One outstanding issue for state-of-the-art silicon devices is achieving high levels of dopant activation for shallow junctions, particularly for 3D device architectures in which processes like solid-phase epitaxial regrowth cannot be easily integrated. Helium ion implantation offers an intriguing potential method of vacancy engineering that is made possible by the stabilizing effect of helium on vacancy clusters, as well as the ability to subsequently desorb the implanted helium upon low-temperature annealing. However, much is still unknown about the dynamic interactions between helium, vacancies, and self-interstitials in silicon during implantation. In this study, these interactions were investigated by systematically varying the dose rate of an elevated temperature helium implant. 10 keV He+ was implanted into (100) Si at a dose of 4×1014 cm–2 and an implant temperature of 450°C. Beam currents were varied from 2.6 to 10.4 mA. Transmission electron microscopy studies show that extended defects are present in the as-implanted state, and the density of these defects decreases with decreasing dose rate, which is unusual for non-amorphizing implants. In addition, cavities are present and their size and density vary systematically with dose rate as well. Thermal helium desorption spectrometry reveals differences in helium retention. These results are compared to those of silicon self-implantation performed under similar conditions. Implantation damage from silicon does not show the same dose rate effect, indicating the unique role of helium in self-annealing of implantation damage and suggesting that helium-vacancy interactions prevent some fraction of self-interstitials and vacancies from recombining. This study is an important step toward understanding the atomic processes that control the creation of excess vacancies in silicon through helium implantation.

New Generation of ReRAM Based on Oxidized Carbon Nanofibers  

Paolo Bondavalli¹, Louiza Hamidouche², Marie-Blandine Martin², Alkaterini F. Trompetta, Konstantinos Charitidis³, Christophe Galindo4 and Elias Kounoulos5; 1Thales Research and Technology, Palaiseau, France; 2Chemical Engineering, National Technical University of Athens, Athens, Greece.

This contribution deals with the first time fabrication of graphitic based memories using oxidized carbon nanofibers (ox-CNFs). In our case we what we have obtained are Metal-Insulator-Metal (MIM) structures where the ox-CNFs are the layer sandwiched between two metal contacts. Thanks to that we are able to fabricate Resistance Random Access Memories (ReRAMs) where the resistance of the layer sandwiched changes in a non-volatile way as a function of the bias applied. Indeed thanks to spray-gun deposition method we are able to deposit thin layer of ox-CNFS on 2 metalized inches substrates. The thickness is around 100nm. The bottom contact is based on Pt and the top contacts are achieved using Cu/Al pads. The change of the resistance is related to the alignment of the oxygen vacancies and therefore to the creation of conductive paths inside the ox-CNFS layers. These paths are disaggeregated cycling the bias. Moreover the oxygen is moved to the top contact and therefore this last is oxidized moving from a low resistance state (LRS) to a high resistance state (HRS). This change is reversible. The results show a typical shape of bi-polar memories when the voltage is cycled between -2 and 2 Volts. We fabricated hundreds of structures and 2/3 showed this behavior. The switching phenomenon is not reproducible if we use CNFs with metal impurities. Indeed in this case the voltage is at the origin of the alignment of the metal impurities that lead to the short circuit of the structure linking the two metal contacts (creating sort of dendrites). For this reason the purification of the fibers is a very important step. The results obtained are extremely interesting and promising result considering that this was the first time in the world that this kind of memories were fabricated and tested. Moreover the ox-CNFs are deposited using spray-gun technique where the CNFs are in stable suspensions in deionized water. This is very important in case of the implementation of the process on very large surface of through roll-to-roll fabrication in order to achieve a low-cost but also operator-friendly process suitable for industrial application.

Impacts of an Asymmetric Stack Structure in TaOx-Based ReRAM Cells on Resistive Switching Characteristics  

Toshiki Miyatani, Yusuke Nishi and Tsunenobu Kimoto; Electronics, Kyoto University, Kyoto-city, Japan.

Resistive Random Access Memories (ReRAM) have huge possibilities for contributions to emerging nonvolatile memories. ReRAM cells exhibit reversibly transitions between high resistance states (HRS) and low resistance states (LRS), which is called resistive switching (RS) phenomenon. Set and reset processes mean the transition from HRS to LRS and that from LRS to HRS, respectively. RS operations are classified as either unipolar- or bipolar-type based on polarities of applied voltage at set or reset processes. ReRAM cells with an asymmetric stack structure usually exhibit bipolar RS operations based on valence change mechanism (VCM) [1]. However, why the asymmetric structure results in bipolar RS characteristics have not been clarified yet completely. In this work, we investigated impacts of an asymmetric stack structure in TaOx-based ReRAM cells on resistive switching characteristics.

Pt/TaOx/Pt and Pt/TaOx/TaOx/Pt stack structures were fabricated. The oxide layers were deposited on Pt/Ti/SiO2/Si substrates as bottom electrodes (BEs) by reactive radio-frequency sputtering. The oxygen composition x in the TaOx layers was controlled to be less than 2.5 by adjusting the oxygen gas flow rate. Then, the Pt layers with a diameter of 100 μm were deposited by electron beam evaporation as top electrodes (TEs). The resistance of Pt/TaOx (5 nm)/Pt cells at 0.1 V in an initial state was roughly 10^8 Ω. On the other hand, that of Pt/TaOx (10 nm)/TaOx (5 nm)/Pt cells was approximately 10^4 Ω. The reduction of resistance by introducing the TaOx layer indicates that diffusion of oxygen vacancies (Vo) from the TaOx layer to the TaOx layer caused film thickness distribution of Vo in the TaOx layer. Consequently, the TaOx layer was effectively composed of a sub-stoichiometric layer (TaOx-δ) and a stoichiometric layer (TaOx).

When a positive voltage was applied to the TEs in the initial state, transition to a particular HRS occurred. We have reported the transition from the initial state to the particular HRS by overcurrent suppression in Pt/TiOx/Pt cells [2]. The particular HRS is referred to as semi-HRS. In the semi-HRS of Pt/TaOx/TaOx/Pt cells, as a negative bias increased, the resistance decreased discretely once, and then increased continuously to reach similar resistance to the initial state. These phenomena originate from the migration of Vo by drift due to electric field and diffusion due to Joule heating. After the gradual reset, a set process occurred as a positive bias increased. The characteristics observed in the semi-HRS are quite different from those of conventional bipolar RS. Moreover, the transition to the semi-HRS is necessary for the bipolar RS operations in Pt/TaOx/TaOx/Pt cells.

These results suggest that understanding of characteristics observed in the semi-HRS is highly significant for elucidation of bipolar RS operations in VCM-type cells. We will discuss characteristics in the semi-HRS and mechanism of the bipolar RS operations in detail.

Non-Volatile Electrochemical Memory Operating Near the Thermal Voltage Limit  

Yiyang Li¹, Elliot J. Fuller¹, Shiva Asapu¹, Sapan Agarwal¹, Joshua J. Yang² and Alec Talirz¹; ¹Sandia National Laboratories, Livermore, California, United States; ²University of Massachusetts Amherst, Amherst, Massachusetts, United States.

Non-volatile, electrically addressable memories like flash, phase-change, and filament forming metal oxides are desirable as synapses for neuromorphic analog computation with the potential to significantly lower power compared to digital processors. Reducing the switching voltage of non-volatile memories is important both to reduce energy consumption and to prevent dielectric breakdowns. Due to the Boltzmann distribution of electrons, it is unclear if any memory can switch significantly below 1V; developing non-volatile memory operating near the thermal voltage limit is a grand challenge.

In this work, we integrate two silicon-free electrochemical devices to demonstrate non-volatile memory that operates as low as 170 mV, just six times the thermal voltage limit. The first device is an ion insertion transistor which electrochemically shuttles lithium ions and electrons between the gate and the channel, analogous to a battery. Because the ions are mobile and move with the electrons, the process is charge neutral, and up to 10^17 cm^-2 of electrons and ions can be reversibly shuttled between the gate and channel without electrostatic charging. The second device is a diffusive memristor operating based on facile Ag²⁺ migration and filament formation only in the ON state. This diffusive memristor ensures that the ion insertion transistor maintains its state when not electrically addressed. The combination of high charge density of the ion insertion transistor and low leakage current of the diffusive memristor enables these two electrochemical devices to retain memory. Because both devices operate at low voltage, we can linearly tune the electronic conductance using sub-200-mV voltage pulses. This device is also compatible with a V/2 crossbar select scheme without a select transistor, and demonstrates that non-volatile synaptic memory near the thermal voltage limit is possible for low-power electronics.

Spatial Distribution of Conductive Filaments and the Effect of Device Geometry  

Sanjay K. Nandi, Shimul K. Nath, Shuai Li and Robert G. Elliman; Australian National University, Canberra, Australian Capital Territory, Australia.

Characteristic resistance changes are observed in two-terminal metal-oxide-metal (MOM) structures when subjected to large electric fields or current densities and are of interest as the basis of nonvolatile memory and neuromorphic computing devices. These resistance changes are often mediated by filamentary conduction, either in the form of a semi-permanent filament created by compositional changes in the oxide or as a transient filament created by inhomogeneous current or field distributions (e.g. current bifurcation). Knowledge of the filament location and morphology, and how these are affected by device geometry and material processing is important for understanding device operation and scaling. For example, enhanced filament formation is expected around the edges of cross-point devices due to local field enhancement or variations in oxide thickness. To gain an understanding of such effects it is desirable to have a simple, robust method of detecting and mapping filaments and to use this to study the statistics of filament formation.

To this end we have developed a simple technique for detecting the location of both permanent and transient filaments based on thermal denaturing of a thin photosensitive layer. The efficiency of this approach is demonstrated by applying it to a MOM cross-point structure comprised of a Pt (25 nm)/Cr (10 nm)/NbOx (45 nm)/Pt (25 nm) heterostructure, with cross point areas of 4x400 μm². A thin positive photosenset layer is deposited on top of fabricated cross-point devices by spin coating and then patterned using photolithography to open access to probe pads. The photosensit is then baked for 2 minutes in air using a hot plate kept at a temperature of 85 °C. After electroforming, a dark spot appeared in the photosensit on the top electrode due to local Joule heating, clearly identifying the filament location. Such analysis is subsequently employed to investigate the number and spatial distribution of filaments produced by electroforming.
Forming is an initial stage required to create conductive filaments in binary transition metal oxides (TMOs) before resistive switching (RS). The dissolution and reformation of the filaments have been widely recognized as an origin of the RS operation. However, where the filaments are created by forming remains unclear. In this study, we investigated correlation between the crystallinity and oxygen composition of TMOs and forming characteristics in TMO-based RS cells.

Pt/(NiO)/Pt and Pt/(TiO2)/Pt cells were prepared. Pt bottom electrodes were deposited by sputtering (SP) or electron beam (EB) evaporation, which is referred to as SP-Pt or EB-Pt, respectively. NiO and TiO2 thin films as binary TMOs were deposited by reactive sputtering. Pt top electrodes were deposited on the TMO layers by EB evaporation. In-plane X-ray diffraction and transmission electron microscopy reveal that NiO layers on the SP-Pt or EB-Pt include columns or granules with a grain diameter of tens of nm, respectively. On the other hand, the crystal orientation of TiO2 layers on the SP-Pt is greater than that of TiO2 layers on the EB-Pt even though the grain size of both TiO2 layers is the same. These results indicate that the crystallinity of TiO2 layers strongly depends on the crystallinity of Pt bottom electrodes [1].

Next, characteristics of the initial cell resistance (Rini) were investigated. In both cases of NiO and TiO2, the Rini values on the SP-Pt were greater than those on the EB-Pt, and the variation of Rini on the SP-Pt were much smaller than that on the EB-Pt. These results suggest that the grain boundary density in TMO layers on the SP-Pt is lower than that in TMO layers on the EB-Pt resulting from the difference of TMO crystallinity. Moreover, TMO layers on the SP-Pt contains fewer oxygen vacancies than those on the EB-Pt, as estimated from our previous results of the segregation of oxygen vacancies at grain-boundary triple points in NiO layers [2]. As a result, the oxygen composition of TMO layers on the SP-Pt is larger than that of TMO layers on the EB-Pt.

Finally, the time to forming (tform) in the cells was measured while keeping a constant applied voltage. All of the cells were confirmed to show repeatable RS operations after forming. Although the variation of tform decreased as the variation of Rini decreased in the case of TiO2 layers, the variation of tform increased as the variation of Rini decreased in the case of the NiO layers. The distribution of forming characteristics depends on both crystallinity and oxygen composition of TMO layers because of the different deposition methods of the Pt bottom electrodes. These clear difference might originate from differences in the oxide deposition mode during reactive sputtering.

The emergence of ferroelectricity in doped HfO₂ thin films has attracted a great deal of attention since its discovery in 2011. Their full compatibility with the complementary metal-oxide semiconductor (CMOS) process make them viable candidates for application in non-volatile memory devices. Amongst hafnia based materials, Hf₁₋ₓZrₓO₂ (HZO) has shown to be one of the more promising candidates. The reason for selecting HZO is a wider and hence more forgiving composition window in mixing HfO₂ and ZrO₂ to obtain ferroelectricity, compared to e.g. Si doped HfO₂. The ferroelectricity in thin doped HfO₂ films is generally accepted to originate from the crystallization of a non-centro-symmetric orthorhombic phase with the space group Pca2₁. During the crystallization, the temperature profile needs to be well controlled in order to favor the formation of the metastable ferroelectric orthorhombic phase against other non-ferroelectric phases. Here we report on the utilization of millisecond Flash Lamp Annealing (ms-FLA) for the stabilization of ferroelectric Hf₁₋ₓZrₓO₂ (HZO) films. The thin film characterization structures are of MIM type and consist of a bottom TiN electrode, a 3-10 nm thick HZO layer and a top TiN electrode, deposited by atomic layer deposition in the same order. For the 10 nm thick HZO sample, the combination of a 120 s long preheat step at 375°C with a 20 ms xenon flash lamp pulse results in ferroelectric characteristics comparable to those obtained when using a 300 s long rapid thermal anneal (RTA) at 650°C. This statement is supported by X-ray diffraction, capacitance voltage, polarization hysteresis and cycling measurements. In 10 nm thick HZO layers a remanent polarization (P_r) of ~21 μC/cm² and a coercive field (E_c) of ~1.1 MV/cm are achieved. Cycling analysis shows an increase of endurance for the ms-FLA compared to RTA by one decade, up to 10⁵ bipolar cycles. An additional SiO₂ encapsulation of the TiN/HZO/TiN stack further increases the endurance up to 10⁶ cycles. For the 3 nm thin HZO sample the preheat temperature of the ms-FLA was increased to 550°C to successfully crystallize HZO in the orthorhombic/tetragonal phase. Unlike for standard anneals, the ms-FLA annealed films do not show any parasitic monoclinic phase, as confirmed by X-ray diffraction measurements. This illustrates the benefits of a fast thermal process to stabilize ultra-thin ferroelectric films, which are promising candidates for non-volatile memory and neuromorphic hardware applications when used as tunnel junctions.

HfO₂-ZrO₂ composites and alloys are of growing interest as dielectrics in advanced DRAM capacitors and ferroelectric devices in emerging non-volatile memory and negative-capacitance FET technology. These versatile oxide materials express dramatically different physical properties depending on their crystal structure, which can be selected by tuning film thickness, processing conditions, or substrate material. In thin films or nanostructures, the P₄/nmc tetragonal (t) phase, which is a high-k dielectric material, and the Pca₂ orthorhombic (oFE) phase, which is ferroelectric, can be stabilized relative to the low-energy P₄/m monoclinic (m) phase. Establishing predictive relationships between thin film processing and device performance therefore requires accurate measurement of the crystal phase distribution. While possible crystal phases can be inferred by electrical testing, the structure may be changed by electric field-induced transformation. X-ray diffraction (XRD) is the workhorse method of non-destructive crystal phase analysis, but the t and oFE phases are notoriously difficult to discriminate. However, differences in the short-range order of metastable ferroelectric orthorhombic and non-ferroelectric phases are notoriously difficult to discriminate. However, differences in the short-range order of t(Hf,Zr)O₂ and oFE-(Hf,Zr)O₂ are readily distinguished using extended X-ray absorption fine structure (EXAFS) measurements. Using a novel EXAFS analysis method, we resolve the φ, ω, and m phase fractions to within 10% in 6 nm nanolaminate bilayers grown by atomic layer deposition (ALD). This structural analysis technique could inform device processing workflows that favor either ferroelectric or high-k dielectric ultrathin (Hf,Zr)O₂ films.
Promising technology boosters for future scaled CMOS can be regarded as 3D nano-sheet (NS)/nano-wire (NW) structures, new channel materials and the combination. Thus, MOSFETs with alternative channels such as Ge and III-Vs on the Si platform have been strongly expected over recent 15 years for high performance and low power logic devices, where the reduction in Vth is the most critical requirement. CMOS using these channels can reduce the gate overdrive (Vg-Vth) and resulting low Vth at a given ion, because of the increased injection velocity due to the low effective mass. These high mobility channels can be more important for NS/NW CMOS than FinFETs, because of limited rooms to increase the channel width, different from FinFETs. In spite of the strong efforts to introduce such alternative channels, however, the implementation into the advanced CMOS platform has not been visible yet, because of wide aspects of difficulties in the device integration. In the more-Moore approach, Ge/Ill-V III-2D structures for stacked CMOS is one of the promising device structures. This is because 3D integration by using low temperature process is much easier for Ge and III-V than Si. In addition, the ultralow contact resistance of Ge and InGaAs with metals can be expected through utilizing Fermi-level pinning of the interfaces with meals under low thermal budget. In the beyond-CMOS approach, on the other hand, steep slope devices have stirred a strong interest from the viewpoint of ultralow power applications. One of the most promising steep slope devices is tunneling-FETs (TFETs). Here, Ge/III-V channels are also expected to enhance the TFET performance, because of the increased tunneling probability due to the small direct bandgap. Furthermore, in the source/channel junctions composed of the type-II hetero-structure are quite effective in improving the TFET characteristics, because the effective bandgap (DEG) between the valence band top of the source and the conduction band bottom of the channel is reduced, resulting in the increase in ion with maintaining low Ioff.

In this paper, we briefly address the current status of MOSFETs and TFETs using alternative materials such as Ge, III-V and oxide semiconductors for future low power scaled devices and review the recent progress in device and process technologies on a basis of our research activities. Among these devices, Ge pFETs can be the closest to the real applications. Although InGaAs-based nFETs are also promising, stringent controls of material quality and super-smooth device geometry are strongly needed. Since Ge nFETs and III-V pFETs are still in an immature stage, the combination of InGaAs nFETs and Ge pFETs and, in particular, the combined 3D stacked CMOS seem promising. We presented highly-strained GOI and InGaAs-OI formation technologies and ultra-thin body InGaAs QW channel design as viable solutions for advanced CMOS. Also, the introduction of alternative channels is more essential for improvement of TFET performance. The possibilities of Ge complementary TFETs and InGaAs QW TFETs were addressed. Here, the suppression of defect-related currents is a key issue. Finally, we proposed and demonstrated the novel bi-layer TFETs using the type-II hetero-structures composed of oxide semiconductors such as ZnO and ZnSnO, and column-IV semiconductors such as Si, SiGe and Ge. We have experimentally demonstrated the operation of Si/ZnO and Ge/ZnO TFET operation with remarkably high Ion/Ioff of ~10^8, low Ioff and minimum SS of 71 mV/dec. As a result, the oxide semiconductors/ column-IV semiconductor bi-layer TFETs are expected to be one of the potential options of TFETs overcoming CMOS in terms of the ultra-low power operation.
nucleate and grow into SiO2 precipitates (oxide precipitates, OPs) under certain high temperature treatments. Small OPs can pin dislocations and slow slip propagation. Large OPs, however, can soften the wafers both by consuming the dissolved Oi, reducing dislocation locking, and by acting as dislocation sources. It is well known that oxygen forms thermal donors at low annealing temperature (300 – 450 °C), which can result in deleterious resistivity shift, as the same temperature range is often used for post-metalization annealing. In RF devices, where high resistivity of the substrates is critical, ultra-low oxygen concentration ([Oi]) wafers are widely used to reduce thermal donor generation. Due to the lack of Oi to lock and pin the dislocations, low [Oi] wafers are weaker and more prone to slip and plastic deformation. Nitrogen doping is known to be effective in locking dislocations and can be added to the crystal to increase strength, but in combination with oxygen generates new donors, which are stable at higher temperatures (up to 1000°C), exacerbating resistivity shift issues.

Germanium (Ge) seems to be a good candidate for strengthening Si, as it is electrically neutral and forms a solid solution with Si at all concentrations. Ge may impede dislocation motion directly by means of its larger atomic size compared to Si, or indirectly through changing the behavior of Oi diffusion and/or precipitation. Little data is available on the effect of Ge doping on the dislocation motion in silicon wafers with ultra-low [Oi] (1.5 – 3 × 10^{19} atoms/cm²). Previous work on Ge at high [Oi] (5 – 12 × 10^{17} atoms/cm²) reported improved slip resistance, due to Ge enhancing Oi precipitation to pin the dislocation motion. It is unclear whether Ge, as a substitutional impurity, can diffuse to the dislocation cores to prevent the dislocation motion by locking, or retard slip propagation by solid solution strengthening.

In this work, we study the dislocation unlocking stress of ultra-low [Oi] Si wafers (1.5 – 2 × 10^{17} atoms/cm²) with Ge doping (5 – 6 × 10^{19} atoms/cm²). Samples with similar [Oi] but without Ge were used as control. Both types were annealed for various times (0.25 – 16 hours) and temperatures (600 – 750 °C) before mechanical testing, to allow the impurities to diffuse and bind to the dislocations. The samples were then loaded in a three-point bending configuration, and the stress required to unlock dislocations was evaluated. The pinning effect of OPs was negligible at such low [Oi], where precipitation was suppressed, which allowed us to investigate the role of Ge on dislocation motion. The average dislocation velocities as a function of shear stress were found to be comparable for Ge and control groups, and independent of the annealing condition prior to mechanical loading. At all annealing temperatures tested, the unlocking stress as a function of annealing time initially rises linearly before taking a constant value. The saturated unlocking stress is lower at higher temperature, indicating the impurities have a higher tendency to “boil off” from dislocations. The rate of the initial rise is found to be strongly dependent on annealing temperature, with an activation energy of 1.52 eV and 1.68 eV for Ge doped and control samples, respectively. The preliminary results showed that Ge by itself does not have a significant impact on the dislocation unlocking stress for the annealing conditions tested.

As FinFET scaling continues for advanced CMOS nodes (10/7nm), contact resistance remains a dominant component affecting device performance. The FinFET S/D contact area has become smaller with scaling (narrower fins due to reduced fin pitch), resulting in drastically increased contact resistance. To achieve higher drive currents and fully realize the performance gain from FinFET architectural changes such as narrower and taller fins, it is critical to achieve contact resistivity $\rho_{c} < 1.0 \times 10^{-4}$ $\Omega \cdot \text{cm}^2$ for both PMOS and NMOS. In this paper, we first review the requirements and recent trends for contact resistance reduction for advanced CMOS devices. Then, we discuss the various approaches that have recently demonstrated reduction in $\rho_{c}$, such as the use of in-situ heavily doped epitaxial films for S/D, and advanced implant and anneal techniques. The implant techniques leverage damage engineering concepts and include (i) pre-silicide amorphization, (ii) cryogenic (-100°C) implantation and (iii) plasma doping (PLAD) for conformal doping. With such high levels of doping from epit and implant approaches, this paper will also discuss the integration of advanced laser anneal techniques for improved dopant activation while minimizing diffusion, such as millisecond laser anneal, and nanosecond laser anneal (for super-activation), that are imperative for contact resistance reduction. Finally, we will discuss an alternative contact approach, which implements wrap-around contacts that cover the entire S/D fin surface in order to increase the effective contact area while maintaining the same contact size, potentially providing a pathway to further reduce the contact resistance for advanced CMOS nodes.

