functional adhesive bound to surfaces by its Dopa and lysine functionalities. On top of this, sits an mfp-3 rich hydrogel about 100-200 nm deep. Mass spectrometry reveals that the Dopa in mfp-3 remains intact despite the ambient oxidizing environment. As mfp-3 variants coacervate during deposition there is conjecture that coacervates are insulating Dopa but the mechanism for this is not yet understood. Certainly, mfp-3 in aqueous solution at pH8 undergoes spontaneous oxidation. Segregation of different redox-active proteins into specific compartments resembles a battery. The mfp-5 containing adhesive film is one compartment; mfp-3 and mfp-6-containing coacervate droplets is another. These two share a common but immiscible interface for redox exchange. Assuming that the film of mfp-5 is vulnerable to oxidative damage and given that mfp-3/6 within coacervate droplets is shielded from oxidation, the reservoir of reduced mfp-3 should offer electrons and protons to restore damaged Dopa in mfp-5 until mfp-3 and -6 are depleted. The significance of this to translational studies is clear: if the aim is to make synthetic adhesives based on Dopa, then the adhesive has to be engineered to include a redox reservoir or battery that will maintain the surface-bound catechols against oxidative damage.

Bio-Inspired Programmable Surfaces for Switchable Wetting and Adhesion

Kurtis A. Laqua and Benjamin D. Hatton; University of Toronto, Toronto, Ontario, Canada.

The microstructures of natural surfaces, such as plant leaves, reptile skin and ciliated tissues can be actuated to provide dynamic, adaptive properties of wetting, transport, and adhesion [1]. Examples include the gecko and the octopus, which can reversibly switch their adhesion to a wide variety of opposing surfaces. Yet, most synthetic surface structures are static, lacking an ability to change dynamically in response to their environment or an applied signal. This work explores how adhesion, friction, and wetting can all be controlled through bio-inspired dynamic surfaces. By engineering the shape, scale, and spacing of surface microtopography on silicone layers, interfacial contact and interaction can be modified. Our dynamic microtopography devices will show droplet wetting transition from Cassie-Baxter to Wenzel, switchable adhesion to structured or flat surfaces and tunable friction capable of ~50% change in peak frictional force. [1] Gorb S. Functional surfaces in biology: mechanisms and applications. CRC Press; 2006. p. 381-97.

Sticking Like Barnacles—Unraveling and Mimicking a Natural Adhesive

Christopher So1, Kenan Fears1, Elizabeth Yates2, Luis Estrella1 and Kathryn Wahl1; 1Chemistry, U.S. Naval Research Laboratory, Washington, District of Columbia, United States; 2Chemistry, U.S. Naval Academy, Washington, District of Columbia, United States.

Macro fouling organisms have plagued mariners and scientists alike since the sailing of the first ships in the ocean. Even today, combating fouling is a global challenge with great economic burden on the world’s navies and maritime operations. Over the last year, our team has applied modern bioinformatic approaches to produce a new, more comprehensive picture of the specialized proteins found in the adhesive of one of the most tenacious fouling organisms in the ocean: the acorn barnacle. Barnacles produce a micron-thick layer of ordered amyloid-like nanofibers from proteins that function as a permanent wet adhesive. Recent proteomic sequencing of the dissolved barnacle glue reveals that, like other fibrous biomaterials such as silk and elastin, small and flexible amino acids play a key role in forming the mesh-like adhesive. Their well-defined, modular, nature result in novel biomaterials that serve many purposes: adhesion, durability, bacterial resistance, and even potent enzymatic activity. Fibers are shaped by a highly conserved domain alternating between short 20-residue low complexity sequences (Gly/Ser/Thr/Ala residues) and regions with alternating charged and non-charged side chains, with more than 80 such domains in just five proteins. The adhesive properties of these unique sequences and their function in an amyloid-like structure remain unclear.

To develop the sequence basis of cement formation, we design short synthetic peptides from homologous cement proteins. Short synthetic peptides demonstrate that materials are formed through a set of patterned sequences that exert specific control over polymerization, curing, and adhesion using recognition mechanisms similar to how globular proteins recognize each other, i.e., structure-based recognition. Specifically, we find that patterned charge domains recognize and activate otherwise dormant peptide sequences through recognition of a unique anti-parallel beta sheet structure as measured by FTIR. While charged domains favor an anti-parallel structure, sequences without charged domains switch fibril assembly to parallel beta sheet aggregates. Our work demonstrates that the structures produced by patterned cement sequences, and the progression of domain interactions, are critical in polymerizing materials that resemble the natural adhesive. Finally, to understand whole protein self-assembly, we demonstrate that emergent platforms such as engineered bacterial biofilms are a viable route for the growth of recombinant cement materials as well as for mapping protein and peptide interactions. Synthetic and recombinant adhesive materials provide a route to scale up and study a scarce but potent class of multifunctional adhesive nanostructures produced by one of the oldest adversaries of naval and maritime technologies.

Functional Superhydrophobic and Icophobic Coatings Made of New Biomimetic “Gecko Leg” Soft dendritic Colloids

Austin Williams, Sangchul Roh and Orlin Velev; Chemical and Biomolecular Engineering, North Carolina State University, Raleigh, North Carolina, United States.

We will report how coatings and nonwovens with outstanding superhydrophobic and icophobic properties can be made from novel types of polymer particles with controlled morphologies and interactions. First, we will introduce the synthesis of a new class of particles named soft dendritic colloids (SDCs). These particles are hierarchically structured, with a branched corona of nanofibers spreading out in all directions. They are nanomanufactured by multiphasic polymer precipitation under intensive shear. The nanofiber corona around these “gecko leg” particles endows them with extraordinary strong adhesion to almost any surface and to each other, and enables unique structure-forming abilities. These particles exhibit the phenomenon of “contact splitting”, which is displayed in the remarkable adhesion of gecko feet. The morphological similarity of the SDCs to the gecko lizards’ setae endows the SDCs with excellent dry adhesion and cohesion properties. The hierarchical surface roughness resulting from the overlapping SDC micro- and nanofibers allows the facile formation of superhydrophobic and superhydrophilic coatings depending on the properties of the polymer used. The adhesion of SDC coatings to substrates can be further improved both through the addition of a poly(dimethyl) siloxane (PDMS) binder and by creating bicontinuous networks of SDCs composed of different polymers. The addition of a PDMS binder and formation of bicontinuous SDCs network modify the surface roughness and contact angle of the SDC coatings and lead to improvements in durability, wettability, and anti-icing properties, including increased ice nucleation time and decreased ice adhesion strength when compared to uncoated and SDC coated substrates. The new functional coatings can find applications in numerous industrial and consumer products.

Morphological Examination of the Adhesive Setae Across the Toepads of Anolis Lizards—Insights into the Fundamentals of Fibrillar Adhesives

Michael C. Wilson1, Austin Garner1, Anthony Russell2, Peter Niewiarowski2 and Ali Dhimojwala1; 1University of Akron, Akron, Ohio, United States; 2University of Calgary, Calgary, Alberta, Canada.

Gecko-inspired fibrillar adhesives have become increasingly prevalent over the past two decades because of the multifunctional behavior exhibited in gecko adhesive toepads,
including self-cleaning, controlled releasability, and reversibility. Many challenges remain in replicating this multifunctionality, a major one being understanding the role of the complex morphology: microscopic hierarchy of the adhesive setae and their macroscopic patterning across the toepad. Deconvolution of the structural effects in producing the desired properties remains daunting, because setal structure is very complex. However, fibrillar adhesion has been independently evolved by Anolis lizards, and these lack the hierarchical branching of their setae. Thus, anole setae more closely resemble the theoretical models used to explore the principles of fibrillar adhesion and the synthetic seta-like fibrils that have been employed in the generation of synthetic adhesives. In this study, we employ scanning electron microscopy to examine the setal dimensions and patterning of Anolis lizards across the toepad and compare our findings with the attributes of the fibrillar adhesives of geckos. Detailed morphological characterization of Anolis adhesive setae provides information which can be used to understand the potential emergent properties of hierarchical complexity and patterning of lizard fibrillar adhesives.

SESSION SM07.02: Bioinspired Materials—From Basic Discovery to Biomimicry II

Tuesday, April 23, 2019
PCC North, 200 Level, Room 226 C

1:30 PM *SM07.02.01  
Bioinspired Elastin-Based Adhesives  

Julie C. Liu; Purdue University, West Lafayette, Indiana, United States.

A successful biocompatible adhesive must be biocompatible, set in a wet environment, match the mechanical properties of the surrounding tissue, and have proper adhesive and cohesive properties. Current technologies do not meet these needs. We developed bioinspired protein-based adhesives that combine adhesion from DOPA residues found in mussel adhesive proteins with the mechanical properties of elastin, which can also coacervate in response to the environment. We demonstrated that these proteins are cytocompatible, provide the strongest bonds of any rationally designed protein when used completely underwater, and can be easily applied underwater because they coacervate in physiological conditions. Recently, we investigated different formulations in physiologically relevant environments by using pig skin substrates and curing in a warm, humid environment.

2:00 PM SM07.02.02  
Extremely Tough Cyclic Peptide Nanopolymers  

Manoj K. Kolel-Veetil, Luis Estrella, Christopher So and Kenan Fears; Chemistry Division, U.S. Naval Research Laboratory, Washington, District of Columbia, United States.

We present a new class of bioinspired nanomaterials that are stabilized by a combination of covalent and hydrogen bonds. Prior work by others has shown that cyclic peptides can self-assemble to form supramolecular assemblies through backbone-backbone hydrogen bonding. To improve upon this molecular architecture, we develop a synthesis route to polymerize cyclic peptides and form a linear polymer chain that can transition between a rigid nanorod and a “soft” unfolded conformation. For a cyclic peptide polymer containing amine-terminated side chains on each ring, we demonstrate that self-assembly can be triggered in aqueous solutions by varying the pH. We measure the elastic modulus of the rigid nanorods to be ca. 50 GPa, which is comparable to our molecular dynamics (MD) prediction (ca. 64 GPa). Our results highlight the uniqueness of our molecular architecture, namely its exemplary toughness (up to 3 GJ m⁻³), in comparison to other cyclic peptide-based assemblies. Finally, we demonstrate that the amphilic cyclic peptide nanoropes are capable of inserting into the membrane of both gram-negative and gram-positive bacteria, and causing their deaths by disrupting their osmotic pressure.

2:15 PM SM07.02.03  
Biomolecules for Non-Biological Things—Materials Construction Through Peptide Design and Solution Assembly  

Darrin J. Pochan; University of Delaware, Newark, Delaware, United States.

Self-assembly of molecules is an attractive materials construction strategy due to its simplicity in application. By considering peptide molecules in the bottom-up materials self-assembly design process, one can take advantage of inherently biomolecular attributes: intramolecular folding events, secondary structure, and electrostatic interactions; in addition to more traditional self-assembling molecular attributes such as amphiphilicity, to define hierarchical material structure and consequent properties. A new solution assembled system comprised of theoretically designed coiled coil bundle motifs will be introduced. The molecules and nanostructures are not natural sequences and provide opportunity for arbitrary nanostructure creation with peptides. With control of the display of all amino acid side chains (both natural and non-natural) throughout the peptide bundles, desired physical and covalent (through appropriate “click” chemistry) interactions have been designed to produce one and two-dimensional nanostructures. One-dimensional nanostructures span exotic rigid rod molecules that produce a wide variety of liquid crystal phases to semi-flexible chains, the flexibility of which are controlled by the interbundle linking chemistry. The two dimensional nanostructure is formed by physical interactions and are nanostructures not observed in nature. All of the assemblies are responsive to temperature since the individual bundle building blocks are physically stabilized coiled coil bundles that can be melted and reformed with temperature. Additional, novel nanostructures to be discussed include uniform nanotubules as well as the templated growth of metallic nanoparticle on and in peptide nanostructures. Included in the discussion will be molecule design, hierarchical assembly pathway design and control; click chemistry reactions; and the characterization of nanostructure as well as inherent material properties (e.g. extreme stiffness, responsiveness to temperature and pH, stability in aqueous and organic solvents).