In summary, incorporating Ti into GeO$_2$ improved. Therefore, Ti-GeO$_2$ confirms a uniform passivation layer prior to deposition with a roughness of 2.9 Å. After 10 ALD cycles of MoSi$_2$, the number of particles taller than 1 nm are reduced by a factor of 4 compared with unpassivated MoSi$_2$. Nuclei on unpassivated SiO$_2$ are roughly 8 nm in height, corresponding with the expected thickness of MoSi$_2$ deposited on Si, whereas on the passivated sample are ~4-8x shorter, consistent with delayed nucleation due to the protection of SiO$_2$. Atomic layer deposition (ALD) processes for high-aspect ratio pattern exist for both Co and Ru, but the need for longer grains requires highly-selective ALD processes proceeding from the bottom-up. Ideal processes nucleate well only Si or metal surfaces, but surface defects on SiO$_2$ and low-k dielectrics can cause unwanted nucleation. In this work, the effectiveness of a self-assembled organic monolayer as both a diffusion barrier and as a passivation agent to enhance selective ALD is investigated.

Previous studies on alternative diffusion barriers have involved amorphous Co-Ti alloys deposited via RF sputtering. Alternatively, sub-2nm thick SAMs containing bulky groups with N or P atoms have also proven to be effective as Cu diffusion barriers on Si and SiCOH. To enhance selectivity of ALD processes, SAMs composed of hexamethyl-disilazane (HMDS) and octadecyl-trichlorosilane (ODTS) have been used to block hydroxyl sites, preventing deposition of HfO$_2$ on SiO$_2$ without blocking deposition on Si. However, these SAMs require extended treatment periods of 24-48 hours. This work demonstrates the use of the molecule 2-diphenylphosphino-ethyl-triethoxysilane (DPPETS), known to be a Cu diffusion barrier, and in the present work, as a rapidly-acting ALD passivant for middle-of-line and back-end-of-line. X-ray photoelectron spectroscopy (XPS) is used to investigate the chemical state of the passivated and unpassivated dielectric surfaces after ALD. On SiO$_2$, passivation of surface defects is observed, with an increase of contact angle from 40° to 82°. However, on SiCOH, the contact angle is not significantly affected by DPPETS passivation.

AFM of the SiO$_2$ after HF pre-clean, after DPETPS passivation at 1 hr, and after 10 cycles of MoSi$_2$ ALD on both passivated and unpassivated SiO$_2$ over a 2x2 µm region confirms a uniform passivation layer prior to deposition with a roughness of 2.9 Å. After 10 ALD cycles of MoSi$_2$ on passivated SiO$_2$, the number of particles taller than 1 nm are reduced by a factor of 4 comparing with unpassivated SiO$_2$. Nuclei on unpassivated SiO$_2$ are roughly 8 nm in height, corresponding with the expected thickness of MoSi$_2$ deposited on Si, whereas on the passivated sample are ~4-8x shorter, consistent with delayed nucleation due to the protection of SiO$_2$ defect sites by the DPETPS monolayer. As shown in XPS studies on Si, deposition readily proceeds as metallic MoSi$_2$, whereas on unpassivated SiO$_2$, only 5.6% residual Mo is present at the surface. However, on DPETPS passivated SiO$_2$, Mo content is reduced to 1.4%. On the unpassivated SiO$_2$, a metallic Mo component is observed, consistent with partial MoSi$_2$ deposition. However, on the passivated SiO$_2$, no metallic Mo component is observed, consistent with nucleation of Mo on -OH sites forming Mo$_2$O$_5$. The Mo present being an oxidized state is consistent with MoO$_3$ nuclei on remaining defect sites blocking further Mo deposition.

Suppression of the Interfacial Layer and Improvement in Electrical Properties of High-K Gate Stack by Atomic-Layer-Deposited AlN Buffer Layer; Chin I Wang1, Teng Jan Chang1, Chun Yuan Wang1, Yu Tung Yin1, Jing Jong Shuye1, Hsin-Chih Lin1 and Min Jiang Chen1; 1National Taiwan University, Taipei, Taiwan; 2Academia Sinica, Taipei, Taiwan.

For high-performance nanoscale transistors and extension of CMOS roadmap, there are still many difficulties that need to be overcome. A low-grade interfacial layer (IL) between high-K gate dielectrics and semiconductors, which results in current degradation, low gate capacitance, and severe short channel effect, is one of the most important issues. However, it is difficult to prevent the formation of the thermodynamically unstable low-K IL such as SiO2 and GeO2. Hence we come up with a concept of introducing a non-oxygen buffer layer between high-K gate dielectrics and semiconductors. In this study, aluminum nitride (AlN) of good chemical stability and electrical characteristics is used as the buffer layer between the crystalline zirconium oxide (ZrOx) high-K gate dielectric and the semiconductor to restrain the formation of the low-K, unstable IL. A suppression of IL is confirmed by the X-ray photoelectron spectroscopy and the high-resolution transmission electron microscopy. A reduction in the equivalent oxide thickness and the leakage current density (JL) are achieved by the AlN buffer layer. In addition, a decrease of interface trap density (DOI) is accomplished because of the hydrogen passivation from the remote hydrogen plasma during the AlN deposition. All the results indicate that the AlN buffer layer is effective in providing a high-quality interface to improve the performance of advanced metal-oxide-semiconductor field-effect-transistors.

High Reliable High-K Dielectric Oxide-Based Nanolaminates for Next Generation Logic Analog and Memory Semiconductor Devices; Yuanning Chen1, Chun Wu2, Deborah Riley1, Israel Mejia1, Jesus Alcantar2 and Orlando Aucillio1; 1MicroSol Technologies Inc., Dallas, Texas, United States; 2The University of Texas at Dallas, Richardson, Texas, United States.

A novel structured material in thin film form, Sub-Nanometer Periodic Stack Dielectrics (SN-PSD) has been developed for applications to a new generation of logic analog and memory semiconductor micro/nano-devices. Compared with conventional single layer dielectric films, SN-PSD exhibits substantial improvement in dielectric breakdown voltage (~2.4V, or 35% improvement), and reduced leakage current by about one order of magnitude. High-density capacitor structures utilizing SN-PSD layer would enable on-chip decoupling capacitors in digital and analog integrated circuits (ICs), data storage elements in IR image sensors, energy storage in transmitters, and DRAM and other semiconductor memories to improve the performance and reduce the silicon footprint. The SN-PSD would also be suitable for use as a gate dielectric in silicon carbide (SiC) CMOS FETs for its low leakage current and high breakdown voltage. Existing single-layer-dielectric capacitors often have a large footprint, and have issues with high leakage current and early dielectric breakdown, making their use in developing devices problematic. The time-dependent dielectric breakdown lifetime extrapolation for SN-PSD indicates that the dielectric breakdown lifetime will exceed 10 years under equivalent electric field of 15.6MV/cm for HfO2/TiO2 SN-PSD-based capacitors, versus 9.1MV/cm for single layer HfO2-based capacitors. Compared to single layer HfO2 capacitors, the breakdown mechanism of the newly developed HfO2/TiO2 SN-PSD capacitors has been changed from hard breakdown to soft breakdown. The capacitance voltage (C-V) characteristics have been analyzed. The charge and discharge cycle has been studied for 10,000 cycles without degradation. The frequency response of capacitor has been characterized for frequencies of 10Hz, 100KHz, and 1MHz. Underlying mechanisms for the SN-PSD functionalities will be discussed.

3:45 PM EP09.09.07
Vertical GaN p-n Diode with Regrown p-GaN by Metalorganic Chemical Vapor Deposition; Kai Fu, Houqiang Fu, Hanxiao Liu, Shanthan Reddy Alugubelli, Tsung-Han Yang, Xuanqi Huang, Hong Chen, Izak Baranowski, Jossue Montes, Fernando A. Ponce and Yuji Zhao; Arizona State University, Tempe, Arizona, United States.

Gallium nitride (GaN) power devices have become one of the most promising candidates for applications in power electronic systems, offering remarkable improvements in energy conversion efficiency, switching frequency, and system volume. As one of the most important fundamental building blocks of semiconductor electronic devices, p-n junctions, created by doping methods using ion implantation, diffusion of dopants, or epitaxy, are also of great importance in fabricating GaN power devices. However, they are still difficult to implement for GaN, especially for p-type doping. It was found that GaN was not very resistant to ion beam disordering and this problem became more severe at higher dose ion implantation. For diffusion of dopants, the understanding of this process in GaN is also in its infancy. Epitaxy on GaN substrates may partly solve these issues due to the reduced dislocation density in the materials and doping during growth is still the most effective way to get well-controlled doping. Moreover, to fabricate high-performance GaN power devices and integrated-circuits, selective-area doping is indispensable. However, some physical mechanisms are still not clear, especially on regrown p-GaN. In this work, to mimic selective-area doping, p-GaN was regrown on an etched GaN surface on GaN substrates by metalorganic chemical vapor deposition. Vertical GaN-on-GaN p-n diodes were fabricated, where the etch-then-regrowth process was used to fabricate the devices. The crystal quality of the sample after each epitaxial step was characterized by X-ray diffraction, where the etch-then-regrowth process led to a very slight increase in edge dislocations. A regrowth interfacial layer was clearly shown by transmission electron microscopy. Strong electroluminescence was observed with three emission peaks at 2.2 eV, 2.8 eV and 3.0 eV, respectively. The 2.2 eV peak was related to the well-known yellow luminescence of GaN, which is due to capture of conduction band electrons by a deep acceptor level centered at 2.2 eV below the conduction band edge (CBE). The 2.8 eV peak originated from the donor-acceptor pair (DAP) luminescence, i.e., the transition from a deep donor level (~0.4 eV below the CBE) to the Mg acceptor level which is ~0.2 eV above valence band edge (VBE). The forward current density increased slightly with the increasing temperature, while the reverse current density was almost temperature independent indicating tunneling as the reverse transport mechanism. This result is very similar to the reported Zener tunnel diode comprising a high doping profile at the junction interface. High levels of silicon and oxygen concentrations were observed at the regrowth interface with a distribution width of ~100 nm. This work provides valuable information of p-GaN regrowth and regrown GaN p-n diodes, which can serve as an important reference for developing selective doping for advanced GaN power electronics for high voltage and high power applications.

The Study on Inhomogeneity of GaOx Schottky Barrier Diodes by Modified Thermionic Emission Model; Tsung-Han Yang, Houqiang Fu, Hong Chen, Xuanqi Huang, Jossue Montes, Izak Baranowski, Kai Fu and Yuji Zhao; Arizona State University, Tempe, Arizona, United States.

Gallium oxide, one of the promising ultrawide-bandgap material, has recently attracted considerable interest because of its potential for high power application and cost-effective growth. Its large bandgap (4.8 eV) and high breakdown electric field (8 MV/cm) result in superior energy density capabilities. The critical field strength of gallium oxide is more than 20 times that of silicon and more than twice that of silicon carbide and gallium nitride. The BFOM of gallium oxide is at least four times larger than those of SiC and GaN, indicating its great potential for high power application. Another advantage of gallium oxide is the availability of cost-effective single-crystal substrates. The edge-defined film-fed growth (EFG) method, described by Labelle and Mlavsky, is one of the main methods to grow large-sized β-Ga2O3 substrates, as its relatively low cost and scalability make it aptly suited for use in mass production. Electronic devices such as field effect transistors (FETs) and Schottky barrier diodes (SBDs) and optoelectronic devices such as solar-blind

The Study on Inhomogeneity of GaOx Schottky Barrier Diodes by Modified Thermionic Emission Model; Tsung-Han Yang, Houqiang Fu, Hong Chen, Xuanqi Huang, Jossue Montes, Izak Baranowski, Kai Fu and Yuji Zhao; Arizona State University, Tempe, Arizona, United States.
Photodetectors fabricated on the β-Ga$_2$O$_3$ substrates have been reported. However, the mechanism of the temperature-dependent performance of these devices is still not very clear. The non-ideal properties including (i) temperature-dependent Schottky barrier height and (ii) ideality factor and (iii) unreasonably small extracted Richardson constant cannot be easily explained by traditional thermionic emission theory with a homogeneous barrier. Similar behavior has been observed for a-IGZO, nanocrystalline ZnO, and ZTO. As a result, in this paper, a modified thermionic emission model over an inhomogeneous barrier having a voltage-dependent barrier height has been investigated and used to explain these non-ideal phenomena.

Optimizing Spin Hall Conductivity in Materials for Low Power SOT-MRAM
Derek Stewart$^1$, Wen Fong Goh$^3$ and Martin Gradhand$^1$; 1 San Jose Research Center, Western Digital; San Jose, California, United States; 2 Physics Department, University of California, Davis, Davis, California, United States; 3 HH Wills Physics Laboratory, University of Bristol, Bristol, United Kingdom.

While current magnetic RAM devices have demonstrated impressive speed, endurance, and retention, the power requirements for this technology still represent a key challenge for its widespread adoption. The ability of a spin Hall material to switch the spin orientation of a neighboring magnetic layer could serve as a key element in future low-power spin-orbit torque (SOT) MRAM devices. The spin Hall angle is given by the ratio between the induced transverse spin Hall conductivity due to spin-orbit interactions and the longitudinal electrical conductivity. While a high spin Hall angle is important, it is also critical to ensure low electrical resistance in order to develop energy efficient memory. In this work, we use first principle approaches to calculate the spin Hall conductivity in leading spin Hall materials: β-W (A15), β-Ta, and Pt-based alloys. We first calculate and confirm the fully relativistic Fermi surfaces and band structures for these materials using multiple ab-initio approaches, including plane wave formalisms (VASP, Quantum Espresso [1, 2]) and a relativistic Korringa-Kohn-Rostoker (KKR) approach [3]. The intrinsic spin Hall conductivity is calculated using two independent implementations of the Kubo formula based on the Berry curvature [4, 5]. For β-W, we predict intrinsic spin Hall angles ranging from 0.24 (bulk) to 0.45 (film) in excellent agreement with experiments [7, 8]. The spin Hall conductivity in β-W is sharply peaked just below the Fermi energy and the origin of this peak can be traced to closely spaced spin-orbit split bands near the Fermi energy. We will discuss how symmetry breaking in the A15 crystal phase leads to enhanced spin Hall conductivity and how this could potentially be leveraged in other materials. Calculations for Ta doped β-W show that the spin Hall conductivity peak can be shifted to the Fermi energy, boosting the spin Hall conductivity and angle by ~20%. This finding agrees with results from a recent study based on plane wave projection to maximally localized Wannier functions [9]. Since oxygen and nitrogen are often used to stabilize the metastable β-W, we also examine the potential impact of these dopants on the electronic structure and spin Hall conductivity. Predicting the spin Hall conductivity in the β-Ta is particularly challenging computationally due to the large tetragonal unit cell with 30 atoms. Our spin Hall conductivity predictions for β-Ta are in good agreement with experiments and our results indicate that the local β-Ta atomic environment could be similar to that found in the A15 phase. Finally, using a virtual crystal approximation, we examine the intrinsic spin Hall conductivity in Pt based binary alloys. We find good agreement with measured spin Hall conductivity for most of the composition range and the deviations from the predicted values can be traced to skew scattering contributions. Taken together, these different materials systems provide important insight on how the crystal structure and doping in a material can be tailored to boost spin Hall conductivity.

Study of Magnetization Precession in Perpendicularly Magnetized W/CoFeB/MgO Films Using TR-MOKE
Dustin M. Lattery, Delin Zhang, Jie Zhu, Xudong Hang, Paul A. Crowell, Jian-Ping Wang and Xiaojia Wang; University of Minnesota Twin Cities, Minneapolis, Minnesota, United States.

Perpendicular magnetic materials with low damping constant and high thermal stability have great potential for realizing high-density, non-volatile, and low-power consumption spintronic devices, which can sustain operation reliability for high processing temperatures. In this work, we study the Gilbert damping constant (α) of perpendicularly magnetized W/CoFeB/MgO films with a high perpendicular magnetic anisotropy (PMA) and superb thermal stability. The α of these PMA films annealed at different temperatures (T_anneal) is determined via an all-optical Time-Resolved Magneto-Optical Kerr Effect (TR-MOKE) method. We find that α of these W/CoFeB/MgO PMA films decreases with increasing T_anneal, reaches a minimum of α ~ 0.015 at T_anneal ~ 350 °C, and then increases to 0.020 after post-annealing at 400 °C. The minimum α observed at 350 °C is rationalized by two competing effects as T_anneal becomes higher: the enhanced crystallization of CoFeB and dead-layer growth occurring at the two interfaces of the CoFeB layer. We further demonstrate that α of the 400 °C-annealed W/CoFeB/MgO film is comparable to that of a reference Ta/CoFeB/MgO PMA film annealed at 300 °C, justifying the enhanced thermal stability of the W-seeded CoFeB films. Further, we discuss the dependence of the TR-MOKE signal on the magnitude and angle of the applied field, by utilizing a numerical algorithm based on the Landau-Lifshitz-Gilbert equation. The optimized operational conditions that produce the largest TR-MOKE signals are predicted and confirmed.

Indium Tungsten Oxide Thin Films for Flexible High Performance Transistors and Neuromorphic Electronics

Thin film transistors (TFTs) with high electrical performances (mobility > 10 cm$^2$/Vs, $V_{th} < 1$ V, $SS < 1$ V/decade, on/off ratio > $10^6$) obtained from the silicon and oxide-based single-crystalline semiconductor materials require high processing temperature and hence not suitable for flexible electronics. Amorphous oxide based transparent electronic devices are attractive to meet emerging technological demands where crystalline oxide/silicon-based architectures cannot provide a solution. Here, we tackle this problem by using a novel amorphous oxide semiconducting material—namely indium tungsten oxide (IWO)—as the active channel in flexible thin film transistors (FTFTs). Post-annealing at temperature at as low as 270°C for a-IWO thin films deposited by RF sputtering at room temperature could result in smooth morphology ($R_m\sim 0.42$ nm), good adhesion and high carrier density ($n \sim 7.19 \times 10^{15}$ cm$^{-3}$). Excellent TFT characteristics of flexible devices could be achieved with linear field effect mobility ($\mu_{FE}$) of 25.86 cm$^2$/Vs, sub-threshold swing SS < 0.30 V/decade, threshold voltage $V_{th} < 1.5$ V, on/off ratio $I_{on}/I_{off} > 5.6 \times 10^6$ at 3V and stable operation during bending of the FTFT. Additionally, IWO TFTs were implemented as synapses, the building block for neuromorphic computing. Paired-pulse facilitation (PPF) up to 138% was observed and showed an exponential decay resembling chemical synapses. Utilizing this characteristic, high-pass dynamic temporal filter was devised providing increased gain from 1.55 to 21 when frequency was raised from 22 to 62 Hz. The high performance and stability of flexible TFTs obtained with IWO films demonstrate their promise for low voltage electronic applications.

Semiconductors Heterovalent Interfaces and Integration Yong-Hang Zhang; Arizona State University, Tempe, Arizona, United States.

Abstract: Semiconductor electronic and optoelectronic materials and devices have experienced very rapid development for more than half a century. The recent progress in development of quantum materials and their applications in quantum computing, communication, and sensing also calls for in-depth understanding of interfaces between dissimilar semiconductors, semi-metals, and superconductor, and broad exploration of new heterovalent integration of these materials from different families. Thin layer quantum structures and their interfaces consisting of materials families such as group II-VI (MgZnCdHg(SeTe), III-V (AlGaan)(PAsSb)), IV-V (SiGeSnPb), and IV-VI PbSe(SeTe) grown on GaAs, InP, GaSb, InAs and InSb substrates offer a very broad spectrum of interface configurations, alloy combinations and their quantum properties for both fundamental physics study and device applications. This talk will focus on the latest progress in the MBE growth of these heterovalent structures and their potential applications in quantum materials research, solar cells, midwave IR light emitting devices, and photodetectors.

2:00 PM *EP10.01.02
Narrow Linewidth Semiconductor Disk Lasers and Progress Towards ZnCdMgSe Vertical Gain Structures George Chappell1, Brynmor Jones1, 2, Thor Garcia1, Maria Tamargo1 and Jennifer Haste1; 1University of Strathclyde, Glasgow, United Kingdom; 2Fraunhofer Centre for Applied Photonics, Glasgow, United Kingdom; 3The City College of New York, New York, New York, United States.

Optically-pumped semiconductor disk lasers (SDLs), also commonly known as vertical external cavity surface-emitting lasers (VECSELs), are of particular interest for applications that require high spatial and/or spectral brightness at novel wavelengths. A typical SDL gain structure consists of a multi-quantum-well resonant period gain region on a monolithic distributed Bragg reflector (DBR). This gain mirror is then optically-pumped and aligned within a conventional air-spaced laser resonator. With their relatively high output power (multi-Watt) and high finesse cavities, SDLs are ideally suited for narrow linewidth operation, demonstrating low frequency and intensity noise; properties we are currently exploiting to develop visible SDLs with sub-kHz linewidth for application in quantum technology, specifically atomic clocks. SDLs have been demonstrated from the deep ultraviolet to the mid-infrared via a combination of III-V semiconductor bandgap engineering and intracavity nonlinear frequency conversion; however, direct emission at wavelengths around the so-called ‘green-gap’ would offer many advantages in size, efficiency, and tunability as well as removing a nonlinear conversion step towards the UV.

With the advent of high power GaN pump lasers, un-doped II-VI materials show promise for optically-pumped gain structures in this spectral region, and there is already a large body of work on II-VI-based vertical structures on GaAs, including high quality DBRs. Our interest is in ZnMgCdSe on InP substrates, which offers optical gain from the blue to the red. Optically-pumped edge-emitting lasers in the blue-green, and red were previously demonstrated by the Tamargo group. DBRs are in development with the possibility of using the superlattice technique that has proved successful for material lattice-matched to GaAs; however, SDLs need not have a monolithic DBR if the quantum well gain region can be transferred to a transparent substrate. Here we present an overview of our recent work in visible narrow linewidth SDLs, and our progress on the design, growth, processing and characterization of ZnCdMgSe multi-quantum well gain structures, including transfer of gain regions to single crystal diamond windows.

2:30 PM EP10.01.03
Strategies for Analyzing Non-Common-Atom Heterovalent Interfaces—The Case of CdTe-on-InSb Esperanza Luna1, Achim Trampert1, Yong-Hang Zhang2, Martha McCartney3 and David J. Smith1; 1Paul-Drude-Institut, Berlin, Germany; 2Arizona State University, Tempe, Arizona, United States.

The selective combination of closely lattice-matched group II-VI/group III-V semiconductors offers potential benefits due to the wide range of band-gap energies achievable and novel effects at the interface arising from the valence-mismatch. Very little has been done so far to exploit these opportunities, in part due to challenges in determining the structure and properties of the interface, for instance using scanning transmission electron microscopy (STEM) techniques.