2:30 PM SM07.02.04  
Solution-Free Fabrication of Robust Silk Materials  

Chengchen Guo, Chunmei Li and David L. Kaplan; Biomedical Engineering, Tufts University, Medford, Massachusetts, United States.

Silk fibers produced by silkworms and spiders are protein-based biomaterials with a combination of excellent mechanical properties and biocompatibility. Due to these attributes, silk-based biomaterials are useful for fabricating bio-devices with important functional performance. Considerable effort has been made in developing techniques to process native silk fiber materials into silk solutions, including aqueous and solvent systems. These solutions can then be processed to generate a variety of regenerated silk materials such as films, foams, sponges and tubes. However, the tendency of silk fibroin to self assemble in solution can result in some limitations in terms of process control windows. To overcome these potential limitations and offer additional processing options for silk materials, new solution-free methods based on lyophilized silk powders help. Further improvements could be made by using silk as a raw material from the start, avoiding the complexities of processing windows and also the addition of lyophilization steps. Such processes could lead to new silk-based materials such as for films, plates, screws, bricks, and sponges prepared with tunable mechanical properties. Such a new approach should impact the field of silk device fabrication by providing new processing routes for the protein and avoiding some of the challenges with more traditional options.

2:45 PM SM07.02.05  
Natural Materials for Daytime Radiative Cooling—An Example of Regenerated Silk Fibroin Film  

Yu-Hsuan Chen¹, Dehui Wan² and Hsuen-Li Chen²; ¹Institute of Biomedical Engineering, National Tsing Hua University, Hsinchu, Taiwan; ²Department of Materials Science and Engineering, National Taiwan University, Taipei, Taiwan.

Natural materials have been widely explored and applied in various fields, especially for biomedical applications. Nowadays, problems of energy crises and climate change pose a threat to human living. The consumption of energy leads to greenhouse gas emission, which causes global warming. Therefore, developing eco-friendly cooling systems is the significant issue that people are still working on. However, most of the current cooling methods needs energy to carry heat away. Radiative cooling is a passive cooling method which can lower the temperature without any energy consumption. It means that the heat can radiate to outer space through a transparency window of the atmosphere between 8-13 μm. In the past, radiative cooling during nighttime has been studied. Radiative cooling during daytime, however, is more difficult to achieve because the cooler needs to have not only high emissivity in the atmosphere windows but high reflectivity in the solar spectrum. Recently several methods have been applied to daytime radiative cooling. For example, photonic solar reflector and thermal emitter, such as HfO₂ or SiO₂ and metamaterial film, can reflect incident sunlight while emitting in the atmosphere windows. However, nano-photonic approaches require complicated fabrication and high cost, which is difficult to scale up to meet the requirements of commercial applications. While the radiative cooling technology based on natural materials is still not well studied, natural materials may have the great potential for applying on daytime radiative cooling devices.

Herein, we studied different kinds of natural materials, such as seashell, wood, bamboo and cocoon. All samples were cut into 2 x 2 cm² for optical measurements. Interestingly, all of them displayed very high absorption (i.e., high emissivity, > 80%) in broadband IR wavelength range (8-25 μm), which were mainly attributed to their intrinsic chemical
composition, such as proteins, cellulose, minerals and some small molecules due to their vibrational transitions. Noteworthy, compared to the typically narrow IR emissivity peaks of artificial daytime cooling materials, the extremely broadband emissivity peak of the natural materials could cover two atmospheric windows (8-13 μm and 16-25μm). The result means they could transfer more heat to outer space via thermal radiation and consequently are able to more efficiently lower the temperature. Among the natural materials, silk cocoon was chosen for further investigation because of its 90% absorption at IR wavelengths and the simple, well-studied fabrication process for different morphologies. We fabricated silk fibrils (SF) thin films from natural cocoon threads using the reported protocol. By adjusting the concentration of SF solution, the thin films with different thickness of 10 and 20 μm could be obtained for optical measurements. We observed that the 20-μm SF film shows a higher average emissivity of 70 % in the atmosphere windows region than the average emissivity of 50 % for the 10-μm SF film, indicating that the film thickness is a key factor. Thus, we performed a thin-film optical simulation to find the optimal thickness for the SF film. Finally, we found that the emissivity gradually increased with thickness and reached a maximum value of 95 % as the thickness of 100 μm. Further optical analyses and cooling temperature measurements for the optimized SF films are in progress and will be reported at the conference. Also, other natural materials and their optical properties as well as cooling capacity evaluations will be reported.

3:30 PM *SM07.02.06

Rational Engineering of Protein-Based Biomaterials Using Folded Globular Proteins—From Single Molecule Features to Macroscopic Traits Hongbin Li; University of British Columbia, Vancouver, British Columbia, Canada.

Elastomeric proteins function as molecular springs in their biological settings to establish elastic connections, and provide mechanical strength, elasticity and extensibility. To fulfill their biological functions, elastomeric proteins have evolved to assume different structures, from simple random coil-like structure to more sophisticated beads-on-a-string conformation, and exhibit distinct mechanical properties. The development of single molecule force spectroscopy techniques has made it possible to directly probe the mechanical properties of such elastomeric proteins at the single molecule level and allowed to understand molecular design principles of these complex protein polymers. This knowledge has enabled us to engineer novel elastomeric proteins to achieve tailored and well-defined nanomechanical properties. Going a step further, we have started to employ these novel elastomeric proteins as building blocks to construct protein-based biomaterials, which in turn provide an ideal system to understand how single molecule nanomechanical features are translated into biomechanical properties of macroscopic materials. These studies will pave the way to utilizing proteins as building blocks to engineer new generations of protein-based biomaterials for diverse applications in biomedical engineering as well as material sciences.

4:00 PM SM07.02.07

Biometric Dynamic Supramolecular Assembly of Peptide Nanostructures Erik D. Spoerke; Jeffrey Vervacke, Brad Jones, Derek Nelson, Sara Russo, Bollinger Jonathan, Mark Stevens and George Bachand; Sandia National Laboratories, Albuquerque, New Mexico, United States.

Supramolecular filaments, such as microtubules (MTs), are key elements behind many of the dynamic and responsive behaviors in biological systems. In particular, MTs enable key processes ranging from intracellular cargo manipulation or changing the shape of a cell to separating genetic materials during cell division. MTs undergo a remarkably dynamic, often cyclic, assembly and disassembly process, known as dynamic instability. Key to the dynamics of the MT system is the balance between the driving forces behind MT assembly and the destabilizing influences that lead to MT depolymerization. While MT assembly is driven by a complex series of intramolecular attractive forces that bring together the tubulin heterodimer building blocks, destabilization of these attractive forces by changes in tubulin molecular shape, variations in temperature, or molecular interference with tubulin binding will cause the MTs to disassemble. Here, we explore how these concepts affect supramolecular assembly of synthetic peptides, based on the tubule-forming peptide, diphenylalanine (FF). We specifically discuss how this system mimics biological concepts of inherent supramolecular instability. We further show how the systematic incorporation of light-responsive, shape-changing azobenzene derivatives enables the use of variable molecular morphology to controllably change both to the stability and morphology of self-assembling peptide nanostructures. Through microscopic and spectroscopic characterization of systematically-modified FF peptide assemblies, we explore the mechanisms behind this dynamic behavior. Taking inspiration from such natural systems, we can learn to control critical, competitive molecular influences that regulate dynamic materials assembly. Understanding these processes will advance the development of new classes of adaptive and reconfigurable materials.

4:15 PM SM07.02.08

Vibrational Spectroscopy of Nanofibrillar Spider Silk Qiue Wang¹, Patrick McArdle², Stephanie Wang², Ryan Wilmington², Doyle Weishar³, Zhen Xing³, Muntaz Qazibush³ and Hannes Schniepp¹; ¹Applied Science, The College of William & Mary, Williamsburg, Virginia, United States; ²Physics, The College of William & Mary, Williamsburg, Virginia, United States.

The origin of spider silk’s superior mechanical properties has been intensively studied for several decades. It is widely accepted that such appealing properties originate from the hierarchical structure of silk threads. Although the protein sequence and macroscopic morphology of the silk fiber are well known, our understanding regarding structural organization for length scales in between is still limited. Nanofibrils have been suggested as an important building block in this intermediate length scale. However, no consensus model regarding their concentration in spider silk fibers or even their dimensions has emerged, which has hindered a systematic analysis of these materials. We study the silk ribbons (major ampullate (MA) silk) of the recluse (Loxosceles) spider, which entirely consist of 20-nm thin nanofibrils. This much simpler silk system thus provides an excellent opportunity to study its structure-property relations. Having performed polarized Fourier transform infrared (FTIR) and polarized Raman spectroscopy on single fibers of this silk, we know that the spectra stem solely from nanofibrils. This has allowed us to quantitatively relate the relative orientation and volumetric percentage of β-sheets vs. other types of protein secondary structures directly. Hence, our approach provides a path toward a significantly improved understanding of the structure of this protein-based material and useful insights towards replicating its merits in synthetic fibers.

4:30 PM SM07.02.09

Nanoscopic Structures and Morphological Phase Transitions in a Quaternary System of Fatty Alcohol and Cationic Surfactant Emily Wonder¹, Sumanth N. Jamadagni², Fred C. Wiroko¹, Haoran Song¹ and Cursy Safinya¹; ¹Materials, Physics, Molecular, Cellular, and Developmental Biology Departments, University of California, Santa Barbara, Santa Barbara, California, United States; ²Sharon Woods Innovation Center, The Procter & Gamble Company, Blue Ash, Ohio, United States; ³Mason Business Center, The Procter & Gamble Company, Mason, Ohio, United States; ⁴Singapore Innovation Center, The Procter & Gamble Company, Singapore, Singapore.

Surfactants and lipids are used in a broad range of applications from basic science to industrial cosmetics, hygiene, and food products. Here, we report on the structure and phase behavior of a system of two fatty alcohols (FA) and a monovalent cationic surfactant (CS). This system provides an excellent opportunity to study its structure-property relations. Having performed polarized Fourier transform infrared (FTIR) and polarized Raman spectroscopy on single fibers of this silk, we know that the spectra stem solely from nanofibrils. This has allowed us to quantitatively relate the relative orientation and volumetric percentage of β-sheets vs. other types of protein secondary structures directly. Hence, our approach provides a path toward a significantly improved understanding of the structure of this protein-based material and useful insights towards replicating its merits in synthetic fibers.

Self-Assembly of Peptides Nanostructures, Characterization and Neuronal Proliferation Prathvushakrishna Machu², Vikas Soni¹, Mariaris Meyes¹ and Milana C. Vasudev³; ¹Georgetown University, Washington D.C., Virginia, United States; ²Bioengineering, BMEBT, University of Massachusetts, Dartmouth, Massachusetts, United States; ³Chemistry and Biochemistry, University of Massachusetts, Dartmouth, Massachusetts, United States.
Self-assembly, involves assembly of molecules into ordered structures to various structures based on different conditions. Self-assembly of structures using biomolecules such as aromatic dippeptides, give rise to functional and biocompatible nanostructures of various forms and biomedical applications. We have synthesized nanotubes using solution-phase self-assembly (SPSA) and plasma enhanced chemical vapor deposition (PECVD), an eco-friendly technique. Quantum chemical computational methods at different levels of theories like dispersion-corrected density functional and Moller-Plesset perturbation were employed to draw insights into the self-assembly process and forces involved.

The biophysicalchemical surface properties of SPSA and PECVD nanotubes were examined using various techniques. Confocal, scanning electron and transmission electron microscopy were used to know the morphological features of these nanostructures. Thermal characterization was carried out using differential scanning calorimetry and thermogravimetric analysis, whereas the chemical characterization was done using Fourier transform infrared spectroscopy, Raman scattering, liquid chromatography-mass spectroscopy, and nuclear magnetic resonance, and circular dichroism spectroscopy, and powder x-ray diffraction. The rat adrenal pheochromocytoma (PC-12), human bone marrow neuroblasts (SH-SY5Y) and neural progenitor cells were used for cytotoxicity studies with MT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide), real-time polymerase chain reaction (q-PCR), and dopamine-enzyme linked immunosorbent assay. The differences in proliferation and expression of the cells on various samples were observed.

Mechanically Manipulation Assisted Assembly of Monolithic 3D Structures from Elastomer Composites
Zheng-Wun Su1, Jiantian Li1, Jiang Liu1, Zhiyang Wang1, Yanbing Zheng1, Jianjiang Chen1, Zhen Xu2

Mechanically guided assembly is considered as a facile and scalable methodology for fabrication of three-dimensional (3D) structures. However, most of the previous methods require multiphase processes for bonding bi- or multi-layers and only result in non-freestanding 3D structures due to usage of a supporting elastomer substrate. Herein, we report a functional elastomer composite that can be transformed to a freestanding and monolithic 3D structure driven by the mechanically guided assembly. Photolithography can be used to selectively tune the mechanical properties of the exposed regions, which exhibit enhanced elasticity compared with the non-exposed regions. Thus, a gradient of the residual strain in the thickness direction makes the films assemble into 3D structures. These 3D structures are also predicted by our computational models using finite element simulations, which yields a reasonable agreement with the experiments. The system designed 2D structures with varied patterns can be transformed to various 3D structures with the control of the residual strain gradient, via key processing parameters including pre-strain, film thickness, and UV exposure time. By integrating different active electronic components on the fabricated 3D structures, potential applications of this 3D platform in electronics were demonstrated. This study offers a unique capability in constructing monolithic and freestanding 3D assembly, paving new routes to many applications such as wearable electronics, soft robotics, and structural health monitoring.

Bioinspired Metal Recovery Using Tannin-Coated Porous Substrates Under Solar Irradiation
Jeong Kim, Kyeong Rak Kim and Yoon Sung Nam

Metal ion recovery from industrial wastewater and electronic waste has attracted increasing attention to recycle precious metals and inhibit emission of hazardous heavy metals. The recovery of the precious metals has been particularly emphasized with a concept of urban mining, which aims to recover precious metals from waste resources. However, current technologies for metal recovery are not cost-effective and environmentally friendly. Recently, bioinspired coating materials have been actively investigated as metal adsorbents. In particular, polyphenols can easily produce excellent coating layers at a low cost and form coordination complexes with various metal ions, which can be used to recover precious metals from the waste. Here, we report a porous bioinspired polyphenolic adsorbent for gold recovery enhanced by light illumination. Mesoporous polymeric microspheres were employed as a porous substrate providing high specific surface area enough to efficiently adsorb gold ions. The polymer substrate was coated with tannin acid via hydrogen bonding, which leads to the coordination of gold ions with galloyl moieties and subsequent photochemical reduction of gold ions. Metal selectivity of the tannin-coated microspheres was investigated using an aqueous mixture of various metal ions. The light-enhanced adsorption and reduction of gold ions were investigated under 1 sun-simulated illumination using adsorption isotherm models. The light-enhanced adsorption and reduction of gold ions was initiated by ligand-to-metal charge transfer mainly due to UV light absorption by tannin acid, and then visible light absorption by the surface plasmon resonance of metallic gold nuclei created additional driving force for the selective reduction of gold ions. This work suggests a new design of environmentally friendly metal adsorbents for efficient noble metal recovery with a low cost by harnessing the solar energy and bioinspired coatings.

Manufacturing Biomimetic Surface with Zinc Oxide-Silver Hierarchical Nanostructures for High Efficiency Water Harvesting
Na Kyong Kim, Dong Hee Kang, Jiyoung Shin and Hyeon Wook Kang

Fresh water collecting technology from fog that known as fog harvesting is one of the solutions to solve water shortage problem specially at desert areas. In this study, we investigate an efficient water collection on a superhydrophilic surface with patterned hydrophobic regions to mimic the *stenocara* beetle surface. Superhydrophilic surface is synthesized on silicon wafer by growth of vertically aligned zinc oxide (ZnO) nanowires. The contact angle of the surface of ZnO nanowires shows 0 degree that is nucleating sites for metal salts. The final BC-curli hybrid membrane decorated with magnetite nanoparticles shows a magnetic response. The surface morphology of the hybrid material was characterized through FESEM and distribution and shape of the nanoparticles was characterized through TEM. The chemical structure and inorganic phase were characterized by FTIR and XRD respectively. Magnetic response of the hybrid material was measured using VSM.

SM07.03.04
Bioengineered Magnetic Bacterial Cellulose Membrane
Vishnu Vadanan Sundaravadanam and Sierin Lim

Bioinspired design develops new solutions in fields that conventionally have few connections with biology. Functional membrane developed through this design approach incorporates natural systems with inorganic compounds to display various functionalities, such as conductivity, magnetism, and hydrophobicity. Bacterial cellulose (BC) membrane produced by *Glucosacetobacter* species forms the skeletal framework and aids in entrapping recombinant *E. coli* bacteria. The recombinant *E. coli* bacteria containing the genetic circuit tuned to produce extracellular amyloid protein, curli, with specific functional peptides. The curli protein in the BC-curli hybrid facilitates the synthesis of magnetite nanoparticle at temperatures below 100 °C by acting as an *in situ* nucleating sites for metal salts. The final BC-curli hybrid membrane decorated with magnetite nanoparticles shows a magnetic response. The surface morphology of the hybrid material was characterized through FESEM and distribution and shape of the nanoparticles was characterized through TEM. The chemical structure and inorganic phase were characterized by FTIR and XRD respectively. Magnetic response of the hybrid material was measured using VSM.
Bioinspired Ionic Diode Membrane with High Ionic Selectivity

Jaehun Jeong1, Jongyoung Kim1, Iluk Kang2 and Kiwoon Choi2; 1NextE&M Research Institute, Incheon, Korea (the Republic of); 2Nano Research Division, National NanoFab Center, Daejeon, Korea (the Republic of).

Biological ion channels embedded in cell membranes with multiple functions have gained attention. Bacterial outer membrane protein F (OmpF) is a multifunctional channel with ionic selectivity, ionic gating, and ionic rectification properties. Also, this plays critical roles in life processes, including maintaining intracellular acidity, keeping osmotic balance, participating in ion exchange, etc. Membranes mimicking these ion channels have important applications in materials science. For practical applications, bioinspired heterogeneous membranes, which generally refer to the composite porous membrane formed by the hybridization of two functional membranes with different chemical composition, have drawn enormous research attention because of their simplicity and potential applications in mimicking various functions of biological ion channels. With respect to maintaining high mechanical strength and promoting the functionality of the fabricated membranes, organic/inorganic hybrid heterogeneous membranes represent an ideal candidate. Here, we prepared a multifunctional heterogeneous membrane by combining a sulfonated tetrafluoroethylene based fluoropolymer-copolymer membrane, Nafion, and a porous anodic aluminum oxide membrane. Despite the morphology of the as-prepared membrane is not nearly as refined as that of the OmpF, we have demonstrated a bioinspired multifunctional heterogeneous membrane capable of achieving high ionic rectification and highly efficient cation-selective gating. We expect that greater levels of multifunctionality can be implemented by optimizing the morphology of the used Nafion, thereby opening new applications in energy conversion, filtration, desalination, etc.

SM07.03.06
Inducing Fluidity in Short Chain, Amphiphilic Block Copolymer Bilayer Membranes via Polymer Functionality

Randolph J. Braun1, Anthony McNeill2, Harrison W. Reid3, Gregory H. Uyeda4, Benjamin P. Thiesing5, Stacy M. Copp6 and Gabriel A. Montano7; 1Northern Arizona University, Flagstaff, Arizona, United States; 2Center for Integrated Nanotechnologies, Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Amphiphilic block copolymers can (ABC) self-assemble into bilayer or monolayer membranes on surfaces. Relatively low molecular weight ABC bio-inspired membranes have previously been reported to be fluid as monolayer but immobile as bilayer membranes. (Goertz et al.) In this study, we investigate low-molecular weight polybutadiene-b-polyacrylic acid (pBD-b-pAA) and polybutadiene-b-polyethylene oxide (pBD-b-pEO) bilayer fluidity as a function of pH. pBD-b-pAA demonstrates the ability to generate fluid bilayers while pBD-b-pPEO bilayers are immobile as previously reported. We investigate the mobility of these short chain ABCs as a function of pH and propose a mechanism for induced fluidity in ABC membranes. Fluorescence recovery after photobleaching (FRAP) and in-situ Atomic Force Microscopy (AFM) are used to characterize the membrane compositions and their functional properties. We report our findings and the potential for generating mobile polymer membranes that more closely mimic fluid bilayers similar to those in biological lipid systems.

Dynamic Wetting of a Droplet on Striped Surfaces

Liang He1,2 and Wenyen Liang1; 1Harbin Engineering University, Harbin, China; 2Bioresource Engineering, Montreal, Quebec, Canada.

Anisotropic wetting of natural creatures like butterfly wings, rice leaves, or bird features have received significant attention due to their potential applications, which include drop transport, microfluidics, and soft robots. The fabrication of surfaces that exhibit anisotropic wetting can be divided into two categories: chemical or geometrical patterns. Considerable effort has been made for understanding the anisotropy in wetting by both experimental and theoretical manners. However, the dynamic wetting behavior of anisotropic wetting is still in initial stages, especially in the theoretical aspect.

Here we present a thermodynamic analysis for the dynamic wetting of anisotropic wetting with the assistance of the Surface Evolver. Two analytic methods are proposed. One method involves simulation of the spreading process of a droplet on anisotropic surfaces. By keeping the droplet volume unchanged, this method is able to predict the maximum advancing contact angle, minimum receding contact angle, and the maximum contact angle hysteresis. In another method, the experimental measurement of dynamic contact angles is simulated with Surface Evolver. By increasing/decreasing the droplet volume and analyzing the wetting stability of the droplet, the minimum advancing contact angle, maximum receding contact angle, and minimum contact angle hysteresis can be determined. Additionally, the variations of droplet shape, three-phase contact line shape, and contact angles with the evolution processes in the two analytic methods are investigated.

Combining the above mentioned analytic methods, the theoretically predicted ranges of dynamic contact angles of anisotropic wetting can be narrowed. This work is also expected to provide guidance for designing surfaces with anisotropic wetting property.

(This work is funded by the International Exchange Program of Harbin Engineering University for Innovation-oriented Talents Cultivation.)