The combination of CdTe (II-VI) and InSb (III-V) implies the existence of a heterovalent non-common-atom (NCA) interface which must contain mixtures of II-V and/or III-VI bonds. Because of the close atomic numbers of the constituent elements, high-angle annular dark-field (HAADF) and large-angle bright-field (LABF) STEM, as well as electron energy-loss spectroscopy measurements are inherently difficult to interpret. In contrast, we show here that the use of the 002 dark-field (DF) imaging technique emphasizes the interface location by comparing differences in structure factors between the two materials. Additionally, detailed analysis of the digitized 002 DF TEM intensity allows quantification of the interface width to be made, which further allows the possibility to address questions such as exploring the presence of (unintentional) interfacial layers or mechanisms governing the interface formation in these complex valence-mismatched interfaces. The approach adopted here for the interface analysis relies on the comparison of experimental and simulated contrast profiles at the CdTe-on-InSb interface, where different functional dependences (e.g. sigmoidal function, error function) for the atomic species are assumed. Since the contributions of the III- (II-) and V- (VI-) elements need to be separately considered, the cation and anion intermixing are independently determined. Furthermore, information at the monolayer level can be unambiguously obtained. Finally, our study reveals that the CdTe-on-InSb interface is structurally abrupt to within about 1.5 nm (10-to-90%-criterion).

The method is of general applicability, and it will be applied in the future to other NCA heterovalent interfaces. Hence, it opens a new route for investigation of the long aimed correlation between the interface-related electronic properties and transport phenomena and the interface characteristics.

Development of Scalable Si-Based Composite Substrates for Various Optoelectronic Materials at 6.1 Å and 6.4 Å Yuanping Chen; U.S. Army Research Laboratory, Adelphi, Maryland, United States.

Silicon CMOS has become a gold standard as the signal processor for various optoelectronic devices. Therefore, it is highly desirable to have the devices built on the sensing materials epitaxially grown on Si base composite substrates to ensure reliable low temperature operation due to thermal match between the device structure and Si CMOS. In
addition, super scalability of readily available Si substrate enables fabrication of large area and low cost optoelectronic devices. However, due to the very large lattice mismatch between semiconductors at 6.1 Å and 6.4 Å and the Si substrate (about12% and 19% respectively), a buffer layer has to be used to bridge the gap and to accommodate the mismatch dislocations generated at the interface, as shown in figure 1. Considering the advantageous properties of II-VI material in accommodating mismatch dislocation, we choose ZnTe and CdTe as buffer materials to fabricate ZnTe/Si and CdTe/Si composite substrates for optoelectronic materials at 6.1 Å, such as GaSb or InAs base-type-2 superlattice and HgCdSe IR material, and at 6.4 Å, such as HgCdTe IR material, respectively. Furthermore, a small percentage of Se added into either the ZnTe or CdTe matrix will create a composite substrate lattice matching to the targeted optoelectronic materials, which will minimize the dislocations generated in device material. In this paper we will present our systematic studies on the molecular beam epitaxial (MBE) growth of Cd(se)Te/Si and Zn(se)Te/Si with emphasis on the techniques to reduce dislocations generated in the buffer layer as well as on control of Se concentration to achieve lattice matching with over-grown device layer. The quality of the buffer layers were evaluated by x-ray diffraction, transmission electron microscopy and etched pit density. Our results indicate a buffer layer of CdTe or ZnTe with dislocation as low as 10^4 cm^-2 can be grown on Si substrate. Photodiodes fabricated from Hg_0.9Cd_0.1Te grown on a lattice-matching CdSe/CdTe composite substrate exhibit excellent I-V characteristics [1]. The results validate the CdSe/CdTe/Si as a low-cost, scalable and high quality composite substrate for optoelectronic device at 6.4 Å.

4:00 PM EP10.02.02 Growth of Silicon Doped InAs by Atomic Layer Epitaxy Guy M. Cohen,1 Marinus Hopstaken,1 Michael R. Saccomanno1, William T. Spratt1, Sanghoon Lee1, Christian Lavoie2, Rene T. Mo1, Doron Cohen Elias2, Shmuel Saad2, Arnold Bloom2, Sergey S. Shusterman2, David Memram2 and Moti Katz2,† IBM T.J. Watson Research Center, Yorktown Heights, New York, United States; 2The Israel Center for Advanced Photonics, Sorokq Nuclear Research Center, Yavne, Israel.

We report the growth of in-situ silicon doped InAs layers over In_{0.5}Ga_{0.5}As/In/In/Si by atomic layer epitaxy (ALE). The use of ALE enables us to obtain uniform smooth layers with Si doping concentration in excess of 5E19 cm^-2 at growth temperatures of 400°C. This high doping level is typically hard to achieve with metal organic chemical vapor deposition (MOCVD) at similar growth temperatures. Furthermore, the growth was selective to silicon dioxide, with deposition taking place only over semiconductor surfaces. We have used doped barium sulphide (TBA) as a source for As, trimethylindium (TMin) as a source for In, and silane (SiH4) as a source for Si. ALE is also a unique tool for investigating amphoteric doping with silicon (a group IV element) in III-V materials. We designed two ALE cycles for growing Si doped InAs. The first cycle comprised of the following pulses: (1) TBA, (2) purge with H2, (3) TMin + SiH4, (4) purge with H2.

The second cycle comprised of:

1. TBA + SiH4, (2) purge with H2, (3) TMin (4) purge with H2.

In the first ALE cycle, Si doping was introduced with the group-III element, while in the second ALE cycle, Si doping was introduced with the group-V element. Secondary-ion mass spectrometry (SIMS) showed that incorporation of Si was 20x larger when Si was introduced with group-III. Furthermore, while the growth rate as a function of TMin pulse length saturates, longer SiH4 pulses did result in higher doping for pulse durations we studied.

4:15 PM EP10.02.03 High-Hole Mobility (500 cm2/Vs) Polycrystalline Ge Thin Film on a GeOx Coated Flexible Plastic Substrate Toshifumi Imao, Kento Moto, Takashi Suemasu and Kaoru Toko; University of Tsukuba, Tsukuba, Japan.

Ge on insulator (GOI) technology has been widely studied for lowering the fabrication cost and improving the device performance of Ge metal-oxide-semiconductor field-effect transistors. Solid phase crystallization (SPC) is a simple method to directly form polycrystalline Ge (poly-Ge) thin films on glass substrates at low temperatures [1]. Recently, we found that the control of the atomic density of an amorphous Ge precursor for SPC dramatically enlarged the grain size and updated the maximum value of hole mobility of semiconductor thin film on insulators [2-4]. The electrical properties of these Ge layers greatly depended on the film thickness, suggesting that the underlying interface influences the electrical properties [3]. Generally, it is known that the grain size of the Ge layer changes depending on the type of the underlayer [5,6]. In this study, we investigated the effect of the underlayer insertion on the SPC-Ge and broke the record with a hole mobility of 560 cm2/Vs by employing a GeO2 underlayer. Furthermore, we achieved a hole mobility of 500 cm2/Vs on even a plastic substrate.

To investigate the effects of the underlayer material, we prepared a 50-nm-thick insulating layer (SiN, Al2O3, GeO2) on a SiO2 glass substrate using RF magnetron sputtering. After that, amorphous Ge (a-Ge) precursors were prepared using a Knudsen cell of a molecular beam deposition system (base pressure: 5 x 10^-7 Pa) while heating the samples at 150°C. The thickness of the a-Ge layer was ranged from 100 to 600 nm. The samples were then loaded into a conventional tube furnace in a N2 atmosphere and annealed at 450°C for 5 h to induce SPC. After that, we performed post annealing (PA) at 500°C for 5 h to enhance the electrical properties. For comparison, samples without forming an insulating layer were also prepared. In addition, a sample with a GeOx coated plastic (polymide) substrate was prepared, which was annealed at 375°C for 150 h. After annealing for SPC, the grown Ge layers were evaluated by using electron backscattering diffraction (EBSD) analysis. The electrical properties of the SPC-Ge layers were evaluated using Hall effect measurements.

The EBSD images showed that the crystal grain size of the Ge layer on glass varied depending on the type of the underlayer. This suggests that the frequency of Ge nucleation was changed because of the change of the underlayer material. The Hall effect measurements showed that the larger grain size provided the lower hole density and the higher hole mobility. From the above results, we found that the GeO2 underlayer provides the largest grains and the highest hole mobility among the underlayer materials. The 400-nm-thick Ge on a GeO2 coated glass substrate, annealed at 450°C, exhibited a hole mobility of 440 cm2/Vs. Furthermore, the hole mobility was improved to 560 cm2/Vs by the PA at 500°C due to the defect compensation effect.

Based on the above results, we prepared a 400-nm-thick Ge layer on a GeO2 coated plastic (polymide) substrate, and induced SPC at 375°C. The resulting Ge layer exhibited a grain size of 9.1 μm and a hole mobility of 500 cm2/Vs. This hole mobility is the highest record among that of semiconductor thin films directly synthesized on a plastic substrate. This achievement will give a way to realize advanced electronic and optical devices simultaneously allowing for high performance, inexpensiveness, and flexibility.

Solar cells based on heterojunction with intrinsic thin layer (HIT) technology use heterojunctions to optimize the collection of photogenerated carriers. The silicon heterojunction (SHJ) solar cell design uses a combination of doped amorphous silicon [a-Si:H(p/n)] and intrinsic amorphous silicon [a-Si:H(i)] to form a contact that is selective to either electrons or holes. This design leads to a heterointerface which is formed between amorphous silicon-a-Si:H and crystalline silicon-c-Si which is critical to overall device performance; and consequently, it is imperative to understand the underlying physics that governs that transport.

There is still debate about the impact of the a-Si:H(i) layer and the defects in this layer on transport and on overall device performance. There have been experimental studies that have attempted to study the modes of hole transport through the a-Si:H(i) layer for a a-Si:H(p) emitter SHJ solar cell. Taguchi et al. did temperature dependent IV measurements and inferred that a multi-phonon process must be dominant[1]; Crandall et al. performed transient capacitance experiments and concluded that ‘hopping’ transport is the dominant mode transport [2]. However, many simulation studies which use commercial simulation tools are unable to rigorously study transport while studying cell level properties [3,4]. In this paper we explicitly simulate the transport of holes across the a-Si:H(i)/c-Si heterointerface and correlate it to overall device performance. We use a traditional drift-diffusion model to calculate the electric fields and potentials within the device for device operating conditions. Previously, we have also developed an ensemble Monte Carlo solver that calculates the energy of photogenerated carriers at the heterointerface [5]. Then we use a kinetic Monte Carlo (KMC) to explicitly study hole transport through the a-Si:H(i) layer for particular device operating conditions. This method allows us to explicitly study transport mechanisms such as multi-phonon injection/extraction, defect assisted ‘hopping’
transport, Pool-Frenkel emission, thermionic emission etc.

In this work we used the KMC to simulate hole transport across the a-Si:H(i) layer. This was done for various device conditions. Our simulations indicate that increasing a-Si:H(i) layer thickness (4 nm → 18 nm) at 300 K at short circuit condition leads to an increase in average collection time for holes (10⁻² → 10⁻¹ sec). However, the average collection time saturates at higher a-Si:H(i) layer thicknesses (>12 nm). Simulations were also conducted for varying temperature, interface defect density, optical phonon energy, and at open-circuit condition and maximum power point conditions for solar cells. We also replicated an experimental study (given in ref 2) by simulating time dependent carrier decay across the a-Si:H(i) barrier and obtained very similar trends. Our simulations in conjunction with the experimental studies strongly indicate that the hole are collected via 'hopping'. We are currently trying to quantitatively correlate our transport simulations to device performance parameters such efficiency, fill factor and open-circuit voltage.

4:45 PM EP10.02.05 Twin Boundaries in GaP Nanowires—Electronic Structure and Optical Properties Divyanshu Gupta1, Nebile Isik Goktas2, Amit Rao2, Ray LaPierre2 and Oleg Rubel1, 1Department of Materials Science and Engineering, McMaster University, Hamilton, Ontario, Canada; 2Department of Engineering Physics, McMaster University, Hamilton, Ontario, Canada.

Semiconductor nanowires are used in optoelectronic devices, such as light-emitting diodes, lasers, solar cells, and photodetectors [1]. Formation of multiple twin boundaries during the growth of nanowires is very common. However, the effects of these planar defects on the electronic and optical properties of nanowires are not very well understood. It is unclear whether twin boundaries act as recombination centers and if they introduce any barriers/traps for charge transport.

Here, we combine ab initio electronic structure calculations with experimental techniques to study these effects [2]. Twin boundaries in GaP are shown to act as an atomically-narrow plane of wurtzite phase with a type-I band alignment homosctructure. Presence of twin boundaries leads to the introduction of shallow trap states. Trapped optical excitations have a weak, but finite dipole matrix element. It results in optical transitions that are otherwise suppressed in the indirect band gap GaP. Sub-band gap peaks observed in photoluminescence studies of GaP nanowires are attributed to twin boundaries and extended regions of wurtzite GaP. Implications of the presence of twin boundaries on the performance of nanowire-based devices will be discussed.

SESSION EP10.03: Poster Session: Heterovalent Integration of Semiconductors and Applications to Optical Devices

EP10.03.01 Fabrication of a One-Dimensional AlGaNpGaAs Microrod via a Top-Down Approach with Micro-Engineering Gang Yeol Yoo1, Joongho Lee2, Yun Jae Fo2, Woong Kim1 and Young Rag Do2; 1Korea University, Seoul, Korea (the Republic of); 2Kookmin University, Seoul, Korea (the Republic of).

The importance of studies of various types of III-V based inorganic materials is increasing rapidly due to their attractive properties, such as their thermal, chemical and moisture stability, direct bandgaps, and the high population density nature of these materials and related devices. Moreover, research on micro- or nano-patterned devices with III-V-based materials has been very active owing to the suitability of these materials in commercialized optoelectronic devices given their enhanced lifetimes, high brightness levels, and the high efficiency of novel optoelectronic devices. Here, an AlGaNpGaAs one-dimensional (1D) microrod was fabricated for use in one-directional micro/nano devices by a top-down approach. These 1D microrod structures, which were fabricated by transferring a 1D patterned microsphere as a mask and using plasma dry etching, in this case reactive ion etching (RIE) and inductive coupled plasma (ICP), can be used as a horizontally aligned single microwire device. To fabricate the 1D AlGaNpGaAs microrod, SiO2 thin films deposited by plasma-enhanced chemical vapor deposition (PECVD) were fabricated as microrod arrays to be used a mask for etching the AlGaNpGaAs microrod arrays. In this study, relative etching rates and etching selectivity of the AlGaNpGaAs layer were studied to fabricate vertical aligned III-V microrods. The morphological properties of the AlGaNpGaAs microrod were studied by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). A defect analysis was conducted of the dry etching process and the enhanced optical properties of the 1D microrod were analyzed in terms of the photoluminescence (PL) and cathodoluminescence (CL).

EP10.03.02 Theoretical Study of Electronic Properties of Heterovalent Semiconductors Based on SnO2: Vyakhlov Yatskina, Cory K. Perkins and Paul H.-Y. Cheong; Oregon State University, Albany, Oregon, United States.

Sn dioxide (SnO2) belonged to a class of transparent conducting oxide materials and had high transparency in the visible spectrum as well as high electrical conductivity [1]. Pure SnO2 was a n-type semiconductor with a bandgap of 3.6 eV [2]. Structure defects and the presence of impurities had great influence on electronic and optical properties of semiconductors [3]. Doping with heterovalent elements (Sb, F) allowed for modification of the electronic structure: the position of the conduction band minimum and valence band maximum may be shifted, thus altering the bandgap value [4]. Systematic study of heterovalent systems of semiconductors established correlations between composition, structure, and electronic properties, allowing for directed synthesis of new materials with desired properties. First principle simulations provided structure and properties predictions for new compounds. Such simulations were based on the density functional theory (DFT) and could be performed within either the local density approximation (LDA) or by use of the generalized gradient approximation (GGA). Both approaches demonstrated severe underestimation of the bandgap especially in the case of systems with strong d-electron interactions (TiO2, NiO, ZnO, SnO2). Bandgaps obtained with the use of hybrid functionals were close to experimental values, although such simulations were much more computationally expensive and were often incomplete. Our study involved the influence on crystal structure and electronic properties as a result of heterovalent substitutions (up to 10% mol) of Sn and O by Sb, Ta, and F. Using different functionals implemented in VASP code [5], we performed relaxation to find optimized cell parameters for pure SnO2 and its solid solutions with Sb, Ta, and F. While GGA and LDA predict the bandgap of SnO2 with 80% and 60% error respectively, hybrid functional based on Heyd, Scuseria, and Emzerhof (HSE) [6] showed an accurate bandgap value of 3.62 eV in comparison with the experimental value. It was shown that heterovalent substitution of Sn by Sb led to a linear decrease of the bandgap from 3.62 to 3.01 eV for the range of 0 to 11% mol. When Oxygen was substituted by Florine the bandgap decreased to 3.06 eV for 10.2% mol of F. The influence of dopant concentration on the bandgap was linear for all functionals used, indicating this was a possible key to manipulating the bandgap in allovalently substituted Tin Dioxide.

Effect of W⁺⁺ Doping on the Structural, Chemical and Dielectric Properties of Ga₂O₃

Vishal Zade¹,², Mallesh Bandy¹,³, Mohan Raj Rajkumar¹,², Ashley Díaz¹,² and Ramana V. Chintalapalli¹,²,³
¹University of Texas, El Paso, Texas, United States; ²CMR, El Paso, Texas, United States.

Among the wide band gap semiconductors oxides, Ga₂O₃ is explored extensively owing to its wide range of applications such as gas sensing, solar deep UV-photodetector, photocatalytic, high power devices and light emitting diodes etc. There are extensive studies exploring the effect of different dopants in Ga₂O₃ to alter the properties, performance, and new device applications. Here, we report the effect of W⁺⁺ doping on structural, chemical, and dielectric properties of Ga₂O₃. W-doped Ga₂O₃ (Ga₂₋ₓWₓO₃, 0 ≤ x ≤ 0.25, GWO) ceramics were synthesized using solid-state reaction route. Phase and crystal structure of the synthesized compounds were confirmed through X-ray diffraction (XRD) analyses. XRD data of sintered samples reveal that W doped compounds stabilize in monoclinic symmetry similar to Ga₂O₃ for x ≤ 0.1, whereas evolution of secondary phases of unreacted WO₃ begins at x > 0.15. Room temperature dielectric properties of GWO compounds reveal increment in dielectric constant as compared to pure Ga₂O₃. A correlation between structural chemistry, vibrational modes, and dielectric properties of W-doped Ga₂O₃ ceramics is established.

Fabrication of a Remote-Type Single-Package Light-Emitting Diode Using the Mixed Narrowband CaMgAl₃O₄:Eu,Mn Green Phosphor and the KSiF₆:Mn⁺⁺ Red Phosphor for Wide-Gamut White LEDs

Hesoon Kang, Changwok Kim, Keeyong Nam Lee and Young Rang Do; Kookmin University, Seoul, Korea (the Republic of).

In this study, we characterized remote-type single-package (single-PKG) white-light-emitting diodes (WLEDs) using the narrowband CaMgAl₃O₄:Eu,Mn (CaM:Eu,Mn) green phosphor and the line-emitting KSiF₆:Mn⁺⁺ (KSF:Mn) red phosphor in order to enhance the color gamut and luminous efficacy of WLEDs at a correlated color temperature (CCT) of 10000K. We synthesized, optimized and mixed CaM:Eu,Mn phosphors and red-emitting KSF:Mn phosphors. The mixed green and red phosphors were successfully applied to conventional blue LEDs (432 nm) to fabricate a remote-type single-PKG white LED. The luminous efficacies of white and the associated red, green and blue LEDs were measured and found to have reasonable values of ~70, 15, 35, and 5 lm/W, respectively, at 20 mA. This resultant color gamut (~111 %) of a filtered white LED is superior to that of the highest ever color gamut of reported phosphors, such as the sharp γ-AION:Mn,Mg green and KSF:Mn red phosphor (~102.4 %) as well as the commercialized InP/ZnQD-based QDEF for LCDs (~100 %). The wide color gamut of a backlight consisting of an InGaN blue LED, the CaM:Eu,Mn green phosphor, and the KSF:Mn red phosphor can meet the color requirements for backlighting in LCD displays.

Electrical Characterization of Silicon–Nickel Iron Oxide Heterojunctions

James N. Talbert and Wilhemmus J. Geerts; Texas State University, Canyon Lake, Texas, United States.

The market for non-volatile memory is potentially about to hit a brick wall with the flash technology as it might not be scalable beyond the 14nm node. The need for other storage devices is a hot topic in said market, and one possibility is Resistive RAM (ReRAM) devices. These devices can store information through a reversible switch from high to low resistance. Two mechanisms bipolar and unipolar are used to explore the reset process. Bipolar switching uses reverse bias to cause recombination of the oxygen atoms. In this project the applicability of NaₓFe₂O₆₋ₓ in ReRAM devices is being investigated.

Device test wafers with different oxygen concentration and thicknesses were made by reactive RF magnetron sputtering on n and p type Si substrates (×100 test grade 0-100 Ohm.cm). The native oxide was removed using HF 2 minutes before loading the samples in the vacuum chamber. The oxide was deposited by reactive RF co-sputtering using two guns on opposite sides of the sampleholder. To further improve the homogeneity of the oxide layer, the substrate holder was rotated during deposition. Samples were deposited at two different oxygen flow rates. The deposition rate was dependent on the flow and varied from 0.15 (40% O2) to 1.1 (10% O2) A/sec. The Au electrodes were deposited through a stainless steel shadow mask which contained 1312 devices ranging in diameters from 800 micrometers to 50 micrometers with a thickness of 100nm. A quartz coupon was used to shield areas of the Si-wafers from the Ni electrode during the previous deposition step, both Si-Au and Si-NiFeO-Au devices were available for characterization on each wafer. After finishing the total device stack the SiO₂ on the back of the wafers was removed by HF and covered with a 100 nm Aluminum layer using thermal evaporation. A linear four point probe was used to determine the resistivity of the Permalloy Oxide (PyO) thin films on the quartz coupon. Low Oxygen concentration samples yielded a resistivity of 4E5 Ohm cm. High Oxygen concentration samples showed a resistivity of 5E3 Ohm cm. A Summit 12000 probe station of FormFactor and a Keysight B1500A Semiconductor Analyzer were used to characterize the device wafers. Current-voltage relationships were measured at room temperature. This probe system is completely automated which allows for instant access to each of the 1312 devices on the wafer. Heterojunctions on n-type silicon showed strong rectification with Ifor/Irev>50 for low O₂ flow devices and Ifor/Irev>10,000 for high O₂ flow devices. The heterojunction on p-Si showed negligible rectification. As for the devices on p-Si two states were identified, an initial high resistance state and a non-linear IV curve with much larger currents after burn in. The electric characteristics scales with the device area for n-type substrates but not for p-type substrates. Our preliminary results suggest the p-type nature of Permalloy Oxide sputtered at high Oxygen flow.

Electrical Characterization of Silicon–Nickel Iron Oxide Heterojunctions

James N. Talbert and Wilhemmus J. Geerts; Texas State University, Canyon Lake, Texas, United States.

High Resolution Ion Beam Analysis (HR-IBA) combines <111> channeling with 3.039 ± 0.01 MeV (16O, 16O) nuclear resonance. Ga, As, and O coverage are measured to within ±0.1%. HR-IBA before and after etching by matching SIMNRA simulations to HR-IBA spectra. IBA shows that after the etch, oxygen coverage on GaAs decreases 50 ± 4% from 7.2 ± 0.2 ML to 3.6 ± 0.2 ML. The 53.47 stoichiometric ratio of Ga to As remains constant after etching within ±1%. The area surface density shows that decreasing oxygen coverage by a factor two is commensurate with decreasing displacement of Ga and As surface atoms, implicating etching doesn’t corode GaAs or alter stoichiometry.
X-Ray Photoelectron Spectroscopy (XPS) measured oxidation states and uniformity of the surface for C, O, Ga, and As on two locations of two wafers for both native oxide and etched GaAs(100). GaAs native oxides include binary oxides (Ga₂O₃, As₂O₅, As₂O₆), ternary oxides (Ga₅AsO₁₃), and metallic arsenic. The proportion of oxidized Ga increased from 40 ± 1% to 47 ± 1% while the proportion of oxidized As decreased from 21 ± 1% to 19 ± 1%. This change in As oxidation reverses the hydro-affinity of GaAs(100) as the decrease in fully oxidized As increases the amount of unfiled bonds of As, increasing γ \textsuperscript{S}.

In summary, 3LCAA measured a change in GaAs hydro-affinity before and after etching by a factor of two from strongly hydrophobic (γ \textsuperscript{S} = 33 ± 1 mJ/m²) to strongly hydrophilic (γ \textsuperscript{S} = 66 ± 1 mJ/m²). HR-IBA accurately determined to within 0.2 ML decreased oxygen coverage and stoichiometry as a function of wet chemical etching. XPS was then correlated with IBA to establish modifications in the proportion of oxidized Ga and As atoms and in their oxidation states. Modification of oxidation states help explain the dramatic change observed in hydro-affinity.

EP10.03.07
External Piezoelectric Fields Induced Further Trap-Depth Decrease and ML Emissions from ZnS: Mn/PVDF Thin-Film Structures Puilei Wang; State Key Laboratory of Crystal Material, Jinan, China.

ZnS:Mn is one of the most promising luminescence materials for large-scale applications, such as artificial skin, self-diagnosis display, etc. However, the mechanoluminescence (ML) process of ZnS:Mn has been come up for two kinds of mechanisms. In this work, a kind of piezoelectric-assisted structures (ZnS:Mn/PVDF Thin-Film Structures) was designed and investigated for promoting the intensity of mechanoluminescence. As is well-known, ML materials emit light during deformation applying a mechanical stress onto these surface, piezoelectric signals responding to the mechanical stress are generated by ZnS and PVDF as well. The luminescence intensity performance of the ZnS:Mn/PVDF thin-film structures can be increased almost double compared with the pure ZnS:Mn particles. The present work could provide an approach to improving the luminescence intensity of ZnS:Mn ML and it supports the piezoelectrically-induced electron detrapping model for the ML in ZnS:Mn particles as an adjuvant proof.

EP10.03.08
The Gas Sensing Properties of CuSbS\textsubscript{2} Quantum Dots/rGO Composites to Ammonia at Room Temperature Yuqiu Liu; Wuhan University of Technology, Wuhan, China.

The reduced graphene oxide (rGO) has drawn much attention as gas sensing material in the field of gas detection. However, there are still some challenges for its application because of the poor stability and selectivity. Therefore, it is particularly significant for the functionalization of rGO. As a new ternary semiconductor, CuSbS\textsubscript{2} quantum dots (QDs) have many special advantages, such as large specific surface area, tunable band-gap, high carrier mobility, which enables to be applied to enhance the gas sensing properties of rGO. In the present work, rGO sheets are prepared by Hummers method and CuSbS\textsubscript{2} QDs/rGO composites are synthesized by hot injection method, and then CuSbS\textsubscript{2} QDs/rGO composites are self-assembled by a solution method. It is found that there are some wrinkles on the rGO sheets and the average size of CuSbS\textsubscript{2} QDs in the composites is 4.9 nm with the even and dense dispersion on rGO sheets. The gas sensing properties of CuSbS\textsubscript{2} quantum dots responding to the mechanical stress are generated by ZnS and PVDF as well. The luminescence intensity performance of the ZnS:Mn/PVDF thin-film structures can be increased almost double compared with the pure ZnS:Mn particles. The present work could provide an approach to improving the luminescence intensity of ZnS:Mn ML and it supports the piezoelectrically-induced electron detrapping model for the ML in ZnS:Mn particles as an adjuvant proof.

EP10.03.09

Recent advances in nanofabrication techniques have generated innovative approaches to engineer lattice strain in materials, with unprecedented spatial and temporal resolutions. Strain engineering has been demonstrated to drastically improve physical properties of materials and even embed unique functionalities in materials for a broad range of applications, including optoelectronics, microelectronics, multiferroics, two-dimensional materials, functional soft crystals, and more recently, high Tc superconductors and quantum materials. Strain has been implemented in varied forms including lattice misfit strain, thermal strain, phase transition strain and strain from point defects or extended defects such as dislocations. The epitaxial strain induced by the lattice mismatch between the nanostructures and the substrate has opened a door to enhance drive current by controlling the electron and hole mobility in Si-based devices. It has been discussed that it should be possible to enhance electronic properties with strain [1]. The concept of carrier pocket engineering used the influence of strain to engineer the band structure of silicon and germanium based superlattices (SLs) to optimize the electronic transport. Theoretical calculations suggested that the basic features of electron bands for the (Si/Ge) superlattice can be understood in terms of folded average bulk bands, and explained the electronic transport in superlattices based on this hypothesis [2]. This was justified since bands of Si and Ge are very much alike. However, in many of these studies, the effect of interfaces has not been taken fully into account. A complete treatment of electronic transport in a multi-interface system requires solving the complex interplay between the confinement and effect of the interface.

In this work, we investigate electron transport in layered Si/Ge superlattices employing first-principles density functional theory (DFT) and Kronig-Penney (KP) model, in combination with semi-classical Boltzmann transport theory. We report the effect of strain on the electronic structure and transport properties of multilayered nanostructures, by computing electronic properties of superlattices with compositional variability, and substrate induced external strain. The structural non-uniformity induces strain that strongly influences the bonding environment and therefore, the electronic charge densities within these structures. The modified charge densities directly impact electronic band structures. We compute the electronic band structures with DFT and KP model and discuss to what extent superlattice band structures can be thought of as composed of average “bulk” bands. We highlight the importance of interfaces to modify the band structures. It is interesting to note the different interface physics captured by these two models. We discuss the impact of strain on band structures and consequentially, cross-plane electronic transport across the multilayered systems. Our work establishes a direct relationship between the introduction of local and global strain and cross-plane transport in multilayered semiconductor superlattice structures. One representative result from our study is that introduction of positive strain (tension) in the in-plane direction of Si/Ge superlattices leads to significant improvement of the Seebeck coefficient at higher carrier concentrations. The project is funded by the DARPA (DSO) MATRIX program. This work used XSEDE, which is supported by NSF grant number ACI-1053575.

SESSION EP10.04: Heteroevalent Integration I
Session Chairs: Yuanping Chen and Maria Tamargo
Thursday Morning, April 25, 2019
PCC North, 200 Level, Room 226 B

8:00 AM *EP10.04.01
Interface Structure and Defect Formation During III-(Sb,As) Epitaxy on Si(001) Achim Trampert\textsuperscript{1}, M. Niehle\textsuperscript{1}, H. Drube\textsuperscript{1}, J.B. Rodriguez\textsuperscript{2,3}, L. Cerutti\textsuperscript{1,2} and Eric Tournié\textsuperscript{1}; \textsuperscript{1}Leibniz-Institut im Forschungsverbund Berlin, Paul-Drude-Institut für Festkörperelektronik, Berlin, Germany; \textsuperscript{2}Université de Montpellier, Montpellier, France; \textsuperscript{3}CNRS, IES, UMR 5214, Montpellier, France.
The integration of III-V compound semiconductor materials on Si provides a unique opportunity to combine the benefits of advanced optoelectronic materials with the capabilities of established silicon technologies. The direct epitaxial growth of III-V lasers on Si-based electronic circuits appears as very promising, cost-effective and versatile approach. Nevertheless, the heteroepitaxy of very dissimilar materials such as group III-Sb or III-As on Si (001) substrates has been shown for a long time to be challenging by reasons of existing large lattice, thermal and polarity mismatches, which typically result in a three-dimensional growth mode accompanied by the development of high defect densities. Although much progress has been made in recent years on the detailed characterization of the nature of the extended defects and their controlling during growth, a comprehensive understanding of the interface structure and defect formation mechanisms has not yet been achieved. In this contribution, we will present our latest results on interface structures of planar III-Sb layers grown on Si including complex GaSb-based laser structures by molecular beam epitaxy [1]. The origin of misfit and threading defects is unambiguously explored by combining the methods of three-dimensional imaging using electron tomography and scanning transmission electron microscopy and spectroscopy [2,3]. The number and distribution of threading dislocations cannot be made consistent with the concept of their generation during three-dimensional island coalescence on the basis of imperfections in the misfit dislocation networks. Differences in the interface chemistry – GaAs/Si versus AlSb/Si – will be discussed and concepts of defect reduction will be outlined.

8:30 AM *EP10.04.02
Heterovalent Integration as a Tool for Controlling Magnetic Properties of Epitaxial Semiconductor and Metal Films Jacek K. Furdyna; University of Notre Dame, Notre Dame, Indiana, United States.

In this presentation I will discuss three examples of heterovalent integration of semiconductors and magnetic films as a means of controlling their magnetic properties. Let us begin with the alloy GaMnAs, a well known ferromagnetic semiconductor grown by low-temperature molecular beam epitaxy (MBE). The Curie temperature of this material naturally depends on the concentration of the Mn magnetic ions in the crystal lattice. It is well known that the divalent Mn ions incorporated into the GaAs lattice act as acceptors, and that the Fermi level of the holes created by this process puts a limit on how much Mn can be incorporated into the crystal, thus naturally putting a limit on the Curie temperature that can be achieved. [1] We have shown that the hole concentration can, however, be controlled by integrating GaMnAs with Ge (which are very closely lattice-matched), either by epitaxially growing GaMnAs on Ge, or Ge on GaMnAs. [2] This possibility is enabled due to the specific valence band offset that exists between these two materials. As a second example, I will discuss the effect of integrating Fe with either Ge, GaAs or ZnSe. Epitaxial films of bcc alpha-Fe are nearly perfectly lattice matched with these three fcc semiconductors, enabling epitaxial growth of very high quality single-crystal films on these materials. I will show that the magneto-crystalline anisotropy of the resulting alpha-Fe films (a property of major importance in spintronic devices) is strongly related to the semiconductor on which the Fe film is grown. Specifically, it has been demonstrated by using ferromagnetic resonance (FMR) and magnetotransport that magneto-crystalline anisotropy of alpha-Fe films integrated with Ge is perfectly cubic; that it is weakly uniaxial in Fe integrated with ZnSe; and that magneto anisotropy of Fe grown on GaAs is quite strongly uniaxial. [3,4] I will discuss the physical reasons for each of these cases. The effects on magnetic anisotropy of Fe arising from integration with Ge, GaAs or ZnSe become important because of current interest in forming magnetic tunnel diodes and related structures involving GaMnAs and Fe, where GaAs, ZnSe or Ge can be used as non-magnetic barriers between the two magnetic layers. [5]

Finally, I will discuss the interesting case when the ferromagnetic semiconductor GaMnAs is integrated with the topological insulator Bi2Se3. Unlike the preceding two examples, in this case the lattice match is not critical because of the van der Waals forces involved in epitaxial growth of Bi2Se3. It has been shown that such integration has two rather profound effects on the ferromagnetic magnetic properties of GaMnAs. First, the proximity of Bi2Se3 results in a significant decrease of the Curie temperature of GaMnAs. And second, equally as important, this proximity profoundly changes the magnetic anisotropy of GaMnAs and results in a significantly higher magnetic coercivity of GaMnAs. [6] The physical mechanism behind this effect is at present not fully understood, and efforts are continuing to resolve this interesting puzzle.

9:00 AM *EP10.04.03
Epitaxial GaAs/Si Solar Cells Minjoo Lee and Shizhao Fan; University of Illinois Urbana-Champaign, Urbana, Illinois, United States.

Si-based tandem solar cells have become a topic of great interest over the past several years due to the fact that Si single-junction cells are approaching their practical efficiency limits. The highest Si-based tandem efficiency of 32.8% was achieved by bonding a III-V solar cell to Si. Perovskite/Si tandems are next highest in the efficiency race, attaining 27.3% efficiency at the time of writing. The efficiency of epitaxial III-V/Si tandems has also risen rapidly, though remains behind the approaches listed above. In this work I will describe our recent work to separately demonstrate 16.5% efficient GaAs top cells and 7.8% efficient GaAsP-filtered Si bottom cells (both certified by NREL). High short-circuit current density was attained in the Si bottom cell due to strong light-trapping, and our best Si bottom cells produce significantly more current than our best GaAsP top cells. We calculate that when combined, our current-mismatched J3 cells could reach a two-terminal tandem efficiency of 23.9%, and progress towards this goal will be reported.

9:30 AM *EP10.04.04
Tunable Optical and Structural Properties of Ga-Doped ZnO Film with In Situ Doped Atomic Layer Deposition Shang-Yu Tsai1, Chun-Chi Chen2, Cheng Jun Wang1 and Fu-Hsiang Ko1; National Chiao Tung University, Hsinchu, Taiwan; 1National Applied Research Laboratories, NARLabs, Hsinchu, Taiwan.

Recently, Transparent Conducting Oxides (TCOs) were one of the central issue in modern life due to their applications such as flat-panel displays, solar cells, and touch screen displays. For TCOs applied as transparent electrodes, the thin films should own lower resistivity, larger transmittance in visible light range, and enduring stability. Zinc Oxide (ZnO) doped with group-III impurities such as Al and Ga have shown satisfactory optical and electrical properties as a relatively inexpensive alternative TCO material. The common deposition techniques of ZnO thin films including Sputtering techniques, Pulsed Laser Deposition, and so on. These processes needed to change Ga to Zn ratio target for different Ga doping concentration and relatively high temperature to grow well quality ZnO films. In contrast, Atomic Layer Deposition (ALD) system could operate ZnO films easily in different Ga doping concentration at low temperature in great uniformity. Traditionally, ZnO films doped with group-III impurities utilized multi-layer deposition method which deposited several ZnO layer plus one impurity Oxide layer to control impurity doping concentration, the process would cause the restriction of thickness and electrically due to the multi-layer depositing and high resists electric oxide layer.

Here, we developed a method of in-situ doping with flow rate-interruption to grow ZnO thin film by ALD system. The difference between traditional multi-layer growth and in situ doping growth is that Ga, Zn, and O are all in the same layer on the process. The advantages of this method are optimized reaction time, controllable doping concentration, low precursor consumption, high step coverage, stable crystal growth, and controllable film thickness. A (002) highly prefer orientation crystal ZnO thin film was successfully grown on 1 um of amorphous Silicon Dioxide (SiO2) film, which normally promotes random crystal ZnO structure growth. In this study, the in-situ doping with flow rate-interruption method demonstrated better crystalline and enhanced-control doping concentration in ZnO thin films. The in-situ doping flow-rate-interruption ZnO thin films were grown with different TEGa pulsed time at 300 degree Celsius by the ALD system. To understand the composition and structural properties of ZnO thin films, EDS spectrum and Gonio scan were measured. The EDS results showed the different Ga composition ratio of 0.67, 1.28, 1.74, 2.86, and 2.42 at% with the pulsed time of 10, 50, 80, 100, and 130 msec, respectively. The results indicated that Ga doping concentration can be controlled by TEGa pulsed time, and concentration reached saturation after 100 msec. The Gonio scan results showed that the trend of ZnO thin films were from poly crystal structure to (002) highly prefer orientation crystal structure with increasing Ga doping concentration from 0.67 to 1.74 at%. When the Ga doping concentration exceeded 1.74% the film reverted back to poly crystal structure.

In order to realize the electrical and optical properties of ZnO thin films, Hall measurement and Ellipsometry was used. The carrier concentration and electrical resistivity ZnO film was about 10^{19} cm^{-3} and 10^{4} Ω-cm respectively, which was comparable to ITO TCO glass. The steady growth rate of 0.67 to 1.74 at% ZnO thin films were 1.3 A/cycles and roughness were around few nanometers by Ellipsometry fitting, agreed with SEM cross section data. The refractive coefficient of the pure ZnO film was at n=2, however the
coefficient down to $n=1.8$ with Ga doping in visible light at 633 nm. The lowest refractive coefficient was achieved $n=1.76$ at 1.74 at% Ga of GZO film. Interestingly, in contrast to ZnO nearly no absorption, the GZO films strongly absorbed with the extinction coefficient $k=0.7$ at 1.55 um in near-infrared range.

9:45 AM EP10.04.05 Orientation Shift of ZnTe Epilayers Grown on M-Plane Sapphire Substrates by Introducing Nano-Facet Structures Taizo Nakasu and Masakazu Kobayashi; 1,2 Department of Electrical Engineering and BioScience, Waseda University, Tokyo, Japan; 1 Kagami Memorial Research Institute for Materials Science and Technology, Waseda University, Shinjuku, Japan.

The growth of single domain ZnTe layers on heterовалent materials is expected for the devices utilizing Electro-Optic (EO) effects. The EO coefficient of ZnTe is one of the highest among the conventional semiconductor materials. (110) or (111) oriented ZnTe layers should be prepared on the heterovalent substrate which does not exhibit the EO characteristics. The transparent substrates should be used since the optical alignment tunings could be simplified. Sapphire was focused on for the substrate, and MBE growth of ZnTe layers have been performed on various substrate surface orientations. It was revealed that the insertion of the low temperature grown thin buffer layers, as well as the high temperature annealing (at 1000 to 1500°C for ten to forty hours) of the sapphire substrate surface to realize atomically smooth surfaces were effective in achieving high crystal quality layers of ZnTe. The single domain ZnTe epilayers with the x-ray rocking curve linewidth of about 400 arcsec were achieved on c-plane (0001) sapphire substrates so far. The nano-facet formation was observed for the m-plane sapphire substrate after the similar annealing. The characteristic nucleation profiles on various nano-facet structures were studied in this study to obtain the insight of the heterovalent interface and the epitaxial relationship. RHEED, AFM and XRD pole figures were mostly used to characterize the interface properties. The un-annealed substrate surface exhibited the featureless surface with the RMS roughness of about 0.3 nm. The m-plane was disappeared after the annealing, and the annealed substrate surface was covered with the periodic nano-facet structure consisting from 5 to 40 nm size of alternately appearing facet structures of r-planes and S-planes. The size of the structure was varied by the annealing condition, and height was about 5 to 10 nm when it was annealed at 1100°C. The height was increased to 50 nm when the annealing temperature was increased to 1300°C. The nucleation profiles of the low temperature buffer layer was drastically varied by those surface structures. RHEED patterns suggested that substrate surfaces of un-annealed and annealed at 1100°C were fully covered with the amorphous layer after 3.5 nm of the deposition at around 100°C. On the other hand, the RHEED pattern of the substrate was barely changed for the 1300°C annealed substrate surface. The low temperature deposition of ZnTe on the r-plane substrate was also monitored in past and the RHEED pattern was barely changed even after the deposition of about 3.5 nm, which suggested that sticking of ZnTe on r-plane sapphire was very poor. It is notable that the deposition of ZnTe buffer layer at such low temperature range was affected by the substrate surface profile. The orientation of ZnTe layers on various surfaces was similarly varied. The (211) oriented ZnTe layer was confirmed when the thick layer was grown on the un-annealed substrate. The orientation was shifted to (331) when the layer was grown on the 1100°C annealed substrate. The epitaxial relationship of ZnTe on S-plane sapphire was studied in past, and the epitaxial relationship of ZnTe (111)/S-plane sapphire was confirmed. The (331) layer formation on the nano-facet structures was observed because this epitaxial relationship was maintained. The poor sticking of ZnTe on the r-plane of nano-facet has resulted in the preferential formation of ZnTe (111) on the S-plane of the nano-facet. The mixture of (211) and (331) ZnTe layer formation was observed for the layer formed on the 1300°C annealed substrate surface. Insufficient formation of the buffer layer has probably caused the deterioration of the crystal quality.

Epitaxial Growth of Transition Metal-Nitrides on GaN
Grace Huili Xing, John Wright, Joseph Casamento and Debdeep Jena; Cornell University, Ithaca, New York, United States.

Several transition-metal nitrides have lattice constants close to that of GaN or AlN and they possess very interesting electronic properties, therefore, offering intriguing possibilities for heterointegration of functional materials on a powerful semiconductor platform. In this talk, I will share our recent work to epitaxially incorporate Nb and Sc in the AlGaN heterostructures. NbN is a well-known superconductor with a transition temperature about 17 K and typically its thin film is deposited using sputtering. Recently, NbN has been epitaxially grown using molecular beam epitaxy on SiC or AlN, which shows an excellent crystallographic registry to the underlying single crystalline substrate. This in turn enabled growth of AlN epitaxially on top of NbN, followed by a GaN high electron mobility transistor heterostructure [Rusen Yan et al. GaN/NbN epitaxial semiconductor/superconductor heterostructures, Nature 555, 183 (2018)]. Alloying Sc into AlN can significantly enhance the piezoelectricity of the resultant thin film, which has led to much improved performance in bulk acoustic wave (BAW) based on AlSeN over AlN. More recently, AlSeN is reported to be even ferroelectric [Simon Fichtner et al. AlSeN: a III-V semiconductor based ferroelectric, arXiv:1810.07968, 2018].

II-VI Intersubband Quantum Structures Compatible with III-V Technologies
Aidong Shen; Electrical Engineering, City College of New York, New York, New York, United States.

The wide band gap II-VI compounds reported here are Zn$_x$Cd$_{1-x}$Mg$_{1-y}$Se-based, with x and y varying independently from 0 to 1. The large tunability of the band gap energy from 1.75 eV (CdSe) to 3.7 eV (MgSe) (at room temperature) makes the material system very attractive for optoelectronic device applications. One specific application is to fabricate intersubband devices that work at short wavelengths by utilizing the large conduction band offset offered by heterostructures made from the material system. Intervalley scattering, which is typically seen in III-V intersubband quantum structures when short wavelength limit is approached, does not exist in the II-VI material system due to the large energy difference among conduction band energy minima along different directions in wide band gap II-VI semiconductors. This may potentially boost the device efficiency when intraband electron energy transitions are employed to realize light generation, detection or modulation.

We report the growth and properties of Zn$_x$Cd$_{1-x}$Mg$_{1-y}$Se-based II-VI intersubband device structures. The structures were grown by molecular beam epitaxy (MBE) on III-V substrates and therefore can be vertically integrated with III-V devices and are compatible with mature III-V device fabrication technologies. By applying band structure engineering to semiconductor quantum structures, intersubband transition in the optical communication wavelength of 1.55 μm has been realized in metastable CdSe/MgSe coupled quantum well structures. The metastable structures were stabilized by the insertion of thick ZnCdSe spacer layers during MBE growth. Both the MgSe barrier layers thickness and the MgSe coupling layer thickness were optimized to achieve structures with the best intersubband transition characteristics. Quantum-well infrared photodetectors (QWIPs) working in long wave IR and medium wave IR, the two important atmospheric windows, have been fabricated with the Zn$_x$Cd$_{1-x}$Mg$_{1-y}$Se-based II-VI materials. Different QWIP structures covering a relatively very large spectral range can all be grown lattice-matched on InP substrate. This can ensure the high absorption quantum efficiency of the detectors and is especially advantageous for two-color or multi-color QWIPs grown on the same substrate.

Growth Kinetics of Chalcogenide Topological Insulators with Applications to THz Optical Devices
Stephanie Law; Materials Science and Engineering, University of Delaware, Newark, Delaware, United States.