Bioinspired Self-Morphing Hydrogel Programmed by Periodical Stiff Patterns

Heng Deng and Jian Lin; University of Missouri, Columbia, Missouri, United States.

By exploiting the spatial distribution of stiff segments in the soft tissues, plants can achieve complex shape transformations in response to external stimuli. Such natural prototype has inspired biomimetic self-morphing systems by arranging stiff segments in soft polymer matrix. Despite much progress in this research field, it is still very challenging to precisely control the distribution of the stiff segments in soft polymer matrix. As a result, the obtained self-morphing materials could only achieve very simply programmable motions such as bending, folding and twisting. To realize more complex shape changing, typical stiff segments should be delicately incorporated in selective domains of soft polymer matrix. Herein, we report a novel self-morphing system, in which non-shrinkable stiff SU-8 segments are precisely and periodically positioned in highly shrinkable soft hydrogel. Firstly, the photosensitive SU-8 is processed into discontinues periodical patterns with arbitrary designs through regular photolithography. Then the stiff SU-8 patterns are laterally stitched with tough PNIPAm hydrogel by chemical bonding, which would overcome the interfacial mechanical mismatch during the following shape transformation process. Upon dehydration, shrinkage of the hydrogel is constrained by stiff SU-8 patterns, which rises laterally nonuniform strain to create 3D structures. Such shape-changing behaviors are encoded synergetically by the soft-stiff mechanical mismatch and also the geometric periodicity of stiff patterns. By tuning the geometries of SU-8 patterns, we demonstrate a series of elegant reversible 3D shapes, such as alternating concave-convex configurations, 3D checkerboard patterns and other Gaussian curvature surfaces.

SM07.03.09
Extraction and Characterization of Ferulated and High-Methoxyl Pectins from Sugar Beet

Claudia Lara-Espinoza, Elizabeth Carvajal-Millan, Alma Campa-Mada, Jorge Alberto Manquez-Escalante, Jose Alfonso Sánchez-Villegas and Agustín Rascon Chu; Centro de Investigacion en Alimentacion y Desarollo, Hidalgo, Mexico.

Ferulated pectins have polysaccharides from the cell wall of dicotyledonous plants and consist of linear polymers formed mainly by galacturonic acid units linked glycosidically by α-(1,4) bonds. Traditionally, pectins are extracted from citrus peels and apple pomace, although they can also be recovered from minor sources such as sugar beet which have particular structural characteristics, like the presence of ferulic acid bound to galactose and arabinose residues, which enables oxidative coupling between polysaccharide chains. Ferulated pectin gels have become relevant in the design of matrices for the controlled release of molecules of therapeutic interest. In the present study, ferulated pectin was extracted from a sugar beet cvr. grown in Mexico, and composition and physicochemical characteristics were investigated. Pectins presented a galacturonic acid content of 63% (w/w) and residual sugar beet cvar. grown in Mexico, and composition and physicochemical characteristics were investigated. Pectins presented a galacturonic acid content of 63% (w/w) and residual sugar beet cvar. grown in Mexico, and composition and physicochemical characteristics were investigated. Pectins presented a galacturonic acid content of 63% (w/w) and residual

Highly Ferulated Arabinoxylans as Gelling Agents Presenting Antioxidant Activity—The Central Role of Ferulic Acid Content

Ana Maria Morales-Burgos1, Elizabeth J. Queguiner1,2, Benjamín P. Thiesing3, Jongyoung Kim4 and Gabriel A. Montaño5; 1International Exchange Program of Harbin Engineering University for Innovation-oriented Talents Cultivation; 2Harbin Engineering University, Harbin, China; 3Bioresource Engineering, Montreal, Quebec, Canada; 4Mechanical Engineering, National Institute of Technology, Mexico; 5Zoology, Los Alamos National Laboratory, Los Alamos, New Mexico, United States.
Effective antimicrobial surface coatings are critical from both economic and health perspectives. In the present study, we aimed to design novel adhesive antimicrobial peptides (AMPs), based on adhesive proteins in mussels, for one-step coating without the need for prior surface functionalization. In the system, we modified the sequence of a potent synthetic AMP, NKC, with additional repeats of an unnatural amino acid, 3,4-dihydroxy-L-phenylalanine (DOPA), at the C-terminus and evaluated their adhesiveness and antibacterial properties depending on the number of DOPA moieties, using the biochinchonic acid assay and minimum inhibition concentration (MIC) test. The peptide containing 7 DOPA residues aggregated excessively and exhibited higher MIC values than NKC-DOPA. Surface characterization assays such as X-ray photoelectron spectroscopy and atomic force microscopy confirmed that NKC-DOPA was successfully immobilized onto the surfaces of polystyrene, titanium, and silicone, when treated with NKC-DOPA solution for 10 min. The antibacterial effect of NKC-DOPA coating was evaluated via a colony formation assay and the peptide-coated surfaces revealed 99.99% growth inhibition of 10° cells of Escherichia coli, Pseudomonas aeruginosa, and Staphylococcus aureus within 2 h. In addition, NKC-DOPA-immobilized surfaces retained their antibacterial activity for at least 84 days. NKC-DOPA-coated polystyrene, titanium, and silicone catheters displayed no cytotoxicity on a human keratinocyte HaCaT cell line, on an MTT assay, thereby indicating a promising biocompatibility. Furthermore, this coating method involves water-based solutions, which are compatible with most surfaces and are environmentally compatible. Overall, the adhesive AMPs developed in this study have high potential for their use as antimicrobial coating agents to prevent material surfaces from bacterial colonization. This study was supported by the Intelligent Synthetic Biology Center of Global Frontier Project funded by the Ministry of Science and ICT of Korea.

SM07.03.12 Production Conditions to Control Mechanical Properties of BC Membrane Florentina Sederaviciute1, Jurgeita Domskienė1 and Paulė Bekampiene2; 1Kaunas University of Technology, Kaunas, Lithuania; 2Textile Institute, Kaunas, Lithuania.

Bacterial cellulose can be obtained through fermentation of sugared tea with Kombucha fungus. Kombucha drink is considered as health and therapeutic agent. Tea fungus is a symbiotic mixture of lactic acid bacteria and yeasts and during fermentation forms cellulose nano-fibers floating over surface. The cellulose mass with attached bacteria and yeasts is secondary metabolite of fermentation which can be utilized as supplement in animal feed or thrown as waste. Presented research analysis is about possibilities to use BC material obtained through Kombucha fermentation as alternative material for sustainable fashion. The effect of washing and chemical treatment on mechanical, structural and water barrier properties of bacterial cellulose material is analysed. The study concerns bacterial cellulose (BC) properties in three different states: 1. Untreated - as natural fermentation product from acetic acid bacteria Komagataeibacteria xylinus; 2. Pretreated - washed with water and weak alkali (0.5 %) solution; 3. Treated with dimethyl dihydroxyethyleneurea (DMHDEU) solid. Through pretreatment washing procedure fermentation side products (acids, input materials, sugars) are removed from BC membrane therefore this process has influence on material structure and properties. The structure of washed BC material can be described as coherent three-dimensional network of nanofibers with low water vapour permeability and low hygroscopicity. The decrease of deformation and of water barrier properties is recorded after BC washing. Applied chemical treatment has positive influence on properties of BC membrane (increase of material elasticity, strength, hygroscopicity and water vapour permeability) and no influence on BC structural transformation (FTIR analysis).
to gold and can offer a tool for multifaceted soft/hard nanomaterials.

9:30 AM SM07.04.03
(Multi)Functional Structured Hydrogels Inspired by ECM Andreas Lendlein1,2; 1Institute of Biomaterial Science and Berlin-Brandenburg Centre for Regenerative Therapies, Helmholtz-Zentrum Geesthacht GmbH, Teltow, Germany; 2Institute of Chemistry, University of Potsdam, Potsdam, Germany.

The extracellular matrix (ECM) is a complex hydrogel material providing multiple functions and is in this way an impressive example for integrating several functions in a material system. It still is a challenge to completely prepare ECM by synthetic methods. However specific principles for generating functions by molecular design or hierarchical organization can serve as concepts for the biospired design of structured hydrogels.

In this lecture a gelatin based porous hydrogel will be presented, which is prepared in a one step process integrating synthesis and shaping [1]. Its elastic properties on the micro- and the macrolevel can be tailored and cell behavior can be influenced. The hydrogel is also capable of a water induced shape-memory effect. The concept of shape-memory hydrogels [2] has been taken further to a triple-shape effect enabling two subsequent shape changes upon heating [3]. Finally, the application potential of multifunctional structured hydrogels will be outlined.

9:45 AM SM07.04.04
Understanding of Liquid-Liquid Phase Separation of Histidine-Rich Squid Beak Proteins—First Step Towards Development of Bioinspired Functionally Graded Composite Materials Bartosz Gabryeleczk1,2, Hao Cai1, Xianguan Shi1, Konstantin Pervushin3 and Ali Miserez2; 1Department of Bioproducts and Biosystems, Aalto University, Espoo, Finland; 2School of Materials Science & Engineering, Nanyang Technological University, Singapore, Singapore; 3School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore.

Liquid-liquid phase separation (LLPS) of intrinsically disordered proteins (IDPs) has been recently associated with formation of intracellular membrane-less organelles and extracellular load-bearing structures, including biocomposite materials. Although the biophysical principles of LLPS of various synthetic and natural polymer systems have been already well characterized, molecular interactions driving the phase separation of IDPs are still poorly understood.

Histidine-rich squid beak proteins (HBPs) are IDPs that are the main component of the beak of Humboldt squid D. gigan. The beak is an interesting example of a graded biocomposite material with remarkable mechanical properties exhibiting a 200-fold variation in stiffness from the soft base to the hard tip. It is exclusively made of chitin and proteins, i.e. lacks a mineral phase such as calcium carbonate or phosphate - the classical load-bearing component of a hard tissue. Thus, the beak represents a promising model of a fully organic material with load-bearing functions for bioinspired materials engineering.

It has been proposed that the HBPs have crucial role in the beak processing in nature due to their intrinsic ability to undergo LLPS (coacervation) that allows them to gradually impregnate chitin nanofibers scaffold in the beak, condense into a solid structure, and form a dense cross-linked network (final beak structure). By studying a model protein (HBP-1) we showed that phase separation of HBPs is mediated through modular repeats located in their C-terminal part. Using maturation approach, we mapped essential minimal peptide sequences required for LLPS to occur and showed critical role of tyrosine residues. We also demonstrated that the morphology of separated phase (coacervates/hydrogel) is correlated with the hydrophobicity of modular repeats and can be tuned by incorporation of specific sequence motifs into a peptide sequence. Utilizing solution-state NMR, we investigated initialization of LLPS of the HBP-1 protein and HBP-derived model peptide sequence (GY-23). We demonstrated that they phase separate in a pH depended process, triggered by deprotonation of histidine residues followed by stabilization of their tautomeric state by transient hydrogen bonding with tyrosine residues. We proposed that these events lead to hydrophobic inter-molecular interactions which are the main driving force of LLPS. Subsequently, we investigated separated phase (coacervates) of GY-23 peptide using SAXS and showed that it possesses internal structure in nm range which is partly ordered. Finally, we studied the molecular features of coacervate phase with solid-state NMR and showed that tyrosine residues stabilize its structure by hydrophobic interactions. Overall, this work provides essential knowledge and guidelines for rational design of pH responsive peptides with LLPS ability for engineering of bioinspired functionally graded composite materials and other applications such as smart hydrogels and drug delivery systems.

10:30 AM SM07.04.05
Dynamic Transition from α-helices to β-sheets in Polypeptide Superhelices Valeri Barsegov1, Prashant Purohit2, Kenneth Marx1 and Artem Zhurnov3; 1University of Massachusetts, Lowell, Massachusetts, United States; 2Department of Mechanical Engineering and Applied Physics, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 3Moscow Institute of Physics and Technology, Dolgoprudny, Russian Federation.

We employed computational molecular modeling and dynamic force spectroscopy in silico accelerated on Graphics Processing Units (GPUs) to perform the mechanical manipulations at the nanoscale on a variety of superhelical protein fragments. We utilized the atomic structures of coiled-coil motifs available from the Protein Data Bank (PDB) for myosin (PDB entry: 2FXO), chemotaxis receptor (2GUV), vimentin (1GK4), fibrin (2GHG), and phenylalanine zippers (2GUS), as suitable study systems. We used the all-atom Molecular Dynamics simulations on GPUs in the underdamped (low-friction) limit in conjunction with the Solvent Accessible Surface Area (SASA) model of implicit solvation. The coiled-coil motifs listed above vary in size as well as topology of their α-helical packing. We loaded these study systems with tension linearly increasing in time, which fully mimics the tensile testing single-molecule force-ramp experiments. When stretched along the superhelical axis, all superhelices showed elastic, plastic, and inelastic elongation regimes, and underwent a remarkable dynamic transition from the α-helices to the β-sheets, which marks the onset of plastic deformation. Hence, the soft α-to-β phase transition in coiled coils is a universal mechanism underlying the mechanical properties of filamentous α-helical proteins. We analyzed in detail the output from the simulations. Microscopically, the α-helical (β-strand) content decreases (increases) with tension, and the transformation from the α-helices to the β-sheets is a two-state transition. This transition is accompanied by redistribution of the dihedral angles ϕ and ψ and reconfiguration of hydrogen bonds (from the intra-chain to the inter-chain hydrogen bonds). Using Abeyaratne-Knowles formulation of phase transitions, we developed a new theory to model the mechanical and kinetic properties of protein superhelices under mechanical non-equilibrium conditions used in tensile testing assays. We also implemented an approach to map out the free-energy landscapes of polypeptides with coiled-coil motifs, in order to resolve the critical extension and to estimate the energy difference between the α-helical state and β-sheet state per helical pitch. The developed theory was validated by directly comparing the simulated and theoretical force-strain spectra. Interestingly, we found that the coiled coils show a roughly additive contribution to the mechanical strength from α-helices, which weakly cooperate to sustain the stress. We also found that the coiled coils with parallel arrangement of their α-helices provides higher mechanical strength as compared to the coiled coils with antiparallel arrangement. The theory can be used to accurately describe dynamic transitions in wild-type and synthetic superhelical polypeptides under mechanical non-equilibrium conditions, and to model their force-strain spectra available from dynamic force manipulations in situ and in silico. The theory can be applied to any coiled-coil superhelical polypeptide, in order to probe its mechanical and kinetic properties and to map out its free-energy landscapes. The derived scaling laws for the elastic force and the force for α-to-β transition to plastic deformation provide an analytical tool to rationally design novel synthetic biomaterials and nanomaterials with the required mechanical strength and desired balance between stiffness and plasticity.

11:00 AM SM07.04.06
Higher-Order Assembly of Coiled-Coil Peptides for Biomaterial Applications Monesisha Nambiar1, Li-Sheng Wang2, Vincent M. Rotello2 and Jean Chimleiwski1; 1Purdue
The successful application of synthetic biomaterials to their ability to mimic naturally occurring biological molecules and systems. The challenge however, has always been to generate materials with hierarchical assemblies down to the atomic level that have precisely tailored chemical heterogeneities and external stimuli-responsiveness. Self-assembling peptides have recently emerged as a potential avenue for the creation of novel biomaterials because they are materials based on natural building blocks. The knowledge about their sequence-structure relationship coupled with the ability to design and synthesize de novo peptides has sparked an interest in the use of coiled-coil peptides as biomaterials in various fields; tissue engineering, drug delivery, regenerative medicine and bio-sensing to name a few. Our approach utilizes a GCN4 leucine zipper sequence-based coiled-coil trimer that has been radically functionalized with aromatic ligands to build hierarchical assemblies. These higher-order assemblies, which take the form of banded rectangular nanosheets, are formed via electrostatic and aromatic interactions. The dimensions and overall shape of these assemblies vary with the strategic placement and number of aromatic ligands on the monomer backbone. Their assembly was observed to be reversible and can be controlled by adjusting the pH of the solvent medium. Additionally, the unmodified variant of the peptide resulted in the formation of microtubes. Our work showcase how small changes in the peptide sequence can translate into distinct differences in the resulting supramolecular architecture. The possible variety of hierarchical structures make coiled-coils suitable for creating novel biomaterial scaffolds.

11:15 AM SM07.04.07
Cytoskeleton-Inspired Biopolymer Design to Reduce Topological Defects in Polymer Networks

David S. Knoff1, Haley Szczechowski1, Fathima Doole1 and Minkyu Kim2, 3, 4; 1Biomedical Engineering, University of Arizona, Tucson, Arizona, United States; 2Materials Science Engineering, University of Arizona, Tucson, Arizona, United States; 3BIOS Institute, University of Arizona, Tucson, Arizona, United States; 4Chemistry & Biochemistry, University of Arizona, Tucson, Arizona, United States.

In mechanical testing, polymers regularly underperform compared to their theoretical calculations due to defects in the network, including dangling chains, free chains, loops, and various forms of bridge entanglements. Efforts have been made to count the number of network imperfections, however, there are no current methods for reducing defects in physically-associated polymer networks. Well-organized biological networks in cell cytoskeletons contain selective binding mechanisms and rigid-structured proteins that reduce defects, inspiring our polymer network design. In this study, a novel mechanism for reducing network defects was investigated by designing protein polymer mid-blocks with rigid and flexible components in specific ratios and module arrangements.

Protein polymers were designed with a rigid rod block and various lengths of flexible coil blocks to modulate polymer chain stiffness, which can potentially control network defects. The rigid component consists of synthetic ankyrin repeats, known for its 3D solenoid structure. The flexible component includes primary-structured polyelectrolyte protein repeats. These rod and coil protein blocks were genetically inserted into a telechelic associative construct with self-oligomerizing proteins to form hydrogels. To determine the optimal copolymer design that reduces network defects, such as self-loops and dangling chains, we investigated the mechanical properties of hydrogels containing mid-blocks with varying rigid-to-flexible lengths, as well as symmetrical and asymmetrical block arrangements within each protein polymer. The incorporation of rigid components increased the elastic moduli compared to flexible controls, providing evidence that network defects can be reduced in telechelic associative polymers by manipulating chain flexibility.

11:30 AM SM07.04.08
Human Aorta Under Tensile Stress

Sabrina Friebe1, 2, Josephina Haensch1, Christian Ett1 and Stefan Mayr1, 2; 1University of Leipzig, Leipzig, Germany; 2Leibniz-Institut für Oberflächenmodifizierung (IOM) e.V., Leipzig, Germany.

An aortic aneurysm constitutes a local enlargement of the aorta that is identified incidentally in most patients due to absence of symptoms. Prevalence of this disease strongly depends on age, gender and distinct risk factors, including smoking, overweight, hypertension and increased level of blood lipids. In case of an increasing aneurysm diameter, rupture within the aortic wall is an acute threat, so the called aortic dissection. At worst, rupture of the entire aorta arises, the so called aortic rupture. Within an interdisciplinary approach we investigate aortic samples from patients who suffer from an aortic aneurysm and underwent a surgery with regard to their mechanical properties. In doing so, tubular aortic portions were harvested from patients and cut into rectangular shapes, originated from convex, concave and longitudinal parts of the aorta, and stretched until rupture. Clinical data of patients as age, aortic diameter, arterial hypertension, elastin and collagen content or type of aortic valve (bicuspid- or tricuspid aortic valve) were correlated with the Young's modulus to contribute to a better understanding of the role of pathological factors in mechanical properties of aorta.

11:45 AM SM07.04.09
Wrinkling 2.0—Methods for Defect and Crack Prevention, Variation of Employed Materials and Upscaling

Bernhard Glatz, André Knapp and Andreas Fery; Leibniz Institute of Polymer Research Dresden, Institute of Physical Chemistry and Polymer Physics, Dresden, Germany.

Wrinkles form, when a system consisting of a hard, thin layer in strong adhesive contact with a soft, thick elastomer is subjected to in-plane compression, just like skin that wrinkles or mountain ranges that fold. The arising buckling instability can be unrepairable, or a highly periodic surface corrugation with well-defined wavelength and amplitude, when a defined stress-field is applied. Manifold preparation methods are known, such as metal deposition on elastomers, plasma treatment of PDMS or the adhesion of stiff polymeric layers on elastomeric sheets. However, most methods are limited in terms of material and parameter variety, only few perform with more than one elastomer or thin layer material, respectively. Also they comprise side features as cracks and line defects, which form in most wrinkling process and are unpredictable yet. Furthermore, controlled wrinkling is still limited to small size ranges in the square millimeter- and centimeter-range. [1]

We demonstrate a new approach, where line defects are confined and subsequently arranged by modifying the substrate, and cracks are suppressed by the implementation of a specific elasticity gradient. [2,3] Furthermore, we show a new approach that is applicable to versatile layer and elastomer materials, and also unlimited in terms of pattern size. [4] We show the utility of both line defect- and crack-free wrinkles, and of different layer and elastomer materials for large-scale wrinkled areas. Such highly ordered, macroscopic patterns can be applied to biologically functional surfaces, like cell- and virus-repelling material for medicine, anti-fouling surfaces in large area for diverse bio-industrial applications or friction-minimizing interfaces.

technologies are still restricted by their lack of nanopattern variability, processing area, and control of surface chemistry, especially in clinically relevant polymers. In this work, we present a method based on directed plasma nanosynthesis (DPNS) for fabricating freestanding nanopillars in a model fibrous hydrogel, i.e., bacterial cellulose (BC), with the aim of designing antimicrobial interfaces that can prevent bacterial contamination in biomedical devices. DPNS is advantageous for the large-area and short processing time as compared to FIBL and similar approaches. Nanopillars are fabricated in BC hydrogel by DPNS using argon at high fluence, normal incidence, and energies of 1 keV. BC is a natural polysaccharide formed by β-1,4-glucopyranose residues and used in biomedical applications such as wound dressing, artificial corneas, and in skin and blood vessel substitutes. The surface morphology of BC after argon plasma treatment was investigated by focused ion beam with scanning electron microscopy. Structural characterization showed that at low argon doses, the BC ribbon structure exhibited nucleation and growth of holes that progressively building-up leaving behind well-organized nanopillars at high fluences with an average height of 220 nm determined by atomic force microscopy. X-ray photoelectron spectroscopy (XPS) spectra revealed an enrichment of the C-C/H bonds and depletion of oxygen with the preferential removal of C-O bonds. The C-O/C-OH bonds also decreased drastically, whereas the C/O=C-O were only slightly reduced. Because oxygen atoms are responsible for linking the glycopyranose monomers and forming the ring structure in the BC, this would cause the restructuration of the polymer chains via ring opening and chain scissoring, driving nanopillar formation. The surface wettability of argon-treated BC measured within the first 24 h after treatment using the static water contact angle showed that this material was superhydrophilic. By tuning the energy, ion dose, and angle of incidence during DPNS treatment, we found that it was possible to custom design the pillar height and nanopillar density. In summary, the nanopillar structures obtained here in a fibrous hydrogel are of practical significance for the application in various fields such as biosensors, optoelectronics, and antibiofouling interfaces of industrial and clinical importance.