Topological insulators (TIs) are materials with a bulk bandgap crossed by surface states that exhibit linear dispersion and spin-momentum locking. Electrons occupying these surface states have low mass and large Fermi velocity, while the spin-momentum locking leads to a reduction in scattering, since a change in momentum requires a spin flip. Due to their unique band structure, these materials are promising for applications in electronics, spintronics, and optics. The crystal structure of standard TIs like Bi$_2$Se$_3$ is layered: one quintuple layer (QL) of Bi$_2$Se$_3$ is bonded to the next in the c-direction by van der Waals (vdW) bonds. The QLs are strongly bonded in the a-b plane. The weakness of the vdW bonding is a key to their unique electronic properties, which is responsible for the large Fermi velocity and the spin-momentum locking. Due to the QLs being strongly bonded in the a-b plane, a transfer of the metallic phase to a semiconductor phase can be achieved by deposition of an additional capping layer. This is achieved by depositing a second QL of Bi$_2$Te$_3$ on top of the Bi$_2$Se$_3$ film and then subjecting it to the appropriate thermal treatments.

In this work, we show that the use of a trivially-insulating lattice-matched buffer layer between the Bi$_2$Se$_3$ film and the substrate substantially improves the electrical properties of the film. This implies that defects at the film/substrate interface are responsible for much of the unwanted doping in the film despite the use of vdW epitaxy. For TIs grown on sapphire substrates, a trivially-insulating buffer layer of (Bi$_{1-x}$In$_x$)$_2$Se$_3$ (BIS) deposited between the film and substrate reduces the carrier density by more than a factor of two providing a modest increase in mobility. We then applied this technique to TIs grown on GaAs(001), a technologically-relevant substrate. We find that BIS grown on GaAs(001) shows a variety of morphologies. In a narrow growth window, this material shows an extremely flat, hexagonal morphology. This is in contrast to the triangular, wedding cake morphology normally observed for vdW materials. We explain this morphology by examining the site-preferential incorporation of indium and biswath. These films show a substantial decrease in bulk doping and an increase in mobility.

Finally, we show data demonstrating that these materials are excellent THz plasmonic materials. By etching the films into stripes, we are able to excite plasmonic resonances from...
the two-dimensional massless surface electrons. These Dirac plasmons are tunable across the THz band and show exceptionally large effective indices while maintaining long plasmon lifetimes. Films grown using the buffer layer technique show improved lifetimes when compared to films grown directly on sapphire. These materials are therefore extremely promising for THz plasmonic applications like gas sensing or on-chip waveguiding.

Electron Microscopic Studies of Epitaxial III-V Materials Laterally Grown Inside Confined Dielectric Templates

Arona Goswami¹, Simone Tommaso Suran Brunelli¹, Brian Markman¹, Daniel Pennachio², Hsin-Ying Tseng¹, Sukgeun Choi³, Aidan A. Taylor⁴, Jonathan Klajmin⁴, Mark J. Rodwell⁵ and Chris Palmstrom⁶, ², ³, ⁴, ⁵, ⁶. ², ³, ⁴, ⁵, ⁶.

Laterally grown III-V epitaxial layers offer multiple advantages over conventional vertically grown layers for fabricating novel semiconductor devices, including choosing growth facets and lowering thickness of fins. To laterally grow epitaxial films, pre-fabricated dielectric templates are used to confine the growth and its direction. This technique was originally developed for Si [1,2] and later used for fabricating III-V semiconductor device structures on Si [3,4]. Such grown nanostructures often suffer from high densities of planar defects like stacking faults and rotational twins. Owing to the sub-micron scale of these embedded epitaxial layers, it is challenging to characterize them. Here we use scanning electron microscopy (SEM), transmission electron microscopy (TEM) and electron channeling contrast imaging (ECCI) to characterize the Confined Epitaxial Lateral Overgrowth (CELO) nanostructures grown by chemical beam epitaxy (CBE) and metal organic chemical vapor deposition (MOCVD) on patterned InP (001) and InP (110) substrates. We explore the influence of growth conditions, growth direction, substrate orientations and fabrication procedures on the evolution of facets and the nature of defects observed. We further show growth and characteristics of CELO heterostuctures and superlattice structures.

CBE growths were performed in a VG-Semicon V80H system using phosphine and trimethylindium as precursors with temperatures varying from 470-520 °C. Tilted SEM images show that the facets are dependent on the growth directions. Vertical facets form in structures growing in the <110> direction, while <001> oriented overgrowths show slanted [111]B facets for an InP(110) substrate. Cross sectional TEM images confirm these facets and reveal stacking faults in the [111] planes propagating throughout the growth. While the growth interface shows excellent crystalline quality in most cases, residues from improper cleaning during fabrication lead to formation of irregular facets. Both the (110) and the (001) oriented InP wafers exhibit similar stacking fault densities, while a reduction of the fault density is observed at higher temperatures. High angular annular dark field scanning TEM (HAADF-STEM) images of MOCVD-grown CELO InP/InAs and InP/GaAs heterostructures, as well as InP/InGaAs superlattices show that atomically flat heterojunctions can be realized in the lateral direction using this growth technique. While TEM shows more microstructural detail, ECCI provides an alternate way to qualitatively compare stacking fault densities and twin domains in these structures, with a much faster throughput and minimal sample preparation.

Shape Engineering of InP Nanostructures Grown by Selective Area Epitaxy

Naoyin Wang¹, Xiaoming Yuan¹,², Philippe Caroff¹,², Li Li¹,², Hong Hao Tan¹ and Chenumpati Jagadish¹, ². ¹Department of Electronic Materials Engineering, Research School of Physics and Engineering, The Australian National University, ACTON, Australian Capital Territory, Australia; ²School of Physics and Electronics, Hunan Key Laboratory for Supermicrostructure and Ultrafast Process, Central South University, Changsha, China; ³Microsoft Station-Q at Delft University of Technology, Delft, Netherlands; ⁴Australian National Fabrication Facility ACT Node, Research School of Physics and Engineering, The Australian National University, ACTON, Australian Capital Territory, Australia.

Group III-V semiconductors have been a hot topic for decades due to the fact that they revolutionize electronics and optoelectronics because of their superior physical and optoelectronic properties including high carrier mobility, direct bandgap and band structure engineering capability. Reducing their dimension to the nanometer level not only brings many unique properties, such as large surface-area-to-volume ratio, high aspect ratio, carriers and photons confinement effect, but also enables the miniaturization of devices. Various nanostructures have already been demonstrated and applied to solar cells, lasers, light-emitting diodes, transistors, photothermochemical water splitting, etc. However, to date most efforts on the growth of group III-V nanostructures have been limited to zero- or one-dimensional, such as quantum dots, nanowires and nanotubes. In this work, we demonstrate selective area growth of InP nanostructures, showing the possibility of obtaining several functional nanostructures, capability beyond the limitation of rod-like nanostructure and opening the way to more advanced device geometries.

Selective area growth of InP nanostructures with shapes such as tripod nanowires, nanocrosses, nanomembranes was conducted on InP substrates of different orientations. We investigate the link between the crystal structures, shapes, designed patterns and substrate orientations. For example, we found the crystal phase transitions from wurtzite to zinc blende with increasing nanoslot length along the certain crystallographic directions, indicating a strong correlation between crystal orientation and pattern confinement on the growth mechanism. Moreover, depending on the growth condition and substrate orientation, nanomembranes can be grown either vertically or tilted with respect to the substrate. Our results provide an insightful understanding on the growth mechanism of various InP nanostructures by selective area epitaxy, which favors the achievement of III-V/Si-integrated devices, and opens up many new possibilities for the shape engineering of III-V nanostructures.

II-VI Quantum Dots in Nanowires—Tools to Fine-Tune Optical Properties

Edith Bellet-Almaric¹, Marta Orrù²,³, Kimon Moratis²,³, Pamela Rueda-Fonseca²,³, Eric Robin¹, Martien Den-Hertog¹, Yann Gennis², Regis André², David Ferrand¹ and Joel Cibert¹, ²,³. ¹Univ. Grenoble Alpes, CEA, INAC, Grenoble, France; ²Univ. Grenoble Alpes, CNRS, Institut NEEL, Grenoble, France.

A light hole ground state in a quantum dot is highly suitable for single spin optical manipulation due to the versatile optical selection rules [1]. By contrast to Stranski-Krastanov growth which results in flat quantum dots under compressive strain, hence a heavy-hole ground state, the dot-in-a-nanowire configuration is extremely flexible and virtually any material combination, any dot shape and any built-in strain can be realized. It allows one to engineer the hole states in semiconductor dots, and tailor their orbital and spin states: the ground state of a very long (L/D>>1) quantum dots is a light hole.

The vapor–solid–solid (VSS) growth mechanism is well adapted for the size and compositional control. Indeed it can result in compositionally abrupt interfaces and well-controlled aspect ratio by restraining the so-called reservoir effect normally observed in the most common vapor-liquid-solid (VLS) growth method.

ZnTe nanowires incorporating CdTe quantum dots and a ZnMgTe shell were grown by molecular beam epitaxy, at temperatures such that the Au nanoparticles are solid, as observed by HRTEM.

VSS growth still remains much less understood than VLS. In particular, up to now, the role of the catalyst nanoparticle has been mainly overlooked. We show that different epitaxial relations with respect to the substrate coexist: this plays a key role in the nucleation of the nanowires.² For all the growth steps, the effect of temperature appears to be crucial, particularly when considering the growth of CdTe used to form the quantum dot. The sublimation of CdTe and of the evaporation of Cd from the Au nanoparticles is crucial: these two effects must be taken into account in modelling the growth.³
As a result, ZnTe nanowires incorporating very long (L/D>1) and very short (L/D<1) CdTe insertions and a ZnMgTe shell of controlled shape and composition were studied. Combining cathodoluminescence, micro-photoluminescence spectroscopy and autocorrelation measurements, we identify single dot excitation lines corresponding to excitons, biexcitons and possibly charged ones. From linear polarization measurement in emission we found that for elongated quantum dots the intensity of the exciton line becomes stronger for polarization parallel to the nanowire axis, suggesting a light hole type ground state, as confirmed by a more complete study of the emission diagram and of magneto-optical spectroscopy.

4:00 PM *EP10.06.02 Transport Properties of MnAs/InAs Heterojunction and InAs Nanowires Formed by Selective-Area Growth Shinjiro Hara1, Matthias T. Elm1,2,3 and Peter J. Klau1,4, Center for Materials Research, Justus Liebig University, Giessen, Germany; 1Institute of Experimental Physics I, Justus Liebig University, Giessen, Germany; 2Institute of Physical Chemistry, Justus Liebig University, Giessen, Germany; 3Research Center for Integrated Quantum Electronics, Hokkaido University, Sapporo, Japan.

Heteroepitaxial structures between semiconducting nanowires and magnetic materials are of great interest for future nanoelectronic and spintronic devices. We have demonstrated the selective-area growth of vertical ferromagnetic MnAs nanoclusters/semiconducting InAs heterojunction nanowires by metal-organic vapor phase epitaxy, which is a catalyst-free bottom-up fabrication method. [1-3] These heterojunction nanowires provide new possibilities and versatility in the creation of novel vertical nanowire devices, e.g., spin-light-emitting diodes, surrounding gate spin-transistors, and THz-emitters. It is crucial to control the MnAs nanocluster formation and improve the size uniformity of heterojunction nanowires for such nanowire devices, and to investigate magnetotransport properties in detail. [4] This invited paper focuses on recent results of the formation and transport characterizations of vertical MnAs/InAs heterojunction nanowires as well as single host InAs nanowires. The vertical heterojunction nanowires were fabricated by endotaxial MnAs nanoclustering after the selective-area growth of host InAs nanowires on partially-SiO2-masked GaAs (111)B substrates. The fabrication processes are described elsewhere in detail. [1, 2] The <0001> direction of hexagonal NiAs-type MnAs nanoclusters is parallel to the <111>-B direction of zinc-blende-type InAs nanowires, as revealed by transmission electron and magnetic force microscopies. After the growth, the nanowires were detached from the substrates by ultrasonic vibration in isopropanol solution, and then, deposited on a SiO2/Si substrate. In order to obtain ohmic contacts, the native oxide layer was removed by Ar milling at 30 W for 60 sec. Afterwards electronic contacts of Ti/Au (25 nm/165 nm) were structured by electron-beam lithography and electron-beam liftoffgraphy. A large positive ordinary magnetoresistance effect up to 150% is observed when the magnetic field is applied in the range between 120 K and 280 K. Angle-dependent transport measurements reveal additional boundary scattering due to the confined transport channel of InAs nanowire. In addition, magnetotransport characterization results of a single host InAs nanowire show universal conductance fluctuations and weak Anderson localization at low temperatures. A single MnAs/InAs heterojunction nanowire, on the other hand, shows only a negative magnetoresistance effect up to 10% at 10 T, which linearly decreases with increasing magnetic field. Refs.: [1] Jpn. J. Appl. Phys. 55, 075503 (2016) open access; [2] Jpn. J. Appl. Phys. 56, 06GH03 (2017); [3] J. Cryst. Growth 464, 80 (2017); [4] Adv. Mater. 26, 8079 (2014) review paper.

4:30 PM EP10.06.03 Characterization of a GaAs(001)/ZnSe/1 ML CdSe/ZnSe Fully-Strained Ultra-Thin Quantum Well with Very Thin ZnSe Barriers Isaac Hernandez-Calderon1, Frantisek Sutara1 and Adrián D. Alfaro-Martínez1, CINVESTAV-IPN, Mexico City, Mexico.

Interface and extended defects severely affect ZnSe/GaAs based heterostructures. Many studies have been devoted to the improvement of this heterointerface interface, and, to the understanding of the defect generation mechanisms during growth and during operation of related optoelectronic devices. The lattice constants of ZnSe (0.5668 nm) and GaAs (0.5653 nm) are very close, however, the slight lattice mismatch produces a small compressive strain parallel to the interface of -0.00265 which is enough to produce misfit dislocations when the ZnSe film reaches the critical thickness h5 ~ 80 nm. On the other hand, due to the large lattice mismatch, h6 for CdSe (0.6077 nm) on ZnSe is only around 3.5 monolayers, after h5, is reached the excitonic emission of CdSe/ZnSe ultra-thin quantum wells (UTQWs) is negligible or even absent. Therefore, under typical growth conditions only 1 to 3 monolayers (MLs) thick UTQWs of CdSe/ZnSe/GaAs(001) with good crystalline quality and intense excitonic emission can be obtained. 1 One ML of the binary refers to the thickness of the cation-anion bilayer given by a/2, where a is the lattice constant. The 1 ML CdSe UTQW represents the thinnest CdSe QW that is possible to grow and some of its physical properties still deserve a detailed explanation and interpretation regarding its high excitonic emission intensity, the quite narrow full width at half maximum (FWHM),2 and the peak energy dependence on growth parameters. Here, we present a study of a nominal 1 ML CdSe UTQW grown by atomic layer epitaxy (ALE) on GaAs(001) at 275 °C within a ZnSe barrier of 20 nm (the barrier adjacent to the substrate, i.e., the buffer layer forming the ZnSe/GaAs heterovalent interface), and a second ZnSe barrier of 25 nm (cap layer). The thickness of each layer and the total thickness of the heterostructure are chosen in such a way that each material is below its critical thickness, so we can obtain a fully strained heterostructure without misfit dislocations, expecting an UTQW with a high-quality crystalline structure. The 19 K photoluminescence spectrum presents an intense excitonic peak at 2.685 eV with a FWHM of 12.3 meV, which is narrower than previous results in CdSe UTQWs grown on relaxed ZnSe barriers.3 The evolution of the excitonic peak as a function of temperature follows very closely the expected slow, monotonic behavior, indicating the absence of QW potential fluctuations due to thickness or composition inhomogeneities. The intensity of the excitonic peak in the photoluminescence experiments decreases rapidly with increasing temperature and it is difficult to observe at room temperature. This can be taken as an indication of the lack of exciton localization caused by potential fluctuations which, as mentioned before, are absent or negligible in the QW structure.

4:45 PM EP10.06.04 Control of Axial to Radial Growth of Ge/GeSn Nanowires with H2 Partial Pressure Andrew C. Meng1, Michael Braun1, Colleen S. Fenrich1, Muyu Xue1, Ann F. Marshall2, James S. Harris3 and Paul C. McIntyre1; 1Materials Science and Engineering, Stanford University, Stanford, California, United States; 2Stanford Nano Shared Facilities, Stanford University, Stanford, California, United States; 3Electrical Engineering, Stanford University, Stanford, California, United States.

Germanium-tin is a promising material for novel devices for optical sensing in the mid-IR region. For sufficiently high Sn compositions, the material has a direct band-gap near 0.5 eV, and could have applications either as a detector or as an emiter. The main challenge to growth of high-quality single crystals is the large lattice mismatch of the system (~14% for diamond cubic Sn on Ge) and the low equilibrium solubility of Sn in Ge (~1%). Demonstrations of core-shell Ge/GeSn nanowire structures have shown that it is possible to take advantage of a thin nanowire as a compliant substrate for high quality single crystal growth.1,2 In this work, we show that a Ge nanowire can act as a template for both axial and radial growth of Ge/GeSn heterostructures by controlling H2 partial pressure during CVD growth of GeSn. We are also able to achieve different Sn compositions varying from 2% to 10% using this method as confirmed by STEM-EDS and photoluminescence measurements. With control over axial to radial growth of GeSn heterostructures, a much wider possibility of device architectures can be achieved.

Probing the Phonon Scattering in the Strong Light-Matter Coupling Regime

These findings not only open new possibilities for the optimization of up-conversion processes through the appropriate engineering of suitable FWM processes at single particle level lead us to all-optical switching phenomena in sub-25 fs reflectivity modulations of >0.1 %, where the responsible mechanism points toward to optical Kerr effect. These findings not only open new possibilities for the optimization of up-conversion processes through the appropriate engineering of suitable dielectric materials, remarkably expand the possibility of localizing signals in hybrid nanosystems, but also contribute to an important step toward nanoscale ultrafast all-optical signal processing.

The strong light-matter coupling is the core of cavity quantum electrodynamics (CQED), which leads to discoveries of fascinating phenomena in solid state system such as Bose-Einstein condensation and photon blockade. Indirect evidence indicates non-fluorescence processes such as phonon scattering are critical to these phenomena. However, the understanding of such processes remains elusive due to their non-radiative nature smeared by the overwhelming fluorescence in cavities. Here we directly probe phonon scattering based on Raman spectroscopy in the strong coupling regime in a plasmonic cavity embedded with a monolayer MoS2. The studied non-fluorescence process is significantly modified by the hybrid properties of the newly formed half-light half-matter quasiparticles, i.e., polaritons. For the first time, we observe nonlinearly enhanced valley-dependent phonon modes, involved with stimulated lattice vibrations and inter-valley scatterings. This work provides a new perspective to investigate fundamental quantum processes in the strong coupling regime.

Ultrafast Spectroscopy and Transmission Modulation of Vibration-Polaritons Blake S. Simpkins1, Adam Dunkelberger1, Andrea Grafton1, 1, Kenan Fears1, Roderick Davidson2, 1, Wonmi Ahn3 and Jeffrey C. Owutsky1

Vibrational polaritons, composed of strongly coupled cavity optical modes and molecular vibrations, have recently been utilized to modify excited-state dynamics (Nature Communications 2016, 7, 13504) and chemical reaction rates (Acc. Chem. Res. 2016, 49, 2403). Ultrafast vibrational spectroscopy has the potential to reveal how strong coupling modifies vibrational relaxation and energy transfer that can mediate molecular reactivity. Toward that end, we have carried out transient infrared studies on cavity-coupled molecules in solution. Our results have revealed several important phenomena, including (1) the presence of polariton excited states that, in the systems studied, relax more quickly than the molecules in free space; (2) a reservoir of dark states which can dominate the transient spectral response; and (3) ultrafast modulation of the coupled system between the weak and strong coupling regimes, leading to dramatic changes in the transmission and reflection of the system. Ultrafast modulation of transmission spectra is uniquely useful in single pulse studies where saturable absorption is substantially modified due strong coupling effects that result in much larger saturation intensities (~15 x) compared to those measured for the uncoupled molecular system. This behavior has potential applications for nonlinear optical and photonic devices.

2:30 PM EP11.01.04
Coupled Plasmon-Phonon Modes Enhanced Light-Matter Interaction in the Hybrid Ag-MoS2 System Yibu Poudel1 and Arup Neogi2, Physics, University of North Texas, Denton, Texas, United States.

Monolayer molybdenum disulfide (MoS2) is at the focus of current research for different applications ranging from the photovoltaics, photodetection to optoelectronics. The absorption from monolayer MoS2 is four times to that of graphene, but it is still to be optimized to enhance the performance of photonic devices. Multiple excitonic absorption states in the energy range from ultraviolet to visible, and the exceptionally high exciton binding energy excitonic states presents many opportunities to enhance the interactions of incident light to these excitonic states. Hybrid metal–MoS2 structures can be formed with different metals, and tuned with the shape and size of these metal nanostructures to enhance the light-matter interaction by coupling with the specific excitonic energy state as expected. The exciton dynamics followed by the optical excitation and the interaction dynamics such as hybrid exciton formation, exciton-exciton annihilation etc. are strongly influenced due to coupling with the lattice vibrational modes. The plasmon modes, when coupled with phonon modes, control the coherent interaction among the excitonic states as well as the interaction between the excitonic states with the plasmonic states. Here we report the activation of a new vibrational mode in the hybrid silver (Ag)–MoS2 monolayer structure at 35 meV, and the dressing of the Raman mode with the plasmon mode significantly contributes in the light-matter interaction process as measured using the pump-probe spectroscopy. By selecting an optical excitation, which is in resonance to the plasmon modes, the absorption of the incident light is increased due to the enhanced electric field of the localized plasmons. In addition, the new Raman mode in the hybrid structure along with the usual active Raman modes in MoS2 are also resonantly driven by the pulses of the femtosecond fs laser source. The driving field due to resonantly excited plasmons with the pump pulses creates the power broadening of the excitonic optical transitions. Also, the driving field generates quantum coherence effect that significantly modifies the absorption of probe light forming the so-called dark state as illustrated using a density matrix model. There is a strong coherent coupling of the plasmon modes with the excitonic states in MoS2. A hybrid exciton-plasmon band of half-width about 250 meV is formed around A and B excitonic states in the transient absorption spectrum at a delay time of about 500 femtoseconds after the optical excitation. The formation of the hybrid states offers an opportunity to strongly enhance the light-matter interaction and hence improve the performance of optical and electrical devices based on MoS2.
The term “hot electron” is frequently used in the literature to describe electrons in a solid with energies exceeding their thermally-created counterparts at ambient temperature. In plasmonic structures, the nonradiative dephasing of plasmons generates excited (i.e., athermal) electrons in the conduction band of metals and a subsequent electron thermalization process leads to the equilibration of the athermal electrons and the formation of a hot-electron distribution. The high energy nature of athermal and hot electrons enables various of optically-driven processes with fascinating applications in photochemical and photovoltaic devices. More recently, exploring the transient dynamics of such energetic charge carriers has gained a growing attention with the hope for the implementation of active plasmonic platforms. Indeed, the optical modulation of the electron temperature in metals enables the tuning of their refractive index and therefore, allows for the all-optical modulation of the plasmonic response at low light intensity. However, the intrinsic slow decay of the hot-electron temperature via the electron-phonon interaction, impedes ultrafast all-optical modulation in plasmonic structures. In this work, we show that the ultrafast transfer of hot electrons from plasmonic metals to electron accepting materials allows for the sup-picosecond (~190 fs) recovery of the refractive index change in plasmonic metals. Our experimental findings suggest that the activation of hot-electron transfer pathways screen the contribution of electron-photon interactions and instead provide an electron-dominated relaxation mechanism. Through the design of a subradiant, high-Q, and polarization-sensitive plasmonic crystal we demonstrate ultrafast modulation of phase, polarization, and intensity of light in an all-optical fashion.