Engineered Polymer Nanopillars with Ultrathin Efficiency and Therapeutic Indices Against Multidrug-Resistant Bacteria and Biofilms
Akash Gupta, Ryan Landis, Cheng-Hsuan Li, Martin Schnurr, Riddha Das and Vincent M. Rotello; University of Massachusetts Amherst, Amherst, Massachusetts, United States.

Overuse of antibiotics has created “superbugs” such as methicillin-resistant Staphylococcus aureus (MRSA) that pose serious threat to global health due to treatment failure and high mortality rates. The threat is further aggravated by chronic infections from biofilms, which exhibit high resistance towards both the host immune response and traditional antimicrobial therapy. Synthetic macromolecules have emerged as an alternative to conventional antibiotic therapy exhibiting broad spectrum activity against antibiotic-resistant bacteria. However, high toxicity towards mammalian cells and concomitant low therapeutic indices have limited their practical applications in clinical settings. Here, we report engineered polymers that can effectively eradicate pre-formed biofilms while maintaining a high therapeutic index against human red blood cells (RBCs). We synthesized a library of quaterary ammonium poly(oxanorborneneimides) possessing different degrees of hydrophobicity and screened their antimicrobial and hemolytic activities. These polymers form 10-15 mm nanoparticles in aqueous solution, increasing their overall cationic charge and molecular mass. We determined that increasing hydrophobicity of the alkyl chains bridging the cationic head group and polymer backbone greatly enhances toxicity against planktonic bacteria while maintaining excellent hemolytic activities towards RBCs (Therapeutic Index >5000). Additionally, nanoparticle polymers readily penetrate and eradicate pre-formed biofilms while still maintaining high therapeutic indices (~120) relative to RBCs. Polymeric NPs demonstrated a 6-log reduction in bacterial count in a biofilm-mammalian cell coculture model. Significantly, we observed that bacteria did not develop any resistance against polymeric NPs even after 20 serial passages. Overall, our engineered polymeric nanoparticle platform shows strong potential as an infectious disease therapeutic and simultaneously provides a rational approach to design novel antimicrobials for long-term combatting of bacterial infections.

2:00 PM SM07.05.03
Biomimetic Moisture Responsive Fabrics
Lihong Liao, Yuen Shing Wu and Jiuntu Fan; Cornell University, Ithaca, New York, United States.

A stoma (plural stomata) is a pore or opening in the epidermis of plant leaves, through which carbon dioxide is received for photosynthesis and water vapor is transpired. A stoma consists of two guard cells, having thicker and inextensible inner walls and outer walls that are thinner and more extensible. The stoma open and close through the swelling and shrinking of the two guard cells in response to environmental stimuli, e.g. high light intensity and high humidity.

In this study, we are fabricating the pores in a breathable fabric to mimic the structure and function of leaf stomata. In the artificial stomata, a special polymer is coated around a slit (“pore”) of the fabric to form “guard cells”. The polymer will bend asymmetrically toward one side under higher humidity (wet), leading the “pore” to open, while it stays still under normal humidity (dry) which keeps the “pore” close. In both conditions, the fabric maintains a flat surface without buckling, which means little effect on the overall dimension of the fabric.

The process is simple and easy to scale. The polymer can be coated via digital liquid dispensers, or various industrial printing techniques, like screen printing or 3D printing. The slit can be cut by laser etching technology, and the dimensions can vary from micro- to millimeters. The dimension change of the pore under “open” and “close” states can be easily measured by the length and wide change, or observed under optical microscope. The fine structure and morphology can be examined under scanning electron microscope (SEM). The air penetration or vapor transmission through the pores can be measured by air permeability tester (e.g. KES-AP) or moisture vapor transmission rate (MVTR) tester.

Deposition Control of LC Polysaccharide at Evaporative Interface to Design Quickly Swelling Oriented Hydrogels
Gargi Joshi1, Kosuke Okeyoshi2, Tetsu Mitsumata2 and Tatsuo Kaneko1;1 Japan Advanced Institute of Science and Technology, Nomi, Japan;2 Niigata University, Niigata, Japan.

[ABSTRACT]

Self-assembly of polymeric liquid crystals (LC) has emerged as a powerful technique to recreate the complex hierarchy found in nature, from simple building blocks. Evaporation is often employed as a driving force to initiate the assembly of LC domains in the solution. By tuning the conditions of drying, it is possible to gain control over their mobility and in turn on the orientation during deposition. Recently, our group reported a macropore-partitioning phenomenon upon drying a polysaccharide aqueous LC solution from a limited evaporative interface.1,2 Vertical membranes were deposited, bridging a millimeter-scale gap between the substrates and formed a highly oriented structure as a result of a non-equilibrium process between polymer deposition and hydration. In this study, in order to generalize this space-partitioning phenomenon and explore structural changes due to temperature variations, we have explored the drying of xanthan gum solution. It is a cholesteric LC polysaccharide commercially used in food industry, cosmetic formulations and as a viscosity enhancer. Most importantly, xanthan gum LC state is intrinsically affected by changes in temperature. By varying the conditions of temperature and initial concentration, the depositions induced in the limited space have been monitored and a comparative phase diagram prepared.3

We observed deposition of a horizontal lid-like membrane preceding the growth of vertical membrane. The restrained availability of space led to a dense layer at the drying interface which resulted in the deposition of this lid structure. To clarify the microstructures of these membranes, the lid and the vertical membrane retrieved after drying xanthan solution at 60 °C were scrutinized in three dimensions. The deposited membranes exhibited an arrangement of fibrous structures with orientations dictated by the experimental conditions and LC mobility. The SEM images showed that the membrane is composed of fibres with ~50 nm diameter in orientation. We also prepared a phase diagram, focusing on the initial polymer concentration, C0 and drying temperature to clarify the effect of the domain’s mobility on the bridging deposition.

Furthermore, the introduction of crosslinking points in the membranes, by annealing at a higher temperature resulted in the formation of oriented hydrogels with quick and reversible anisotropic swelling. Such hydrogels with inherent biocompatibility and fast response rate have great demand for drug delivery, tissue engineering, and biomimicking applications. The imitation of condensation by drying in this work will provide not only a gain in understanding of the self-organization of biopolymers in living systems but also a simplified methodology to design self-assembled biomimetic materials with highly-ordered structures.

Effects of Nanoparticle Composition and Size on the Crosslinking and Mechanical Behavior of Nanoparticle Hydrogels

Brian B. Lynch\(^1\), Jake Song\(^1\), Qiaochu Li\(^2\), Niels Holten-Andersen\(^3\) and Joseph B. Tracy\(^4\); \(^1\)Materials Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States; \(^2\)Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Materials inspired by the byssal threads of mussels are of interest for their strong mechanical properties, which are based on coordination of catechol moieties with Fe\(^{3+}\) ions. A 4-arm polyethylene glycol terminated with catechols (4PEG-c) was used to investigate the chemistry and rheology of crosslinking with a set of different compositions (Fe\(_2\)O\(_3\), CoFe\(_2\)O\(_4\), NiFe\(_2\)O\(_4\), Co, and Ni) and sizes (3-7 nm diameters) of NPs. A ligand exchange process was developed to prepare the samples for dispersion in water and coordination with 4PEG-c to form hydrogels. Raman spectroscopy showed less binding of 4PEG-c to Co- and Ni-based NPs than for Fe\(_2\)O\(_3\) NPs, but rheology measurements revealed significantly slower relaxation times for Co- and Ni-based NPs than for Fe\(_2\)O\(_3\) NPs. We attribute these results to initial binding of catechols to Co- and Ni-based NPs, which could catalyze the oxidation of catechols and drive covalent crosslinking between 4PEG-c molecules. We propose such crosslinking results in a polydopamine-like structure. Thus, Co- and Ni-based NPs can serve as catalysts, drive crosslinking, and slow the relaxation times, only while weakly binding to the catechols. These results provide a foundation for incorporating other types of NPs into synthetic, physical hydrogels and highlight the potential role of Co- and Ni-based NPs in catalyzing crosslinking of catechols.

Molecular Mechanics of Mussel Inspired Polymer Coatings

Peyman Delavarast\(^1\), Katerina G. Malollari\(^1\), Haesin Lee\(^2\) and Phillip B. Messersmith\(^3,4\); \(^1\)Materials Science and Engineering, University of California, Berkeley, California, United States; \(^2\)Mechanical Engineering, University of California, Berkeley, Berkeley, California, United States; \(^3\)Bioengineering, University of California, Berkeley, Berkeley, California, United States; \(^4\)Lawrence Berkeley National Laboratory, Berkeley, California, United States; \(^5\)Chemistry, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Korea (the Republic of).

Inspired by the catechol and amine-rich adhesive proteins of mussels, polydopamine (pDA) has been widely adopted for coating solid surfaces due to the versatility and simplicity of pDA film deposition. Conformal pDA films of thickness 1–100 nanometers spontaneously form at the solid-liquid interface on nearly all types of solids by simple immersion in an aqueous alkaline solution of dopamine. Little is understood about pDA film formation except that oxidation of dopamine gives rise initially to dopamine-quinone and dihydroxyindole. An open question concerns whether the final product is a covalent polymer or a supramolecular aggregate of small molecules and oligomers. We employed single molecule force spectroscopy (SMFS) to show that pDA exhibits characteristic features of a polymer with contour lengths up to 200nm. pDA chains exhibit mostly weak interactions with oxide surfaces with occasional “sticky” points along the contour length, suggestive of a copolymer structure composed of building blocks of variable composition. Our findings provide the first direct evidence for the polymeric nature of pDA, and offer a foundation upon which to better understand and tailor its physicochemical properties.

Mussel-Inspired Coatings of Mesoporous Polymer Particles for Photo-Enhanced Gold Recovery from Electronic Wastes

Kyeong Rak Kim, Jeonga Kim and Yoon Sung Nam; Department of Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Metal ion adsorption from electronic wastes (E-wastes) has received much attention for the elimination of heavy metals and the recovery of precious noble metals. However, cost effectiveness and metal selectivity still remain to be solved. Herein, we introduce a simple method to efficiently increase gold adsorption from metal ion mixtures using bio-inspired polyphenol chemistry under light illumination. Mesoporous poly(ethylene glycol dimethacrylate-co-acrylonitrile) (poly(EGDMA-co-AN)) microspheres were prepared by suspension polymerization and used as polymer templates. The internal surfaces of the polymer templates were coated by polydopamines via the oxidative polymerization of dopamines. The polydopamine layers served as a metal ion adsorbent activated by 1 sun-simulated illumination. The adsorption isotherm curves and maximum capacities of gold ions were evaluated by Langmuir, Freundlich, and BET adsorption models. The maximum amounts of chloroauric ions adsorbed per unit mass of the adsorbents under the 1 sun-simulated light were 25 times higher than the adsorbents in the dark. The gold ions could be removed from the adsorbents in a thiourea solution. Metal ions complex solutions were used to determine the selectivity of the polydopamine-coated particles for gold ions among various metal ions. High adsorption capacity and selectivity toward gold ions at a high concentration (1.5 mM) of a metal ion mixture containing six kinds of metals (Cu, Co, Ni, Pt, Pd, and Au) was demonstrated. The structural properties and the surface chemistry were investigated using SEM, TEM, XPS, XRD, and BET analysis, and the amount of gold ions were analyzed by ICP-MS analysis. Our bio-inspired approach to photo-enhanced adsorption of gold ions using polyphenol chemistry will lead to practical applications for the recycling of the precious metals from E-wastes. This research was supported by Nano-Material Technology Development Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and Future Planning (2017M3A7B4042235).

Hairy Graphenes—Assembling Nanocellulose Nets Around Graphene Oxide Sheets

Rui Xiong\(^1\), Ho Shin Kim\(^1\), Lijuan Zhang\(^1\), Volodymyr F Korolovych\(^1\), Shuaiqi Zhang\(^1\), Yaroslava G Yingling\(^2\) and Vladimir V. Tsukruk\(^1\); \(^1\)Georgia Institute of Technology, Atlanta, Georgia, United States; \(^2\)North Carolina State University, Raleigh, North Carolina, United States.

Self-assembly of diverse natural component is critical for biological phenomena understanding and advanced materials development; however, self-assembly of 2D heterostructural nanosheets from 1D biocolloid is extremely challenging because of complex interactions, geometrical structure, flexibility and limited processing window. Herein, we report a simple, efficient, and universal amphiphility-driven self-assembly strategy to construct 1D stiff nanocellulose into 2D flexible nanosheets with graphene oxide (GO) monolayer as template core. This self-assembly is facilitated by highly tunable amphiphilic interaction via tailoring the surface chemistry of GO nanosheets, resulting in unprecedentedly ultradense nanocellulose coverage. These as-obtained ultradense nanocellulose nanosheets demonstrated record-breaking elastic modulus cellulose nanocomposites, even comparable to single nanocellulose. Additionally, the presence of nanocellulose significantly enhances the surface wettability of hydrophobic rGO nanosheets, enabling the long-term stable rGO dispersion and allowing fast water transport through these hybrid thin films for dye and nanoparticles separation.
Fiber-reinforced materials are used increasingly in many high-end technical applications including aviation and space flight, automotive, and also for sports equipment and medical applications as e.g. for protheses and orthoses. Technical fiber-reinforced composite materials share many properties with their biological counterparts and proved to be very suitable for the fabrication of innovative biomimetic products. Examples for light-weight materials with excellent mechanical load bearing properties and an benign fracture behavior include biomimetically optimized branched fibrous composite materials with gradient structure and with or without concrete filling inspired by branched stems of dragon trees (Dracaena spp.), dwarf umbrella trees (Schefflera arboricola) and columnar cacti (e.g. Mammillaria sp. or Pachycereus sp.). However, fiber-reinforced materials systems can do much more than stiffening as well as in biology and in technology. The hierarchically structured fibrous bark of the giant sequoia (Sequoia gigantea), for example, represents not only a brilliant heat insulator and is self-extinguishing (protection against wild fires) but additionally is a very efficient and light-weight damping system (protection against rock fall). In addition, also complex motion patterns can be imprinted in the fibrous structure of fiber-reinforced plant materials systems allowing for one, two and three-phase motions. Examples include one and two phase model patterns found in pinecone scales (Pinus spp.) and three phase motions occurring in the involucral bracts of the silver thistle (Carlina acaulis). What’s more: these organs combine sensor, actuator, reactive movable element and support structure in one materials system, are entirely passive (no energy consumption), show high level of functional integration and display extraordinary high functional resilience and robustness. The latter was proven for 11.5 to 16 million years old charcoalified conifer cone scales (Keteleeria sp.) that still show the same motion pattern in hydration/dehydration cycles as their extinct counterparts. New production methods, as e.g. 3D-4D-printing or 3D-braining pulltrusion, allow to produce similar as in biology from small to big and to create a hierarchical structuring similar to that found in the biological role models. They therefore enable for the first time the transfer of many outstanding properties of the biological role models into innovative biomimetic products at reasonable costs. Based on a thorough analysis of the hierarchical structuring of the biological role models and of their scale overarchning mechanical properties these production methods will allow for the development of novel sophisticated living, adaptive and energy-autonomous materials systems. This challenge is central to the new Custer of Excellence livMatS, which has started in January 2019 at the University of Freiburg and aims to come from biinspired materials to living materials systems.

9:30 AM SM07.06.02 Enhancing Tensile Properties by Bio-Inspired Porous Arrangement—Modeling, 3D Printing, Mechanical Testing and Optimization Cheng-Chie Tung and Po-Yu Chen; National Tsing Hua University, Hsinchu city, Taiwan.

Cellular structures provide high material usage efficiency, specific strength, and energy absorption for lightweight structural materials. The mechanical properties can be maintained or increased through appropriate porous and wall designs even the material selections are limited. In this research, we focused on the enhancement of lightweight structure tensile properties based on single material. Voronoi tessellation, often appears in cells and bone microstructure generation modeling, was used to partition a plane into several pores after the distribution of pore centers were calculated. Mathematical models were proposed to describe the distribution of pores in tensile specimens. The Fibonacci sequence divides planes or spaces regularly, often found in nature such as sunflowers, pinecones, etc. The Poisson-disc sampling mimics cells growth distribution in two-dimensional plane. The hexagon model is proposed to tile the plane in highly symmetric situation. The regular model and Monte Carlo sampling correspond to a completely regular and completely random distribution models. The porosity variance of specimens was controlled by changing the distribution and quantity of the pores. A series of polymer-based tensile specimens for tensile tests were produced via additive manufacturing. The numerical models were systematically simulated to verify the stress-strain behaviors under physical tensile tests. Extended finite element method cause divergence and errors by the discontinuity of the mesh boundaries and micro-cracks in cellular structures under tensile condition. In this work, lattice spring model was used to simulate micro-cracks generation and propagation. We found when the porosity is 40%, the Poisson-disc sampling and the Fibonacci sequence have higher elongation at break (20% enhancement), ultimate tensile strength (15% enhancement), and toughness (35% enhancement) than other models.

Toughening mechanisms such as crack deflection/tortuosity and uncrack ligament bridging were observed and validated. This research proposes a feasible analysis of lightweight structures, tensile measurement methods, and developed bio-inspired structural materials that can be potentially applied to structural engineering, civil engineering, and aerospace technology.

Shape-transformation is a prevalent function observed in living systems, from moisture responsive plants that self-disperse seeds, to muscle actuation by calcium concentration within myocytes. A number of classes of synthetic materials, which mimic this natural behavior, have been developed that use physical or chemical stimuli such as temperature or pH to cause shape changes. However, these stimuli are not specific to the material and may affect various components of the surrounding environment. Additionally, these materials lack the ability of living organisms to respond to specific biomolecular cues and respond accordingly. Here we use the tools of synthetic biology to create living composites capable of responding to pre-determined and very specific stimuli (e.g. biomolecules). Specifically, we present a new method to create programmable shape-morphing living composites using polyacrylamide hydrogels that encapsulate Saccharomyces cerevisiae yeast cells. Proliferation of these microorganisms is controlled to cause the macroscopic shape of the polymer matrix to change (volume expansion up to 300%). As the composite only changes shape in the presence of an appropriate growth media, composites that sense and respond to changes in glucose concentration or the presence of an essential amino acid (e.g. histidine) can be fabricated. Moreover, we utilize optogenetic tools to regulate DNA transcription upon light illumination in modified yeast strains. Shape-change of the composite and proliferation of cells can be spatially and temporally controlled using low power blue light. This extracellular cue induces protein expression in cells and can be used to pattern shape changes in the material. Additionally, the use of these tools enables precise and directional control of shape-morphing with potential applications in tissue engineering, sensing, and drug delivery systems.

Designing for Disorder—The Mechanical Behaviour of Bioinspired, Stochastic Honeycomb Materials

Derek Araznour van Esmond, Benjamin D. Hatton and Glenn D. Hibbard; Materials Science and Engineering, University of Toronto, Toronto, Ontario, Canada.

In nature, structure, material and function are constantly evolving in tandem. This work employs polymer additive manufacturing to study the mechanical properties of new honeycomb materials inspired by disordered, hierarchical architectures in bioinspired organisms. Inorganic structural features encountered throughout biology are particularly fascinating due to their mechanical resilience and toughness, which arise despite limitations in the available molecular phases of environmental precursors. From very basic and often brittle building blocks, nature has found ways to extend material performance beyond the compositional limitations of its biomineral constituents, e.g. calcium carbonate, apatite and silica. Such improvements have been shown to rely in part on the architectural arrangement of the inorganic phase, which is often non-periodic. This is exemplified in the spongy trabecular bone of load-bearing mammalian limbs, the arrangement of aragonite platelets in the nacre system, and the cellular sandwich-core morphology of biosilica in diatom frustules. The primary aim of this work is thus to elucidate the mechanical role of structural order vs. disorder in natural cellular solids by way of a bioinspired polymer analogue. New honeycomb materials are proposed with improved damage tolerance. A mathematical Voronoi “regularity parameter” controls the degree of cell stochasticity. Uniaxial tension, compression and fracture experiments reveal significant crack path deviations and strain delocalization. These lead to enhancements in e.g. ductility and fracture toughness, \( K_c \), between 30-90% beyond equivalent periodic hexagonal geometries. Optimal cell irregularities are suggested, revealing a relationship between damage tolerance and cell size. Conserving spatial relative density, honeycombs with members composed of hierarchical micro-trusses are also presented. Depending on design objective, a 100% increase in compressive strength and three-fold energy absorption limits \( U_c \) have been achieved. These results comprise novel design spaces, where disorder and hierarchy are capitalized as design variables. Capitalizing on the spatial manufacturing freedom afforded by a modern MultiJet 3D printing technique, iterative tailoring of cell regularity and micro-truss architecture in the honeycomb enables new pursuits toward minimization of energetic tradeoffs. The result is a balance between high stiffness, high weight and damage tolerance from an otherwise brittle constituent polymer.

Dynamic Structural Color from Iridescent Bacteria

Clareeta J. Sullivan1, Chia Hung1, Joseph Tang1, Kennedy Brown1, Isaiah Weidmann1, Vincent Chen1, Vincent Tondiglia1, Pam Lloyd1, Miliana C. Vasseu2, Abigail Juhi1, Wendy Goodson1 and Patrick B. Dennis1; 1Materials and Manufacturing Directorate, Air Force Research Laboratory, WPAFB, Ohio, United States; 2University of Massachusetts Dartmouth, Dartmouth, Massachusetts, United States.

Biofilms from the marine bacteria, Cellulophaga lytica, have been reported to display structural, iridescent colors that were found to be both reversible and dynamic. Here we present several scientific and technological advances using micro-spectral imaging, confocal microscopy, angle-dependent reflection measurements and atomic force microscopy. To facilitate these studies, we have successfully fixed C. lytica colonies which remain stable iridescent for months. Micro-spectral imaging revealed angle-dependent reflection in the blue, green, yellow, orange and red structural color regions. Since cells displayed a similar size in all structural color regions, the different reflected colors likely came from different crystalline planes and/or periodicities. Cross-section images of C. lytica in the different colored regions demonstrated highly-ordered end-to-end assembly of hexagonal photonic crystals through crystalline plates, and the small refractive index mismatch between the bacteria and aqueous environment explains the small angle reflection peaks. Together, our studies imply that C. lytica is an excellent light scatterer that reflects different wavelengths of light through self-organization. Moreover, since our studies focused on a C. lytica strain with a known genomic sequence, future synthetic biology approaches will be aimed at producing low-cost, tunable photonic crystals based on programmable, self-assembling microorganisms for optical and sensor applications.