Colloidal plasmonic nanocrystals (NCs) are known for their size- and shape-dependent localized surface plasmon resonances. Here we show these plasmonic NCs can be used as building blocks of mesoscale materials. Chemical exchange of the long ligands used in NC synthesis with more compact ligand chemistries brings neighboring NCs into proximity and increases interparticle coupling. This ligand-controlled coupling allows us to tailor a dielectric-to-metal phase transition seen by a 10th in DC conductivity and a dielectric permittivity ranging from everywhere positive to everywhere negative across the whole range of optical frequencies. We realize a "diluted metal" with optical properties not found in the bulk metal analog, presenting a new axis in plasmonic materials design and the realization of optical properties akin to next-generation metamaterials. We harness the solution-processability and physical properties of colloidal plasmonic NCs to print NC superstructures for large-area, active metamaterials. We demonstrate quarter-wave plates with extreme bandwidths and high polarization conversion efficiencies in the near- to mid-infrared. By combining superparamagnetic ZnFe2O4 NCs and plasmonic Au NCs, we fabricate multifunctional, smart superparticles, which in suspensions switch their polarization-dependent transmission in the infrared in response to an external magnetic field. Finally, by juxtaposing plasmonic NCs and bulk materials, we exploit their different chemical and mechanical properties to transform lithographically defined two-dimensional structures, upon ligand exchange, into three-dimensional structures and use this approach to achieve chiral metamaterials.

Near Infrared Absorbing Copper (II) Complexes—Improvement of Absorbance and Hydrothermal Stability Mi-Jeong Kim1, Haeran Kim1, Yong Joo Lee1, Jae-Jun Lee1, Sunjung Byun2, Jae Gwan Chung2 and Ginam Kim1; 1Film Material Laboratory, Material Research Center, Samsung Advanced Institute of Technology (SAIT), Samsung Electronics, Suwon, Korea (the Republic of); 2Platform Technology Laboratory, Samsung Advanced Institute of Technology (SAIT), Samsung Electronics, Suwon, Korea (the Republic of).
Mobile device has developed display, memory, and various sensors for helping human life. CMOS image sensor is important technology to include human eye function into mobile devices. RGB imaging in visible wavelength range (430 ~ 565 nm) can be disturbed by near infrared light (NIR, 700 nm ~ 1200 nm). In order to protect NIR light, we have developed NIR absorbing dye materials and its formulations composed of copper complexes, organic dyes, and binding polymers. Depending on ionic ligand types, absorption wavelength and solubility can be controlled. By adding coordinative ligands, absorption intensity and hydrothermal stability can be improved by John-Teller Distortion effect and binding energy, respectively. In this presentation, we will discuss about what is the failure origin to be stable under hydrothermal condition by analysis with XPS and FT-IR. Finally, designing photo-crosslinkable ligand without hydroxyl group, NIR absorbing Cu (II) phosphate/sulfonate materials will be presented.

4:15 PM EP11.02.03
Enhanced Surface Raman Laser with Organic Monolayer in Silica Hybrid Resonator Hyungwoo Choi, Xiaqin Shen and Andrea M. Armani; University of Southern California, Los Angeles, California, United States.
The performance and functionality of integrated optical devices are governed by their fundamental physical properties. In passive systems, such as waveguide arrays and interconnects, this limitation has pushed the field towards ultra-low loss materials that are compatible with conventional CMOS processing. However, this singular focus has resulted in a decrease in the functionality of these components and placed limitations on the ultimate system footprint. For example, one of the current drivers in the field is Si photonics. However, the refractive index of silicon places a fundamental minimum size in order to confine the optical mode. Similarly, due to its low second and third order optical nonlinear coefficients and high dispersion, it is challenging to achieve active components without high input power. By expanding the optical material toolbox, new strategies for designing optical devices and circuits will be possible. One emerging strategy for changing device performance is based on surface engineering. Originally focused on adding biologically active groups to a device for bio/chem detection, more recent work has explored developing passivating surface chemistries to stabilize or protect device surfaces. However, the majority of these efforts involved changing the device properties by adding material layers instead of directly changing the device material. In the present work, we develop and demonstrate an approach to directly change the Raman gain of the optical device by modifying the Raman of the dangling surface functional groups. The initial device studied as a proof of concept is an optical resonator; however, the basic strategy is suitable for any on-chip device. Optical resonators act as optical amplifiers, allowing low input powers to be significantly increased. One type of resonator is a traveling wave resonator or whispering gallery mode resonator. This cavity confines light in circular orbits, and due to photon storage times (or quality factors, Q) in the nanosecond regime, the input power can be amplified by over 100,000x. The large circulating optical intensities can reveal nonlinear phenomena that otherwise would require large pulsed laser systems. For example, previous work using silica cavities has demonstrated Raman lasing with only a few hundred micro-Watts of input power. However, the efficiency of the Raman generation was poor due to the intrinsically low Raman gain of silica.
In this present work, we fabricate silica resonators on chip. However, instead of relying on the intrinsic bulk Raman gain of the silica, we leverage surface chemistry to modify the disordered surface or boundary layer. As a result, a monolayer of oriented organic molecules is aligned with the circulating optical field in a microcavity. This optimization improves the light-matter interaction at the boundary layer, and the total Raman gain of the device. The two ordered monolayers studied are methylsilane (MS) and dimethylsilane (DMS). After attachment on the device surface, the devices still maintain ultra-high Q factors (over 10^7). Due to the alignment of the Raman modes of the siloxane molecule with the optical field, the efficiency and lasing thresholds are significantly improved. With an excitation source of 765 nm, low threshold SRS located at ~465 cm^{-1} is observed in both the MS and DMS functionalized devices with SRS efficiencies of approximately 40%. These efficiencies represent over 5 times enhancement as compared to bare silica devices. This work represents a new strategy for dramatically increasing the nonlinear optical performance of integrated photonic devices using organic molecules with a hybrid structure.

4:30 PM EP11.02.04
Thermally Soldered Au Nanogrids with Enhanced Plasmon Quality for Quantitative Multiplexing of Trace-Amount Molecules via SERS
Seunghee H. Cho and Yeon Sik Jung; Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daegon, Korea (the Republic of).

Trace-amount toxins in drinking water are not only serious environmental pollution but also threaten human health through long term accumulation. In need for sensors capable of detecting low-concentration, trace-amount molecules, highly sensitive and selective detection technologies have been long developed. Research has recently expanded to multiplexing, which can significantly reduce analysis time and sample volume while also providing a more thorough information of a given system such as that of the environment or a living cell. So far, multiplexing has largely been realized through assays based on highly sensitive fluorescent or electrochemical sensors, yet they lack in ability to differentiate from similar molecules and selectively recognize target molecules within mixed samples. Surface-enhanced Raman spectroscopy (SERS) has recently drawn much attention as a multiplexing technique owing to its fingerprint-spectra specificity and single-molecule level sensitivity. However, conventional approaches using lithography or metallic nanoparticles are either costly and time-consuming or show insufficient reproducibility. Recently, our group has demonstrated highly reproducible 3D cross-point Au nanostuctures for SERS based on high-resolution nanotransfer printing with uniform average enhancement factor of 4.1 × 10^4 over a macro-scale area. Herein, we present thermally soldered Au nanogrids with enhanced plasmon quality for highly sensitive detection of trace-amount molecules and accurate quantitative multiplexing via SERS. The Au nanogrids were fabricated by a thermal annealing method to solder multi-stacked 3D Au nanostucture into a single entity while preserving the sub-20 nm nanostructures. The enhanced plasmon qualities of Au nanogrids can be attributed to the reduced grain-boundary areas, enabling highly sensitive detection of low-concentration molecules through SERS. Au nanogrids were also functionalized with multiple single-stranded DNA (ssDNA) aptamer probes each specifically designed for different toxin molecules to achieve selective multiplexing and quantitative analysis. We used scanning electron microscopy (SEM) and transmission electron microscopy (TEM) to characterize the nanostructure and grain morphology of Au nanogrids, atomic force microscopy (AFM) and X-ray photoelectron spectroscopy (XPS) to confirm aptamer-functionalization. As a result, we achieved three-component multiplexing and quantification of drinking water toxins each down to 10^{-11} M via SERS even without the use of Raman reporter dye-molecules.

4:45 PM EP11.02.05
High Performance Visible-Blind UV Photodetector Using ZnO@Au Core-Shell Nanostructures
Manjiri Singh1,2, Nisha Prakash1, Gaurav Kumar1,2, Suraj P. Khanna1,2, Prabir Pall1, Anil K. Thakur3 and Surinder P. Singh1,2; 1CSIR-National Physical Laboratory, New Delhi, India; 2AcSIR- Academy of Scientific & Innovative Research, CSIR-NPL Campus, New Delhi, India; 3Department of Nano Science and Materials, Central University of Jammu, Jammu, India.

Nanostructured materials with tailored geometries on the atomic scale having tuneable physico-chemical properties are of immense interest for applications in photodetectors. Among different reported nanostructured, metal nanoparticle on semiconductor nanowires has been proposed to improve performance parameters such as minimum dark current and enhanced UV performance of a photo-conducting device.1-3 However, the mentioned device geometries suffer from poor UV-to-Visible rejection ratio, as the top metal nanoparticle coating resists visible illumination.2 Therefore, we envisioned to develop the ZnO@Au core-shell nanostructures with metal (Au) core and semiconductor (ZnO) shell for photocductive device, to enhance UV emission1 detection as a result of SPR mediated carrier generation and transport with suppressed dark current. In present work, we have synthesized the ZnO nanostructures, without and with Au core, using wet chemical route. The ZnO and ZnO@Au nanostructures, were then deposited on ITO coated glass substrates followed by thermal annealing at 300 °C, under ambient conditions, forming ZnO/ITO and ZnO/Au) TIO nanostructures thin-film, respectively. Optical properties revealed that the incorporation of Au core in ZnO nanostructures reduces the overall optical bandgap of the material and also suppresses the visible emission originating from ZnO defect. Further, the electrical measurements shows suppressed dark current with enhanced light current under 380 nm UV illumination for ZnO/Au/ITO device, leading to 7 folds increase in photocurrent to dark current ratio (at 10 V applied bias) compared to the ZnO/ITO device. Additionally, the ZnO/Au/ITO device also demonstrates an improved UV-to-Visible rejection ratio (~1×10^{12}) compared to the ZnO/ITO device (~1×10^{10}) at 10 V applied bias and thus suggests its application in designing high performance Visible-blind UV photodetector.

8:30 AM *EP11.03.01
Dressing Quantum Emitters with Nanoantennas and Microcavities
Vahid Sandoughdar; Max Planck Institute for the Science of Light, Erlangen, Germany.

Solid-state quantum emitters make up the most crucial components of any quantum information processing device. The quest for finding the ideal quantum system has led to a large effort on different materials, including organic molecules, semiconductor quantum dots, diamond color centers, rare earth ions in inorganic crystals and a variety of two-dimensional materials. While each system offers interesting features, the ideal system is still not within reach. One possible strategy to address this issue is, thus, to modify and improve the properties of the existing quantum emitters, e.g. by modifying their radiative decay rates and pathways using concepts from Cavity Quantum Electrodynamics. In our laboratory, we pursue this strategy and investigate the coupling of solid-state quantum emitters to microcavities and plasmonic nanoantennas.

In the first part of this presentation, I will discuss the room-temperature coupling of colloidal quantum dots to plasmonic nanostuctures. Semiconductor quantum dots are capable of emitting one, two or more photons after each excitation because of the possibility of generating multiple excitons within the same quantum dot. In practice, however, such multiphoton emission is often inefficient due to fast nonradiative decay channels such as Auger recombination. We have recently demonstrated that the biexciton emission efficiency can be significantly improved by a large radiative enhancement in the near field of a gold nanocone antenna fabricated by focused ion beam milling. We show that the quantum efficiency of the biexciton emission is increased by more than one order of magnitude to 70% in the coupled system. Moreover, by performing many quantitative in-situ measurements on the very same quantum dot, we demonstrate more than 100-fold radiative enhancement by the gold nanocone antenna for both excitonic and biexcitonic emission channels.

In the second part of my talk, I will show results on the cryogenic coupling of single organic molecules to open Fabry-Perot microcavities at the onset of strong coupling. Organic dye molecules are very strong emitters with near-unity quantum efficiency. However, their internal vibrational degrees of freedom and their coupling to the phononic landscape of their host matrix give rise to various sources of decoherence such that their use in quantum engineering becomes limited. To get around this effect, we couple an organic dye molecule to an ultrasmall Fabry-Perot cavity made of a curved (fabricated by focused ion beam milling) and a flat mirror. The ability to tune the cavity and scan it laterally across a thin molecular crystal allows us to perform several experiments with an exquisite control. Our results show that a dye molecule can be turned into a two-level quantum coherent...
system.

In closing, I discuss the prospects of hybrid quantum material based on plasmonic nanoantennas for use at room temperature.

9:00 AM • EP11.03.02
Manipulating Quantum Light on a Chip—From Heralded Single Photon Purification to Effective Photon-Photon Interactions Ronen Rapaport; Racah Institute of Physics and the Applied Physics Department, The Hebrew University of Jerusalem, Jerusalem, Israel.

Photons are a potential resource for a growing host of applications in quantum technologies and quantum information sciences. A particular interest is in effectively harvesting pure single photons from simple quantum emitters operating at room temperature, and in finding effective ways for strong interactions between only a few photons.

In this talk I will review our progress towards a realization of bright, high-purity single photon sources from impure photon emitters, by designing hybrid nano-emitter – nano-antenna devices that can efficiently extract and direct single photons using indeterministic two- photon states. I will also introduce our recent results showing on-chip low-loss guiding and large electrically-controlled enhancement of effective photon interactions in an optical waveguide by utilizing strong interactions of photons with dipolar excitations in semiconductors.

9:30 AM EP11.03.03
Path Selectivity, Lasing and Super-Radiance Effects in Plasmonic Nano-Structures—Experimental and Numerical Investigations Renaud Vallee1, Ibrahim Lounis2, Daniel Neuhauser3 and Serge Ravaine1; 1Centre de Recherche Paul Pascal, Pessac, France; 2LP2N, University of Bordeaux, Talence, France; 3University of California, Los Angeles, Los Angeles, California, United States.

Hybridisation of organic emitters and plasmonic nano-structures has attracted much attention over the last years, due to their interest in the design of plasmon-based nano-lasers [1,2] or to achieve long-range qubit entanglement [3,4]. Recent theoretical studies [5,6] suggest a plasmonic super-radiant mechanism to increase the rate of emitters, similar to Dicke super-radiance [7].

In this talk, we will report on the impact of plasmonic super-radiance and organic emitters close to a metal nanopore at room temperature. This observation of plasmonic super-radiance at room temperature opens questions about the robustness of these collective states against decoherence mechanisms which are of major interest for potential applications. A complete quantum theoretical/numerical approach will be presented, which will give full account of the obtained experimental results [8].

ii) We proposed a new type of nanodevice, capable of both path-selectivity and anisotropic lasing that is based on loss-compensation and amplification by a localized plasmon polariton [9]. The nano-device is a Y-shaped plasmonic nanostructure embedded in an anisotropic host medium with gain. The anisotropy leads to the path selectivity, an effect which is more pronounced once gain is included. The path-selectivity may be coupled with activation of a rotation of the anisotropic host medium for inducing a light-guiding switching functionality. On the experimental side, we used a DNA origami structure to precisely localize three different fluorescent dyes close to the tips of hollow gold nanotriangles. A spectral dependence of plasmon-enhanced fluorescence is evidenced through co-localized AFM and fluorescence measurements. The experimental results match well with explanatory FDTD simulations. Our findings open the way to the bottom-up fabrication of plasmonic routers operating through plasmon energy transfer. They will allow one to actively control the direction of light propagation [10].

Photonic Band Engineering in Absorbing Media for Spectrally-Selective Optoelectronic Films Botong Qiu, Yida Lin, Ebuka S. Arinze, Arlene Chiu, Lulin Li and Susanna M. Thon; Johns Hopkins University, Baltimore, Maryland, United States.

Spectrally-selective materials are of great interest for optoelectronic devices in which wavelength-selectivity of the photoactive material is necessary for applications such as multijunction solar cells, narrow-band photodetectors, transparent photovoltaics, and tailored emission sources. Achieving controlled transparency or opacity within multiple wavelength bands in the absorption, reflection, and transmission spectra is difficult to achieve in traditional semiconductors that typically absorb at all energies above their electronic band gap and is generally realized by the use of external bandpass filters. Here, we propose an alternate method for achieving spectral selectivity in optoelectronic thin films: the use of band engineering in 2D photonic crystal slabs within the absorbing region of a semiconductor in which resonant and confined photonic states are strongly coupled to the external reflecting and transmitting fields that share lateral wave-vectors.

As a first step, we use optical simulations to systematically study the effect of material absorption on the properties of the photonic bands in a slab-type photonic crystal structure. We find that adding weak loss, which is realized by introducing a small (~10%) imaginary part to the permittivity, does not appreciably change the frequencies of the photonic bands but does weaken the definition of the band structures. This is the result of reduced quality factors of the associated resonance modes due to the presence of dissipation. The results are also confirmed by qualitative analysis using perturbation theory. Critically, in the case where external propagating waves are incident upon or out-coupled from the photonic crystal slab structure, the radiating photonic bands induce multiple strong Fano resonance features in the slab transmission and reflection spectra, due to coupling between the bands and external fields. The Fano resonances display large transparency contrasts across the center of the resonances that should enable transmission and reflection wavelength selectivity and introducing material absorption into the model widens the bandwidth of this selectivity. Moreover, the absorption spectra also peak at these resonance frequencies, due to the associated concentrated field intensity inside the slab, with peak widths increasing under increasing dissipation, giving rise to the possibility of achieving spectral selectivity in the absorbing region of semiconductors.

We also demonstrate this tuning method experimentally by fabricating a proof-of-principle photonic structure consisting of a self-assembled polystyrene bead monolayer infiltrated with PbS CQDs that displays both near-infrared absorption enhancement and visible transparency enhancement over a homogeneous control film, qualitatively matching the bands and external fields. The Fano resonances display large transparency contrasts across the center of the resonances that should enable transmission and reflection wavelength selectivity and introducing material absorption into the model widens the bandwidth of this selectivity. Moreover, the absorption spectra also peak at these resonance frequencies, due to the associated concentrated field intensity inside the slab, with peak widths increasing under increasing dissipation, giving rise to the possibility of achieving spectral selectivity in the absorbing region of semiconductors.

In closing, I discuss the prospects of hybrid quantum material based on plasmonic nanoantennas for use at room temperature.

10:30 AM • EP11.03.05
Diamond Quantum Photonics Constantin Dory and Jelena Vuckovic; Ginzioni Laboratory, Stanford University, Stanford, California, United States.

Optical quantum technologies will likely operate at the level of single or few photons. To guarantee high fidelity optical quantum computation and fast quantum communication rates, efficient, scalable, and versatile photonics is required. However, many promising material platforms, which host interesting quantum emitters, have challenging fabrication protocols. Moreover, to comply with the stringent fabrication constraints, traditional optimization methods are slow and device functionalities are limited.

Diamond hosts versatile color centers, some of which exhibit very long coherence times and/or minimal inhomogeneous broadening. Moreover, site-controlled implantation of color centers enables precise integration into on-chip optical circuits. To develop a diamond photonic platform that can match the scalability potential of the diamond color centers, major improvements in fabrication and device design are necessary. In our work, we have optimized fabrication methods based on quasi-isotropic etching and developed a
computational approach to inverse design photonics based on desired performance. Our design approach can include fabrication constraints as part of the optimization and thus results in robust designs. As our optimization methods can probe the entire parameter space our device designs are non-intuitive, but are fabricable using standard techniques, are robust against typical fabrication errors, and outperform state-of-the-art counterparts in footprint, efficiency and stability.

11:00 AM EP11.03.06
Photonic-Joined Structures—Microcavity Enhancement
Aziz D. Ruiz1,2 and Jorge A. Reyes-Esqueda1,2; 1UNAM, Mexico, Mexico; 2Instituto Física, UNAM, Coyoacan, Mexico; 1Postgrado Fisica Unam, Coyoacan, Mexico.

High light transmission microcavities are a greatly studied and applied topic [1, 2]. Lately, joined structures have drawn even more attention [3], like Fibonacci conjugated mirrors [4], because of its optical properties, as perfect transmission or field localization. Here, we study a simpler and novel joined structure, which presents high transmission (quasi-perfect for short arrays) in a resonant condition. In particular, we explore the transmission and field localization via simulations to manufacture the best arrangement in porous silicon: a Microcavity-3 Bragg Mirrors array. This is not a common microcavity, since it is composed by 3 Bragg mirrors, where the first two are in a symmetric configuration (microcavity), while the third one is in a conjugated configuration.

This sequence improves all the characteristics of common microcavities, particularly those for microcavities formed by absorbent materials.

Electron Transfer in Confined Electromagnetic Fields
Alexander Semenov2 and Abraham Nitzan1,2; 1Chemistry, the University of Pennsylvania, Philadelphia, Pennsylvania, United States; 2Chemistry, Tel Aviv University, Tel Aviv, Israel.

The interaction between molecular (atomic) electron(s) and the vacuum field of a reflective cavity generates a significant interest thanks to the rapid developments in nanophotonics. Such interaction which lies within the realm of cavity quantum electrodynamics can substantially affect transport properties of molecular systems [1-3]. For the last several years cavity-induced modifications of charge transport properties of molecular systems have drawn a considerable interest [4,5]. In our work we consider non-adiabatic electron transfer process in the presence of a cavity mode. We worked out a generalized framework of interaction between a charged molecular system and a quantized electromagnetic field of a cavity and applied it to the problem of electron transfer between a donor and an acceptor that are put in a confined vacuum electromagnetic field. The effective system Hamiltonian presents a unified Rabi and spin-boson model which includes a self-dipole energy term. This term which is usually neglected in the standard light-matter interaction models plays a crucial role in our formalism. Two limiting cases were considered: in the first case the electron is much faster than the cavity mode (slow mode) whereas in the second case the tunneling time of the electron is significantly larger than the period of the mode (fast mode). In the latter case the presence of the cavity does not alter the electron dynamics. In the case of slow mode, a Marcus-like electron transfer (ET) rate is obtained by summing over all final states and averaging over initial states of the electromagnetic field. We computed ET rates varying different system parameters. It was found that at high temperatures, high reorganization energies and/or low mode frequency the total rate can be described by a single Marcus rate with an increased reorganization energy whereas at low temperatures, low reorganization energy and/or high mode frequency the energy gap dependence of the rate exhibits local maxima which positions are defined by a resonance condition. Our study showed that a significant rate enhancement can be produced by the coupling to the field mode if the system is in the inverted region. The cavity-induced enhancement factor is larger at lower temperatures and/or at higher energy gaps. In the normal region the cavity-modified rate is smaller than the cavity-free one. The results of this work may offer a new way to control electron transfer. Using tunable highly-confined IR nanocavities one can easily manipulate the magnitude of ET rate by adjusting the mode volume or/and changing the relative orientation of the system with respect to the polarizability vector of the field. This opens new opportunities for manufacturing of nanodevices and stimulates new developments in infrared plasmonics.

Nanoscale Self-Assembly to Smart Optical Materials
Yadong Yin; University of California, Riverside, Riverside, California, United States.

Smart nanostructured materials with optical properties responsive to external stimuli are gaining increasing interests due to their intriguing potential applications in printing, sensing, signage, security documents, displays, and other color-related devices. In this presentation, I will update our recent progress on the development of novel self-assembly approaches for the fabrication of various nanostructured materials whose optical properties can be dynamically tuned by controlling the spatial arrangement of the nanoscale building blocks. In particular, I will discuss the self-assembly of anisotropically shaped magnetic colloidal particles such as ellipsoids and cuboids into three-dimensional photonic crystals with strong field-direction-dependent diffraction. Then I will report the assembly and disassembly of plasmonic metal nanostructures and the associated opportunities in the development of novel optical devices such as humidity-responsive colorimetric sensors.