11:45 AM SM07.06.08

Facile Fabrication of Dry Adhesives Based on Hierarchical Fibrillar Structure of Poly (Dimethyl Siloxane) (PDMS)

Sung-Ryong Kim, Wu M. Canh and Nhat Anh T. Thieu; Korea National University of Transportation, Chungu, Korea (the Republic of).

We present a simple and low cost method of utilizing nanosized anodized aluminium oxide (AAO) and microsized silicon membrane as a reproducible template to prepare hierarchical fibrillar poly (dimethyl siloxane) (PDMS) dry adhesives that can be used as a medical patch. On the contrary to the adhesives containing only micrometer-size fibrils, the hierarchical fibrillar adhesives exhibited a higher adhesion force. Normal adhesion force on the glass substrate was higher than 8 N/cm² and this value was higher than that of homogenous PDMS micropillars. The successful fabrication of such hierarchical adhesive could be potentially used in applications requiring repetitive adhesion without significant loss of adhesion strength.

1:30 PM SM07.07.01

Bioinspired Extrinsic Control of Freeze Casting

Steven Naleway, Isaac Nelson, Anthony Yin, Max Mroz and Paul Wadsworth; University of Utah, Salt Lake City, Utah, United States.

Freeze casting is a bioinspired technique for the fabrication of tailored, porous ceramic materials. Mimetic of the growth of mammalian bone and other biomaterials where biopolymers template the deposit of biominerals to create complex composites, freeze casting employs a template of growing ice crystals to create a complex porous microstructure in any ceramic. We propose that this bioinspired technique can be controlled through either intrinsic (those that modify from within by altering the constituents) or extrinsic (those that apply external forces or templates) means. Through these classifications, examples of extrinsic (through energized external fields) freeze cast, bioinspired structures will be discussed with a focus on providing advanced control of the final material structure and properties. Applications in energy and filtration technologies will be...
Helmholtz coil-based freeze casting setup is used to control the fabrication of porous structures. With this setup, a magnetic field can be created in any direction which is utilized to optimize the alignment of biopolymers. When functional ceramics are added to the initial PVA slurry, which increases the diversity of material selection and extensive potential applications. This research is funded by the Ministry of Science and Technology, Taiwan (MOST 103-2221-E-007-034-MY3).

The structure of many biological materials is hierarchical in nature meeting specific needs at each length scale. This includes human bone, which has a porous structure that plays a critical role in arresting crack growth, energy absorption and mechanical strength in specific loading directions. In this research, a novel tri-axial nested Helmholtz coil-based freeze casting setup is used to control the fabrication of porous structures. With this setup, a magnetic field can be created in any direction which is utilized to manipulate particles to align the microstructure. The ability to control the particle alignment results in user-specific mechanical properties at user-specific locations. These structures provide a path to better mimic the mechanical characteristics seen in human bone.

Freeze Casting Using a Tri-Axial Nested Helmholtz Coil to Fabricate User-Specific Porous Scaffolds

Isaac Nelson, Max R. Mroz, Anthony Yin, Paul Wadsworth and Steven Naleway; University of Utah; Salt Lake City, Utah, United States.

Regulation of Apatite Biomineralization in the Mantis Shrimp Dactyl Club by a Newly Discovered Protein, CMP-1

Hortense Le Ferrand1, Shahrouz Amini1, Maryam Tadayon1, Jun Jie Loke1, Akshita Kumar1, Deepankumar Kanagavel1, Martial Duchamp1, Manfred Raida1, Shawn Hoon1 and Ali Miserez2; 1Nanyang Technological University, Singapore, Singapore; 2National University of Singapore, Singapore, Singapore; 3A*STAR, Singapore, Singapore.

The dactyl club of the mantis shrimp (stomatopod) is a fascinating example of a highly organized hierarchical hard composite material that combines strength and toughness. Another peculiar feature of this appendage lies in its formation process through molting cycles: as a crustacean mantis shrimps grow an entirely defect-free functional exoskeleton within just a few weeks. This feature makes the mantis shrimp an ideal model organism to monitor biomineralization processes. In this study, a protein from the club (club Mineralization Protein 1, CMP-1) was identified and sequenced using a combined transcriptomics/proteomics approach, and shown to regulate calcium phosphate mineralization of the club. After recombinantly expressing CMP-1, we show that CMP-1 can form dense organic microdroplets through liquid-liquid phase separation induced by calcium ions. Furthermore, in vitro experiments with TEM demonstrate that CMP-1 can participate in the formation of precursor-like amorphous calcium phosphate granules that subsequently grow into preferentially oriented crystalline apatite nanofibers.

This work not only corroborates recent observations made in other systems that proteins regulating biomineralization can initially undergo phase separation [3], but also provides a comprehensive picture of key steps involved in the growth of a mechanically functional highly mineralized composite. The study thus offers guidelines for advanced bioinspired manufacturing methods for strong and tough ceramic-organic composites.

SYMPOSIUM X

Frontiers of Materials Research

12:15 PM *X.01.01*

**Designing Bio-Responsive Hybrid Materials**

Molly Stevens; Imperial College London, London, United Kingdom.

**Abstract:** Bio-responsive hybrid materials are of growing importance with potential applications including drug delivery, diagnostics and tissue engineering. A side effect of longer life-spans is the failure of one part of the body. The search for replacement body parts has fuelled the highly interdisciplinary field of tissue engineering and regenerative medicine. This talk will describe our research on the design of new hybrid (nano)materials and nanomaterials to direct stem cell differentiation for regenerative medicine. We have also designed and developed porous silicon “nanoneedles” capable of efficiently, rapidly and safely delivering sensitive biocargoes to cells and tissues in vivo as well as interfacing with cells to inform intracellular pH and high resolution demarcation of tumorous region boundaries. This talk will also provide an overview of our recent developments in the design of materials for ultrasensitive biosensing, applying these nanomaterial-based approaches to high throughput drug screening and to diagnose diseases.

**Biography:** Molly M. Stevens is currently Professor of Biomedical Materials and Regenerative Medicine, Research Director for Biomedical Material Sciences in the Department of Materials, Department of Bioengineering and the Institute of Biomedical Engineering at Imperial College London, and Director of the UK Regenerative Medicine Programme Hub for Smart Materials. She received her PhD from The University of Nottingham in 2000, then conducted her postdoctoral research at MIT in the labs of Prof Robert Langer, where she co-developed innovative techniques for the regenerative of bone and other tissues. She joined Imperial College in 2004 and was promoted to Full Professor in 2008. Research in the Stevens Programme focuses on designing and developing innovative bio-inspired materials for applications in regenerative medicine, tissue engineering and biosensing. Her research has been recognised by over 20 major awards. More information on the Stevens Group can be found at http://www.stevensgroup.org.

12:15 PM *X.02.01*

**Hydrogen and Fuel-Cell Technology Perspectives**

Today the technology around generating efficient and sustainable energy is rapidly evolving and hydrogen and fuel cells are versatile examples within a portfolio of options. This presentation will provide an overview of the U.S. Department of Energy’s Fuel Cell Technologies Office early-stage R&D activities in hydrogen and fuel cells within the Office of Energy Efficiency and Renewable Energy. Dr. Satyapal will highlight technology status and progress towards achieving DOE targets, discuss R&D needs and challenges, and provide specific examples where advanced materials research is relevant to address those challenges. The presentation will also cover DOE’s H2@Scale initiative which will enable innovations to generate cost-competitive hydrogen as an energy carrier, coupling renewables, as well as nuclear, fossil fuels, and the grid, to enhance the economics of both baseload power plants and intermittent solar and wind, enhancing resiliency and avoiding curtailment.

Sunita Satyapal is the Director for the U.S. Department of Energy’s (DOE) Fuel Cell Technologies Office within the Office of Energy Efficiency and Renewable Energy. She is responsible for the overall strategy, program execution and staff in the area of hydrogen and fuel cell technologies, including oversight and coordination of approximately $100 million per year in research, development, demonstration and deployment activities. Dr. Satyapal has more than 20 years of experience in academia, industry and government and has 10 patents issued. She received her Ph.D. from Columbia University and did her postdoctoral work in Applied and Engineering Physics and Physical Chemistry at Cornell University.

12:40 PM *X.02.02*

**Development of Fuel Cells and Hydrogen Technologies in Europe Toward Commercialization from 2020 Onward**

Bart Biebuyck; The Fuel Cells and Hydrogen Joint Undertaking, Brussels, Belgium.

The Fuel Cells and Hydrogen Joint Undertaking (FCH JU) was set up in 2008 to accelerate the development of fuel cells and hydrogen (FCH) technologies in Europe toward commercialization from 2020 onwards. To reach this target the FCH JU brings together resources under a cohesive public-private partnership to ensure commercial focus, to match RTD activities to industry's needs and expectations and to scale-up and intensify links between the Industry Community and the Research Community. The FCH JU support stretches from research and demonstration projects in the different areas of FCH including energy and transport applications. The €893 million in grants already allocated under the FCH JU support provides specific examples where advanced materials research is relevant to address those challenges. The presentation will also cover DOE’s H2@Scale initiative which will enable innovations to generate cost-competitive hydrogen as an energy carrier, coupling renewables, as well as nuclear, fossil fuels, and the grid, to enhance the economics of both baseload power plants and intermittent solar and wind, enhancing resiliency and avoiding curtailment.

Bart Biebuyck is the Executive Director of the Fuel Cells and Hydrogen Joint Undertaking (FCH JU), a public-private partnership aiming at facilitating the deployment of fuel cells and hydrogen technologies in Europe. Before the FCH JU, Bart Biebuyck was at the Fuel Cell department of Toyota Motor Europe where he held the position of Technical Senior Manager. His expertise in the automotive industry includes extensive knowledge related to the deployment of new technologies in the European market. It is as part of the Clean Energy Partnership (CEP) programme in Berlin that Bart worked at reinforcing European trials for the Toyota Fuel Cell Hybrid Vehicle. He also had the opportunity to develop and expand his knowledge in Japan, where for two years he worked on the PSA-Toyota Small Vehicle Development Project which resulted in the launch of the Toyota AYGO in 2006. In addition to his industrial experience, Bart has been politically active in his local town since 2006. In 2013 he became the vice president of the City Council, responsible, among others, for the local economy and education. Bart joined the FCH JU as the new Executive Director on the 16 May 2016.
This talk introduces the James Webb Space Telescope, NASA’s next large astrophysics mission. Webb’s science goals; detection of the universe’s first light, assembly of galaxies, birth of stars and observation of planets and exo-planets are introduced. We will explore how the design responds to mission requirements and produces the performance necessary to achieve the mission’s goals. Many of the unique elements of the architecture will be explored. The main engineering challenges for largest telescope ever built in space are discussed and the role of materials highlighted. Finally, the current status of the hardware and path to launch will be given.

Jonathan Arenberg is currently the Chief Engineer for Space Science Missions at Northrop Grumman Aerospace Systems. Dr. Arenberg has worked the Chandra X-ray Observatory and James Webb Space Telescope. He co-conceived and developed the Starshade concept for the direct imaging of extra-solar planets and other innovative mission concepts. He has worked on laser systems and component engineering, metrology, inspection issues and technology development. He is a member of US National and International committees charged with writing standards for laser and electro-optic systems and components, SPIE, American Astronomical Society, AAAS, AIAA and Sigma Xi. Dr. Arenberg holds a BS in physics and an MS and PhD in engineering, all from the University of California, Los Angeles. He is the author of over 180 conference presentations, papers and book chapters and a recent book. He holds a dozen European and U.S. Patents in various areas of technology and is an SPIE Fellow.