SESSION EP11.04: Excitons, Phonons and Polaritons

PCC North, 200 Level, Room 225 B

1:30 PM *EP11.04.01
Polaritons Beyond the Rotating Wave Approximation
Junichiro Kono; Electrical and Computer Engineering, William Marsh Rice University, Houston, Texas, United States.

Recent experiments have demonstrated that light and matter can mix together to an extreme degree, and previously uncharted regimes of light-matter interactions are currently being explored in a variety of settings, where new phenomena emerge through the breakdown of the rotating wave approximation [1]. This talk will summarize a series of
experiments we have performed in such regimes. We will first describe our observation of ultralong strong light-matter coupling in a two-dimensional electron gas in a high-Q terahertz cavity in a quantizing magnetic field, demonstrating a record-high cooperativity [2]. The electron cyclotron resonance peak exhibited splitting into the lower and upper polarization branches with a magnitude that is proportional to the square-root of the electron density, a hallmark of cooperative vacuum Rabi splitting, known asDicke cooperativity.

Additionally, we have obtained clear and definitive evidence for the vacuum Bloch-Siegert shift [3]. The second part of this talk will present microcavity exciton polaritons in a thin film of aligned carbon nanotubes [4] embedded in a Fabry-Perot cavity, also exhibiting cooperative ultralong light-matter coupling with unusual continuous controllability over the coupling strength through polarization rotation [5]. Finally, we have generalized the concept of Dicke cooperativity to a condensed matter system, demonstrating that it also occurs in a magnetic solid in the form of matter-matter interaction [6]. Specifically, the exchange interaction of N paramagnetic erbium(III) (Er3+) spins with an iron(II) (Fe2+) magnon field in erbium orthoferite (ErFeO3) exhibits a vacuum Rabi splitting whose magnitude is proportional to N\(^1/2\). Our results provide a route for understanding, controlling, and predicting novel phases of condensed matter using concepts and tools available in quantum optics, opening up a variety of exciting possibilities to combine the traditional disciplines of many-body condensed matter physics and cavity-based quantum optics.

Tunable Metamaterials for Vacuum Field Engineering of Two-Dimensional Systems
Jerome Faist; Institute of Quantum Electronics, ETH Zurich, Zurich, Switzerland.

When a collection of electronic excitations are strongly coupled to a single mode cavity, mixed light-matter excitations called polaritons are created. The situation is especially interesting when the strength of the light-matter coupling \(W_p\) is such that the coupling energy becomes close to the one of the bare matter resonance \(\omega_0\). For this value of parameters, the system enters the so-called ultra-strong coupling regime, in which a number of very interesting physical effects were predicted. Using metamaterial coupled to two-dimensional electron gases, we have demonstrated that a ratio \(\omega_0/W_p\) close to or above unity can be reached.

We also demonstrated that such ultra-strong light-matter coupling can be achieved using special geometries where the only less than 100 electrons are effectively coupled to the resonator. Other metamaterial engineering include the inter-meta-atoms coupling using a surface plasmon polariton resonance. This feature enables to restore the dispersion to the metamaterial ensemble and to control the linewidth of the latter. One very intriguing feature of ultra-strong light-matter coupled system is the prediction that photon pairs will be emitted through non-adiabatic modulation of the coupling. To this end, we have realized metamaterials based on high Tc superconductors that retain a high quality factor resonance for magnetic field up to \(9\) T and coupled them to two-dimensional electron gases. Because the resonator is designed to be switchable using the superconducting transition, experiment can now be conducted using very intense terahertz fields. We have also used transport to probe the ultra-strong light-matter coupling. As shown in Fig. 1, the longitudinal magneto-resistance of a two-dimensional electron gas is modulated by the irradiation by a weak, tunable THz source revealing the dispersion of the polariton branches. The effect of the vacuum field could be evidenced by a special metamaterial in which the vacuum field could be tuned by a mechanical plate brought in the vicinity of the resonator.

Enhanced Light-Matter Interactions in Phononic Superlattices with Fine-Tuned Shape
Chun-Yu T. Huang1,2, Fariborz Kargar1, Bishwajit Deb Nath3, Topoji Deb Nath2, Adane Geremew2, Michael D. Valentin1,4, Ludwig Bartels1, Roger Lake1 and Alexander A. Balandin2; Phonon Optimized Engineered Materials (POEM) Center, Department of Electrical and Computer Engineering, Bourns College of Engineering, University of California, Riverside, Riverside, California, United States; 2Laboratory for Terascale and Terahertz Electronics (LATTE), Department of Electrical and Computer Engineering, University of California, Riverside, Riverside, California, United States; 3Materials Science and Engineering Program, University of California, Riverside, Riverside, California, United States; 4U.S. Army Research Laboratory, Adelphi, Maryland, United States.

Similar to electron waves, the phonon states in semiconductors can undergo changes induced by external boundaries. The possibility of controlling the acoustic phonon spectrum in periodic structures has led to an explosive growth in the field of phononic crystals. A possibility of the acoustic phonon confinement effects in individual nanostructures has also been demonstrated experimentally [1]. The same periodic structures with properly tuned dimensions can act as phononic crystals affecting the light-matter interactions further. In this work, we conducted experimental and computational study to develop pillar structures, which act simultaneously as phononic and photonic crystals. The “pillar-with-hat” structures were fabricated using the electron beam lithography on a silicon (100) substrates, followed by the inductively-coupled plasma (ICP) cryogenic dry etching. The hats of the pillars were created with a special design to have exactly the same orientation plane as the substrate. The pillars, with the diameter and height of 280 nm and 362 nm, respectively, were positioned in the square array of 1×1 µm\(^2\) dimensions. We used Brillouin-Mandelstam light scattering spectroscopy as a tool to measure the dispersion of acoustic phonons with energies in the range from 0.5 GHz up to 900 GHz near the Brillouin zone center [2]. Changing the angle of light incidence with respect to the substrate allowed us to vary the probing phonon wave-vector, and determine the dispersion near the Brillouin zone center. We analyzed the contributions from all three mechanisms, which contribute to light scattering in our samples. They include scattering from the bulk, i.e. the volume of the substrate via the elasto-optic mechanism, from the surface of the substrate via the surface ripple mechanism, and from the side-facets of the pillars via the surface ripple mechanism. The finite-element modeling guided the nanostructure fabrication. We have found clear signatures of the phonon spectrum modification in the appearance of confined phonon sub-bands at the energies in the range from 2-20 GHz. The light reflectance has been strongly enhanced in certain directions. The experimental results confirmed the dual function of the structure as the phononic-photonic crystal. We argue that the dual function of the structure allows better control of the light-matter interactions, with important implications for engineering the radiative and non-radiative processes in the materials.

The work of the Balandin group was supported, in part, by the DARPA project W911NF18-1-0041 Phonon Engineered Materials for Fine-Tuning the G-R Center and Auger Recombination. Numerical simulations were supported in part by the NSF EFR-1433395. L.B. also acknowledges support from AFOSR under grant number FA9550-17-1-0377.

Study of the Plasmon-Exciton Coupling in Hybrid Nanostructured Superlattices
Nicolas Large and Jose Luis Montaño-Priede; Department of Physics & Astronomy, The University of Texas at San Antonio, San Antonio, Texas, United States.

Plasmon-exciton coupling (plexciton) is a subject undergoing intense research to understand the electromagnetic interaction between plasmonic (metallic) and excitonic (semiconducting) materials and their promising applications in photonics. We investigate the extent on the plexciton (plasmon-exciton) coupling in a superlattice built with
periodically-distributed plasmonic cores with exitonic shells. We calculate the optical properties (extinction, transmittance, and reflectance) and the photonic band structure of micoscale cubic superlattice composed of 40-nm gold core (Au NPs) with 5 nm quantum shell (with exciton at 630 nm) arranged in a cubic array as a function of the inter-nanoparticles spacing (or lattice constant) from 5 to 35 nm. The photonic band structure of the smallest lattice constant present a band gap from 300 to 545 nm and a lower energy band density than those of large lattice constant in which the band gap disappears. The calculated extinction cross-section, transmittance, and reflectance show the plasmon-exciton coupling of the core-shell NPs and its decoupling as the distance between NPs increases. For these gaps, oscillations in their transmittance and reflectance appear as Bragg resonances above 600 nm wavelength. The resonance modes can be used to excite and enhance the interaction between the plasmons and the excitons.

3:30 PM *EP11.05.01
Topological Photonics via Parametric Driving Aashish Clerk; University of Chicago, Chicago, Illinois, United States.

Interest continues to grow in photonic and phononic analogues of topological electronic phases. These systems are typically non-interacting, and have the same band structure and edge state structure as their fermionic counterparts. In this talk, I’ll discuss recent theory work in my group on a class of photonic systems where this correspondence fails. They involve using parametric “two-photon” driving, and have Hamiltonians that superficially resemble those of topological superconductors. Among the surprising effects that emerge are the presence of topologically-protected instabilities that can be harnessed for non-reciprocal quantum amplification, and effective non-Hermitian dynamics in a bosonic analogue of the Kitaev-Majumdar chain. From an application point of view, parametric driving is an attractive route to topological photonics, as the generated gain inherently helps offset the impact of losses. I’ll discuss how our ideas could be realized in a variety of different experimental platforms.

4:00 PM *EP11.05.02
Hybrid Plasmonic and Dielectric Metasurfaces—From Optoelectronics to Nonlinear Optics Igal Brener and Raktim Sarma; Sandia National Laboratories, Albuquerque, New Mexico, United States.

Metasurfaces, which are two-dimensional equivalent of metamaterials, offer a unique and efficient platform to study and control light-matter interactions in the sub-wavelength limit. When combined with semiconductor heterostructures, the metasurfaces can be coupled to fundamental excitations such as intersubband transitions in quantum wells. Such hybrid devices can provide opportunities for both fundamental studies of light-matter interactions as well as for new ultrathin optical devices such as voltage tunable optical modulators and nonlinear frequency generators. In the first part of this talk, I will present a low dissipation optical modulator using a hybrid plasmonic metasurface where the tuning mechanism relies on field induced tunneling of electrons in semiconductor heterostructures. In the second part of the talk, I will concentrate on hybrid dielectric metasurfaces that use using leaky mode resonances coupled to intersubband transitions for high efficiency and broadband second harmonic generation. I will finally conclude by presenting fundamental studies of strong-light matter interaction between Mie modes in dielectric resonators and intersubband transitions in semiconductor quantum wells.

EP11.06.01
Detecting Visible Light by Solution Processed Oxide Absorption Layer for IGZO Phototransistor Jusung Chung, Won-Gi Kim and Byung Ha Kang; Yonsei University, Seoul, Korea (the Republic of).

Recently, many researches have been investigated on oxide semiconductor materials as alternative substance to silicon for various applications such as thin film transistor (TFT), photosensor, gas sensor, etc. It’s because they have superior electrical characteristics, compatibility with flexible substrates, high transparency, high field effect mobility, and low off-state current comparable to amorphous silicon. Among the applications, photosensor is attracting attention because it can be applied in various fields such as health care industry, intelligent display, and smartphone. However, the photosensor with oxide semiconductor has some issues that the wavelength range of the detectable light is limited due to its wide bandgap (>3 eV). Therefore, there are various studies about oxide semiconductor materials based photo transistors to detect visible light by stacking additional absorption layer composed of quantum dot, organic materials, and metal nanoparticle. However, they have disadvantages of high fabrication process, poor uniformity, and vulnerability to external environment.

In addition, some papers researched about the phototransistors with the only oxide semiconductor by controlling the sub-gap states in the oxide semiconductor to improve the light absorption characteristics in the visible light region (400-700 nm). They applied zinc tin oxide (ZTO) or indium zinc oxide (IZO) which have relatively higher oxygen related defects compared to indium gallium zinc oxide (IGZO). These oxide semiconductors act both channel layer and light absorption layer so that oxygen related defects could aggravate electrical characteristics and stability. By these problems, the phototransistor with oxide semiconductor cannot operate as photosensor device for a long time. Additionally, oxygen related defects mainly affect deep trap site, so the wavelength range of absorbable visible light by the oxide semiconductor is limited. Because of these factors, further studies are needed to absorb the entire range of visible light including red light. In this paper, we proposed indium-gallium-zinc-oxide (IGZO) phototransistors with...
simple fabrication process of stacking solution processed oxide light absorption layer (SAL). The phototransistor with the SAL was designed to have superior electrical and optical characteristics by separating the role of channel layer and light absorption layer. We generated sub-gap states in bandgap of SAL by low annealing temperature resulting in improved light absorption in visible light region (400 – 700 nm). The SAL was composed of IGZO which was similar with IGZO channel layer. The low annealing temperature process affect two type of defects, oxygen related defects and organic residue defects. The mechanism of visible light absorption by the SAL was verified by comparing the two type of defects, oxygen related defects and organic residue, and the results of optical characteristics of the phototransistor with the SAL. These sub-gap states caused SAL to absorb visible light despite the wide bandgap of IGZO (>3.0 eV). As a result, IGZO phototransistor with SAL has superior light absorption characteristics such as high photosensitivity of 127 A/W and photosensitivity of ~106 in red (635 nm) and green (532 nm) light region.

EP11.06.02
Robust Stretchable Photodetectors Based on Graphene/Co Heterostructure Shuchao Qin, Qianqian Du, Xinran Wang, Yongbing Xu, Yi Shi, Rong Zhang and Fengjie Wang; Nanjing University, Nanjing, China.

Graphene is being actively explored as a candidate material for flexible and stretchable photonic devices. However, the weak optical absorption of a monolayer carbon atoms and the absence of a gain mechanism have limited its responsivity. Here, we report a flexible photodetector with a high photosresponsivity and a fast response time from UV to visible range, using the graphene-Co all-carbon film on PET substrate, which is attributed to the efficient exciton dissociation at the graphene-Co interface and enhanced optical absorption of Co. In addition, the device exhibits good robustness against repetitive bending, suggesting its applicability in large-area array flexible photodetectors.

EP11.06.03
Improved Photovoltaic Performance of GaAs Solar Cells Enabled by Plasmonically Enhanced Spectral Upconversion Hyundong Chen1, Sung-Min Lee2, Angelo Montenegro3, Dongseok Kang3, Boju Gai4, Haneul Lim5, Chayan Dutta3, Wanting He3, Minjoo Lee3, Alexander Benderskii6 and Jongseung Youn4,5; 1Department of Chemical Engineering and Materials Science, University of Southern California, Los Angeles, California, United States; 2School of Materials Science and Engineering, Kookmin University, Seoul, Korea (the Republic of); 3Department of Chemistry, University of Southern California, Los Angeles, California, United States; 4Department of Electrical and Computer Engineering, University of Illinois at Urbana–Champaign, Champaign, Illinois, United States; 5School of Chemical Sciences and Environment, University of Illinois, Urbana-Champaign, Urbana, Illinois, United States; 6Department of Chemistry, Seoul National University, Seoul, Korea (the Republic of).

Spectral upconversion is a promising approach to circumvent the sub-bandgap transparency of single-junction solar cells by converting longer wavelength sunlight into high energy photons that can be readily absorbed. However, low intensity of one-sun illumination at relevant wavelengths of spectral upconversion inherently limits their practical application in photovoltaics. Here we present a composite module of GaAs solar cells that can provide meaningful enhancement of their one-sun photovoltaic performance by additionally capturing sub-bandgap photons via plasmonically enhanced spectral upconversion. Ultrathin GaAs solar cells with a specialized epilayer design are integrated on an upconversion medium containing NaYF4: Er3+, Yb3+ upconversion nanocrystals (UCNC), coated on a plasmonic reflector composed of hole-photonic hybrid silver nanostructure. The solar-to-electric conversion efficiency of GaAs solar cells on a UCNC-incorporated plasmonic substrate is improved by ~6.4% (relative) and ~11.8% (relative), respectively, compared to those on a nanostructured silver reflector without UCNC and on a plain silver reflector with UCNC, which is attributed to the combined effects of local electric-field amplification to enhance the absorption of UCNC, augmented upconverted emission via coupling into radiative modes, waveguided light concentration, as well as photon recycling.

EP11.06.04
Metal Nanoparticles on Crystalline Oxide Nanostructures for Surface Enhanced Raman Spectroscopy Bo Xiao; Norfolk State University, Norfolk, Virginia, United States.

We demonstrate a new paradigm for large-scale fabrication of metal nanoparticles on crystalline oxide nanostructures for surface enhanced Raman spectroscopy (SERS). A single-cell vapor-solid deposition was introduced to yield high-throughput SnO2 nanostructures with flexible control of size and geometry. Subsequent high-density Au nanoparticles with three-dimensional coverage on the oxide nanostructures were achieved through nucleation control in Volmer-Weber growth mode using physical vapor deposition at elevated temperatures. Au nanoparticles on SnO2 nanostructures operating in different “hot spot” modes exhibit the remarkable sensitivity of detecting trace concentrations molecules. This strategy also enables surface modification to alter hydrophilic to super-hydrophobic surfaces with contact angle over 150°. The manifestation of high-density metal nanoparticle formation presents a route to develop multifunctional nanostructures.

EP11.06.05
Tunable, Vivid Reflective Color Pixel Based on Active Fabry-Perot Broadband Absorber Soo-Jung Kim1, Heon Lee1 and Sung-Hoon Hong2; 1Korea University, Seoul, Korea (the Republic of); 2Electronics and Telecommunications Research Institute, Daejeon, Korea (the Republic of).

Structural colors based on Fabry-Perot (F-P) structure [1] has been received much attention in developing ink-free color painting for applications such as security devices, reflective display and functionalized color decoration. F-P absorbers have a simple structure thin metal-dielectric cavity- opaque thick metal without the need for complicated lithography process. F-P absorber can be fabricated over a large-area, and the reflective colors can be easily controlled according to the thickness of the dielectric layer for practical applications. However, asymmetric F-P cavities composed of bulk metal film exhibit an absorption spectra that has very narrow bandwidth, and it is difficult to achieve vivid color and wide color gamut in reflective color generation. [2] In previous other studies, the Cr and Ni lossy metals have been applied to F-P absorber instead of Ag and Au to widen the absorption band. But, a general metal deposition process such as sputtering or the vacuum evaporation has several drawbacks. One is that the physical properties of deposited metals are hardly controlled making it difficult to change the characteristics of the absorber. The other is that it is difficult to fabricate a large-area on various substrate because of high cost and time consuming.

In this study, we proposed a new active, vivid reflective color pixel based F-P cavity absorber using a lossy nanoporous material by the solution process. The nanoporous material made of chemically coupled silver nanocrystals (Ag NCs) with a conductive ligand, and this metal-dielectric composite film was applied to the top layer of the absorber to achieve a broadband absorption. Through finite-difference time-domain simulations and systematic experiments, we demonstrated that this combination generates enhanced color purity and provides an extended color gamut by controlling the dielectric cavity thickness. And, micro-size color pixel was actually actuated by incorporating a phase change material on F-P absorber.

EP11.06.06
Indium–Gallium–Zinc Oxide Based Visible Light Phototransistors Using Selenium Passivation Layer Hyukjoon Yoo, Won-Gi Kim, Byung Ha Kang, Hyoung Tae Kim and Hyun Jae Kim; Yonsei University, Seoul, Korea (the Republic of).

Recently, oxide semiconductors have attracted attention as new materials that can be widely used due to the outstanding characteristics of oxide semiconductor based devices, such as high mobility, low off current, and transparency compared to amorphous silicon based devices. Owing to these characteristics, oxide semiconductors are applied for a lot of electronic devices such as sensors and thin film transistors. In spite of this versatility, however, there is a limit to use oxide semiconductors as a phototransistor for detecting visible light region due to the high band gap energy (> 3 eV) of oxide semiconductors. Since the light of visible region has an energy of about 2 eV, the oxide semiconductor having high energy band gap cannot absorb the visible light. In order to overcome such disadvantages, researches have been conducted to fabricate visible light phototransistors by depositing a visible light absorption layer using quantum dots, nanowire, and 2D materials but there are problems such as complicated material synthesis process and difficulty in large area application.

In this study, indium–gallium–zinc oxide (IGZO) based visible light phototransistors were fabricated using a selenium passivation layer (Se PVL) as a visible light absorption layer. Selenium (Se) has photoconductive properties and exhibits conductive property only when light is irradiated. The Se PVL could be easily deposited by thermal evaporation process without any post treatment. It was confirmed that the IGZO phototransistors with Se PVL had the highest photoresponse characteristic at the Se PVL thickness of 150 nm. The IGZO phototransistors with Se PVL exhibited high photoelectronic characteristics such as photoresponsivity of 303.12 A/W, photosensitivity of 6.86 x 106, and detectivity of 60.
5.18 x 10⁻³⁴ Jones under 635 nm light illumination. Se showed the characteristics of p-type semiconductor and formed a large difference of valance band maximum in energy band alignment with IGZO layer. Therefore, electrons generated through absorption of visible light in Se PVL could be easily transferred to IGZO and affect electrical characteristics, while holes are not easily migrated due to valance band energy difference, so that recombination is prevented. The IGZO phototransistors with Se PVL exhibited excellent alignment with IGZO layer. Therefore, electrons generated through absorption of visible light in Se PVL could be easily transferred to IGZO and affect electrical characteristics, thereby creating patterned letters that emit different colors such as blue or green, from their backgrounds. Furthermore, the diffusion of dye molecules in the bleached region promoted a self-healing characteristic that could erase the patterned letters, which could enable the rewriting of different letters using the same PDMS. Using the proposed approach, we could pattern multi-color-emitting PDMS by taking advantage of the light-induced photobleaching phenomenon that is usually regarded as an undesirable effect in microscopy research. The introduction of this new way to realize rewritable, light-driven technology is highly meaningful because current approaches synthesize process. Using the conventional-dye-incorporated PDMS and photobleaching phenomenon for the reversible color changes would be an alternative approach to resolve the remaining challenges. We believe that this novel concept may find potential applications in many research fields, such as secure printing and optical storage devices.

EP11.06.07 Laser-Driven, Rewritable Writing Technology in a Full-Color Fluorescent Dye-Diffused Polydimethylsiloxane Elastomer Seongkyu Song and Soon Moon Jeong; Daegu Gyeongbuk Institute of Science and Technology, Daegu, Korea (the Republic of).

In this work, we present a new approach to demonstrate rewritable, light-driven recordings in polydimethylsiloxane (PDMS) by manipulating the light-induced photobleaching phenomenon [1]. The selectively photobleached red dyes turned transparent, thereby creating patterned letters that emit different colors such as blue or green, from their backgrounds. Furthermore, the diffusion of dye molecules in the bleached region promoted a self-healing characteristic that could erase the patterned letters, which could enable the rewriting of different letters using the same PDMS. Using the proposed approach, we could pattern multi-color-emitting PDMS by taking advantage of the light-induced photobleaching phenomenon that is usually regarded as an undesirable effect in microscopy research. The introduction of this new way to realize rewritable, light-driven technology is highly meaningful because current approaches synthesize process. Using the conventional-dye-incorporated PDMS and photobleaching phenomenon for the reversible color changes would be an alternative approach to resolve the remaining challenges. We believe that this novel concept may find potential applications in many research fields, such as secure printing and optical storage devices.

EP11.06.08 Absorption Enhancement of the Solar Spectrum with Arrays of Subwavelength Silicon Trumpet Non-Imaging Light Concentrators Ankit Chauhan1, Ashish Prajapati1, Dor Keizman1 and Gil Shalev2; 1Department of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer-Sheva, Israel; 2The Ilse-Katz Institute for Nanoscale Science & Technology, Ben-Gurion University of the Negev, Beer-Sheva, Israel.

Light trapping and the broad absorption of the solar radiation is important for photonic and nanophotonic applications ranging from sensing to harvesting of the solar energy. For example, appropriate light trapping supports the utilization of ultra-thin photovoltaic cells with enhanced efficiencies1-3. Efficient light trapping was demonstrated with surface arrays of subwavelength structures such as nanopillar (NP) arrays, nanocone arrays, etc4. In the current study we numerically explore light trapping based on surface arrays of subwavelength trumpet non-imaging light (NLC) concentrators (henceforth, trumpet arrays)5. Non-imaging optics was formulated in the regime of geometrical optics in the early 1970s. There are various members to the NLC family such as light cone (LC) NLC, paraboloidal NLC, conic paraboloid concentrators (CPC) and its derivatives, etc. The trumpet NLC (or hyperboloidal NLC) is an important NLC with an ideal concentration ratio as it accounts for both meridional rays as well as skew rays. We use finite-difference time-domain (FDTD) electromagnetic calculations to examine light trapping and broadband absorption of the solar radiation for laterally infinite cubic-tiled substrate-less silicon trumpet array under normal illumination. The absorptivity spectra of trumpet arrays are characterized by strong absorption peaks, some of which are just below the Yablonovitch limit, which is solely attributed to efficient occupation of the array Mie modes. We show that the absorption enhancement at the near infrared is an order of magnitude higher than that of optimized NP arrays. We show superior broadband absorption of the solar radiation in trumpet arrays (with unoptimized geometry) compared with that of optimized nanopillar arrays (~26% enhancement).

We show that low reflectivity is governed by modal excitations at the upper part of the trumpets (which is also supported by the weak dependence of the reflectivity on the array height), whereas the transmissivity is governed by modal excitation at the lower part of the trumpets. We show that the strong absorption peaks of trumpet arrays are governed by the interplay between reflectivity and transmissivity, and the corresponding excitations, which is tuned by adequate selection of the trumpet bottom diameter. The higher optical absorption in trumpet array is governed by low transmissivity, in contrast with nanopillar array in which the absorption is governed by low reflectivity.

EP11.06.10 Anthracene Dimers-Crosslinked Polyurethanes as Mechanoluminescent Polymeric Materials Lei Kan, Hao Wei and Ning Ma; Harbin Engineering University, Harbin, China.

Mechanoluminescent polymers have received arising attention in the research field of photovoltaic and material science in recent years. Anthracene compounds, which can photo-dimerize to form non-fluorescent dimers under 365 nm UV light irradiation and recover to the fluorescent monomers via heating or UV light of 254 nm, are good candidates of dynamic covalent systems for the research on mechanoluminescent polymeric materials. In this work, the anthracene dimers-crosslinked materials were pressed or scratched, indicating that the anthracene monomers were regenerated by mechanical attack chain scission of the dynamic dimer structure. 1H-NMR investigation confirmed the formation of anthracene monomers after the mechanical experiments and the process of the regeneration of the anthracene was simulated by finite element analysis. Furthermore, the average and total intensity of fluorescence increased with the increasing pressure applied on the PU materials, suggesting the formation of anthracene monomers was closely related to the external force. We hope that these anthracene dimers-crosslinked PU materials could provide a new avenue for fluorescent mechanosensitive materials. (This paper is funded by the International Exchange Program of Harbin Engineering University for Innovation-oriented Talents Cultivation.)

Neutral transparent solar cells (TSCs) are highly desirable for building integrated photovoltaics and automobile applications. Transparency and photovoltaic conversion efficiency (PCE) have a trade-off relationship in the photovoltaics. Achieving high performance of TSCs while maintaining transparency is therefore extremely challenging. Here, we report the use of light absorption engineered Si microwire – transparent polymer composite films (SiMPF) as free-standing form to fabricate transparent hybrid solar cells with neutral color and high efficiencies. The controllable spacing between microwires enables to tune transparency of the devices. Moreover, the slanted SiMPF by a solvent-assisted wet etching exhibits excellent anti-reflection property while maintaining the transmittance of the devices compared to the flat ones. Finite-difference time-domain simulation reveals that the hemispherical losses are minimized and slanted SiMPF exhibited enhanced electric field distribution, encouraging the light-matter interaction. Finally, we apply p-type conductive polymer on the top and transparent conductive oxide on the bottom of the SiMPF, enabling us to fabricate neutral-colored semitransparent solar cells. Such devices demonstrate – 8% power conversion efficiency for visible transparencies of almost 10% retaining color-neutrality. These slanted SiMPF platforms are shown to have a significant advantage beyond the trade-off relationship between transparency and PCE, making them ideal TSCs.
Flexible Omnidirectional and Polarisation-Insensitive Broadband Light Absorber Weiling Dong1, Yun Cao2, Kuan Liu3 and Robert Simpson; 1Singapore University of Technology and Design, Singapore; 2Singapore; 3School of Optoelectronic Engineering and Instrumentation Science, Dalian University of Technology, Dalian, China.

Large-scale perfect light absorption in visible and near-infrared (VIS-NIR) spectrum are vital for efficient solar energy harvesting technologies. A wide range of metamaterial absorbers have been demonstrated, but they are limited by issues such as their high manufacturing cost, narrow band absorption, and incident angle sensitivity. We show a facile method to fabricate wafer-scale Ag-Sb2S3 nanoporous plasmon enhanced absorbers on plastic, crystalline and glassy substrates. This method is non-lithographic, and wet chemistry-free that exploits the immiscibility of Ag and Sb2S3 to control the surface morphology of the nanoporous structure[1]. Experimental results and numerical modelling show that the nanoporous structure has a high absorptance >80% over a wide spectral range from 300 to 2400 nm[1]. The high absorptance of the proposed Ag-Sb2S3 nanoporous structure is attributed to the excitation of Ag plasmon resonances and semiconductor bandgap absorption[1]. The high absorptance is independent of the polarisation state of the light and insensitive to the angle of incidence[1], which is a substantial advantage over many other metamaterial absorbers. We have also found that the Ag-Sb2S3 nanoporous structure is an effective absorber on both flexible and rigid substrates[1]. The simple room temperature co-sputter deposition method ensures that the Ag-Sb2S3 nanoporous structure can be grown on substrates such as flexible plastics, glass and ceramics, and other substrates at an industrial scale. In addition, these Ag-Sb2S3 plasmonic absorbers have other inter disciplinary applications including biosensing, which will also be introduced in this presentation[2].

EP11.06.14

Significant Broadband Photocurrent Enhancement by Epsilon-Near-Zero Gold Nanostructures Photocathodes Shih-Hsuan Huang, Jian-Ming Chiu and Yian Tai; National Taiwan University of Science and Technology, Taipei, Taiwan.

The engineering of broadband absorbers to harvest white light in dye sensitized solar cells (DSSCs) is a major challenge in developing renewable materials for energy harvesting. In this study, gold (Au) rod-like sub-branches are successfully attached to the FTO substrate using an adhesive to produce the gold electrode. The proposed approach for fabricating photocathode is demonstrated to be facile and cost-effective, as opposed to existing techniques. Compared with electrodes prepared with sputtered Au, the Au rod-like sub-branches photocathode demonstrates significant increase of the power conversion efficiency (PCE) of a photoelectrochemical solar cell of 65% and higher catalytic activity with a cobalt-complex electrolyte. More importantly, the PCE of Au rod-like sub-branches photocathode improved by 16.6% compared to standard platinum (Pt) counter electrode. The increased efficiency is attributed to broadband absorption in the visible light region which due to incredible broadband plasmonic effect and presented lower lose in light-mater interaction of the Au. We have developed an electrochemical deposition process that enables scaled-up production of this nanostructures for large-scale energy-harvesting applications.

SESSION EP11.07: Light-Matter Interaction in Low-Dimensional Materials

Session Chairs: Andrea Alu and Antoine Reserbat-Plantey

Thursday Morning, April 25, 2019

8:30 AM *EP11.07.01

Control of Light-Matter Interaction in van der Waals Materials Vinod Menon; Physics, City College & Grad Center of CUNY, New York, New York, United States.

Two-dimensional (2D) van der Waals materials have emerged as a very attractive class of optoelectronic material due to the unprecedented strength in its interaction with light. In this talk I will discuss approaches to control this interaction by integrating the 2D materials with microcavities, and metamaterials. I will first discuss the formation of strongly coupled half-light half-matter quasiparticles (microcavity exciton-polaritons) in the 2D transition metal dichalcogenide (TMD) systems and approaches to optically/electrically control them [1-3]. The possibility to enhance the nonlinear optical response of the polariton states by exploiting the higher order Rydberg states in TMDs will also be discussed. We will also present our recent work on chiral metasurfaces to address and route the valley excitons in 2D TMDs. Finally, we will discuss the realization of room temperature quantum emitter array using strain engineered hexagonal boron nitride [4] and coupling them to high quality factor resonators.

9:00 AM *EP11.07.02

The isolation of stable atomically thin two-dimensional (2D) materials on arbitrary substrates has led to a revolution in solid state physics and semiconductor device research over the past decade. 1 A variety of other 2D materials (including semiconductors) with varying properties have been isolated raising the prospects for devices assembled by van der Waals forces. 2 A fundamental challenge in using 2D materials for optoelectronic devices is enhancing their interaction with light, ultimately responsible for higher performance and efficiency in the devices. In particular, for photovoltaics; inorganic materials (e.g., Si, GaAs and GaInP) can concurrently maximize absorption and carrier collection. But thin film absorbers have lacked the above ability due to surface and interface recombination effects. In contrast, Van der Waals semiconductors have naturally passed surfaces with electronically active edges that allows retention of high electronic quality down-to the atomically thin limit. In this seminar, I will show our recent work on photovoltaic devices from transition metal dichalcogenides of molybdenum and tungsten such as MoS2, WSe2 etc. We have recently demonstrated near-unity absorption in the visible part of the electromagnetic spectrum in < 15 nm films of these semiconductors by placing them on reflecting metal substrates such as gold and silver. We have further shown that these highly absorbing, ultrathin films can be further used for fabrication of simple Schottky junction photovoltaic devices with microfabricated metallic top contacts. 3 While, this work helps solve the light-absorption problem, the external quantum efficiency EQE was < 10% for our Schottky junction devices. Very recently, we have extended this early work to fabricate p-n heterojunctions from p-WSe2/n-MoS2 and use graphene as a transparent top contact to amplify our current collection efficiency and push the EQE up to 50%, 4 approaching that of many emerging photovoltaic technologies with active layers in the 100s of nm range. This represents a significant development as both light-absorption and charge collection have been addressed in these devices.

9:30 AM EP11.07.03

Extraordinary Light Absorption and Photoluminescence of Graphene Nanostripes Deepan Kishore Kumar2, Jacob Bagley3, Wei-Shiuan Tseng4, Dorte R. Danielsen1 and Nai-
Graphene has gained enormous research interest over the past two decades due to its unique electronic and optical properties. A single atomic layer of carbon atoms with the honeycomb structure has a universal optical absorption around \(\alpha \approx 2.3\%\), which is defined by the fine structure constant \(\alpha\). This is scientifically unprecedented for materials, but is too small for useful optoelectronic applications. Here we report the production of nearly perfectly light absorbing graphene nanostripes (GNSPs) from a single-step, high-yield, plasma enhanced chemical vapor deposition (PECVD) method using an aromatic precursor (Dichlorobenzene) that enables vertical growth of graphene nanostripes on substrates. The quality of the GNSPs was evaluated using Raman spectroscopy, EDS and XPS techniques to confirm the absence of any dopant, and UPS measurements of the work function at \(\approx 4.45\) eV further confirmed the purity of GNSPs was comparable to pristine graphene. The optical absorption spectra of vertically grown GNSPs revealed nearly perfect absorption over the visible spectral range from 400 nm to 900 nm. The mechanism for nearly complete light absorption may be understood from the gapless nature of graphene that can absorb all wavelengths through carrier excitations and the presence of multiple internal light scattering mechanisms of GNSPs that are stacked in a turbostratic fashion (i.e., rotationally disordered). To investigate whether GNSPs, being a good light absorber, may also be a good light emitter, we investigated the photoluminescence (PL) of GNSPs using a confocal laser scanning Light Sheet Microscope (LSM 880). GNSPs were transferred from the growth copper substrates by either mechanical exfoliation onto a glass substrate or liquid phase exfoliation using N-methyl-pyrrolidone (NMP). We observed a broadband nonlinear emission in the visible spectral range for continuous wave (CW) laser excitation wavelengths at 405nm, 450nm, 488nm, 514nm, 561nm, 589nm and 633nm. The nonlinear nature of emission was manifested by the experimental observation of a blue shifted emission tail above the energy of the excitation laser. Under the same laser power, the emission spectrum was found to redshift with decreasing laser excitation energy, and the emission intensity also decreased substantially with decreasing laser excitation energy, showing ~5 times weaker emission intensity for excitation wavelength at 633nm relative to that for excitation wavelength at 405nm. While emission for a given laser excitation energy only appeared above a threshold laser power, strong light emission was already observed for laser powers as low as ~0.03mW, which was much stronger than most conventional fluorophores. These preliminary findings suggest that the mechanism of light emission may be qualitatively attributed to thermal emission of hot electrons that interacted with strongly coupled optical phonons (SCOP) and topological defects (e.g., the Stone–Wales defects as confirmed by TEM and AFM) in GNSPs, although more systematic and quantitative studies are still necessary to elucidate the underlying physics. All in all, the extraordinary light absorption and photoluminescence found in PECVD-grown GNSPs suggest that GNSPs are promising for use as an active layer in high efficiency photovoltaic devices and tunable light emitting devices.

10:15 AM *EP11.07.04 Plasmonics over Hybrid Metasurfaces Siyuan Dai1, Alex Krasnok1 and Andrea Alu1,2; 1City University of New York, New York, New York, United States; 2The University of Texas at Austin, Austin, Texas, United States.

In this talk we discuss our recent effort in the context of hybrid metasurfaces formed through nanophotonic engineering metasurfaces and 2D materials, reporting our recent theoretical and experimental results in the context of hyperbolic plasmon propagation and embedded eigenstates. During the talk we will discuss their highly unusual light-matter interactions and potential opportunities for nanophotonic devices.

10:45 AM *EP11.07.05 Active Control of Single Photon Sources Using 2D Materials Frank Koppons and Antoine Reserbat-Plantey; ICFO - The Institute of Photonic Sciences, Castelldefels, Spain.

Solid state quantum emitters are a mainstay of quantum nanophotonics as integrated single photon sources (SPS) and optical nanoprobes[1,2]. Integrating such emitters with active nanophotonic elements is desirable in order to attain efficient control of their optical properties but typically degrades the photostability of the emitter itself[2]. In our group, we have developed optomechanical[3] and optoelectrical[4] approaches to either tune energy and decay rate of single photon sources. In this talk, I will present recent experiments[4] that demonstrate a tuneable hybrid device which integrates lifetime-limited single emitters (linewidth 40 MHz) and 2D materials at sub-wavelength separation without degradation of the emission properties. Our device’s nanoscale dimensions enable ultra-broadband tuning (tuning range > 400 GHz) and fast modulation (frequency 100 MHz) of the emission energy, which renders it an integrated, ultra-compact tuneable SPS. Conversely, this offers a novel approach to optical sensing of 2D material properties using a single emitter as a nanoprobe, present a new type of hybrid system, consisting of an on-chip graphene SNSs suspended a few tens of nanometres above nitrogen-vacancy centres (NVCs), which are stable single-photon emitters embedded in nanodiamonds.

Oulton2; 1University of Oxford, Oxford, United Kingdom; 2Imperial College London, London, United Kingdom; 3ICFO–The Institute of Photonic Sciences, Barcelona, Spain; 4National Physical Laboratory, London, United Kingdom; 5Nanoinstitut München, Munich, Germany.

While graphene is a promising material for novel photonic devices due to its broadband optical absorption, ultrafast carrier dynamics and electrical tunability [1], the quantum efficiency of graphene devices is intrinsically limited by low absorption of graphene (2.3% of normal incident light). To enhance light-matter interaction, optical focusing elements such as plasmonic metal nanoparticles (NP) can be utilized [2]. Here, we report our recent results on the graphene plasmonic NP hybrid structures. Femtosecond pump–probe measurements of graphene nearby plasmonic gold nano-disc structures confirm the presence of a strong near-field interaction leading to hot carrier generation in the graphene; however, the results suggest that the hot carriers arise dominantly from direct photoexcitation in the graphene with a minimal contribution from charge transfer from the gold [3]. Next, asymmetric plasmon-nanobar electrical contacts are employed with a view to create an electronic temperature gradient across a homogeneous graphene channel, which results in photothermal electricity (PTE) current generation [4]. At certain conditions, the plasmon-induced PTE photocurrent can be directly isolated. In this regime, the device effectively operates as a sensitive electronic thermometer providing access to plasmon induced local carrier temperature which is estimated to be of the order of 2000 K. These results are of particular importance for development of hot carrier based plasmonic devices.

11:30 AM EP11.07.07 Anomalous Second Harmonic Generation in Monolayer Molybdenum Disulfide Brian Squires, Yuri Rostovtsev and Arup Neogi; University of North Texas, Denton, Texas, United States.

The second order nonlinear optical process of second harmonic generation should theoretically scale quadratically with respect to input power. Deviations from this exponent can be used as a tool to characterize dissipative and coherent processes at the micro scale. We use this new methodology to characterize dissipative processes in monolayer MoS2, which can be attributed to two-photon-absorption, free carrier absorption, and phonon related processes. Additionally, we observe a significantly reduced second harmonic generation power factor for CVD grown MoS2 on GaN which we attribute to efficient electron-phonon coupling due to lattice-matched interface phonons, indicating enhanced thermal dissipation at the boundary. When pumped below the band gap but close to two photon resonance to the C-exciton band, we observe a substantially enhanced second harmonic generation power factor which we explain via a quasi-two-state superradiance model. A singularity in the density of states in MoS2 arises at the C-exciton energy due to
Enhancement exceeding the theoretical double-pass absorption (J<sub>p</sub>) of state-of-the-art efficiency of 19.9%. A detailed loss analysis is conducted and provides a pathway for reaching 25% conversion efficiency in ultra-thin GaAs solar cells using the same light-capturing and conversion mechanisms.

Flexible and Reconfigurable Plasmonics

Over the past decade, significant progress in controlling light-matter interactions at the nanoscale has been achieved. Most of the advances, however, have relied on static systems limited to the as-fabricated or as-synthesized metal nanostructures. This talk will discuss how the ability to tune plasmonics responses reversibly may address key challenges in future nanoscale optics. We will highlight how the fabrication and scalability of responsive nano-optical substrates can be used in diverse applications from stretchable nano-lasing to reconfigurable sensing and imaging.

Light Trapping in Nanowires for Photovoltaic Applications

Optical absorption in nanowire arrays is intensively explored to enhance performance of photovoltaic devices. At normal incident light, vertically standing nanowires act as optical nano-antennas and show up resonant optical modes in their absorption spectra at special wavelengths due to their comparable dimensions to optical wavelengths. To achieve high performance photovoltaic devices, near-unity absorption spectra of nanowires are necessary and are gained through optimizing geometrical parameters of the nanowires [1]. Conventionally, longer nanowires or denser arrays of nanowires (smaller pitch) are used to approach near-unity absorption of the excited optical modes at the expense of larger material volume of nanowires. However, employing light trapping mechanisms in nanowires are the alternatives to enhance absorption of the excited optical modes without increasing the material volume [2], reducing the total cost. The light trapping through increasing optical path length of the optical modes improves absorption of an excited optical mode in constant material volume, enhancing absorption efficiency due to both reducing light reflection at the interface of air/nanowires, and reducing light transmission at the interface of nanowires/substrate. In this study, we improved the effective near-unity absorption spectra in nanowires, we take advantage of light trapping mechanisms in nanowires through embedding distributed Bragg reflectors (DBRs) in the bottom as well as in the top part of InP nanowires, respectively. Our calculations show that by employing the DBRs of only two periods of InGaAs/InP, an unselective absorption spectrum is obtained at normal incidence. At the presence of oblique light incidence, the integration absorption efficiency enhances up to about 85% at 50° compared to 79% at normal incidence. Increasing the period number of the DBRs from two to five, this value increases even upper to about 95% [3]. The improvement is due to decreasing light transmission of the excited optical modes from the nanowires into the substrate. The results are expected to be valid for other direct bandgap III-V semiconductor materials. Taking advantage of DBRs to enhance optical absorption in nanowires offers a great potential for novel high-performance photovoltaic applications.

Quantum Dots: For High-Efficiency Solar Cells

Quantum dot antennas have potential to increase the light trapping efficiency and concentration factor for planar luminescent solar concentrators. We report here on quantum dot antennas designed for a fabricated tandem luminescent solar concentrator (LSC) that consists of a Si bottom cell and a top cell LSC with highly efficient CdSe/CdS quantum dot (QD) isotropic lumineshores evenly dispersed in a poly(laurylmetacylate) (PLMA) waveguide, optically coupled to a micro-array of InGaP top cells. The QDs absorb light in in 300-500 nm wavelength range and emit luminiscence radiation at 653 nm, a wavelength matching the band edge of the InGaP cells. In previous LSC top cell designs, wavelength-selective mirrors have been used to spectrally reflect and trap the radiated QD emission within the waveguide. We compare the light trapping and concentration factor for planar waveguide designs employing Bragg filter top mirrors and metasurface bottom mirrors with quantum dot antennas. Metasurface mirrors are formed from a high index (n>3) material patterned as a hexagonal array of cylindrical pillars of subwavelength thickness onto a glass (n≈1.5) substrate. This LSC is integrated with a Si bottom cell to form a 4 terminal tandem with a maximum theoretical efficiency of 29.4% with a projected tandem module cost of $8130/m². A limiting factor in current LSC design is related to the tandem efficiency of the QDs. The radiated emission can be lost through the escape cone or be parasitically lost within the waveguide. By forming quantum dot antennas, consisting of QDs coupled directly to the pillars of the metasurface bottom mirror, we can induce highly directional, oblique anisotropic QD emission, reducing escape cone losses, and thus potentially eliminating the need for a spectrally-selective top mirror. We simulate quantum dot antennas composed of aluminum antimonide, silicon, and silicon carbide and find a maximum achievable efficiency of 32.2% with a lower projected tandem module cost of $6387/m².
Nanosized structures introduce new ways for manipulating light injection, coupling and trapping at the subwavelength scale. A number of nanoscale light trapping structures that can efficiently control and enhance light absorption have been reported such as, inverted nanoprisms, nanowires, quasi-random patterns, and nanocones, mainly focusing in the optical domain, with very few modifications. The famous nano-structure in this study area is known as “black silicon” exhibiting nearly zero reflection over a broad solar spectrum range. The complexity of these structures comes when are integrated into real devices. The challenging problem is not to compromise the optical enhanced character of silicon by the electrical losses such as the recombination at the solar cell surfaces. Since black silicon devices exhibit large surface areas, minimising surface recombination is mainly difficult. There are reports on high efficient black silicon solar cells thus far have yet not been able to compete with conventional silicon devices. Jibun and the co-workers have reported an 18.2% efficient all back contact (ABC) black silicon device$^6$. They find that the dominant recombination process can be reduced by careful monitoring of the doping profile of the structured surface. They report that efficiency limitation is mainly due to Auger recombination whereas surface recombination only dominates at low doping density profiles. In contrast, Hele Sevin et al. report a 22.1% black silicon IBC device by passivating the surface recombination through the deposition of a conformal layer of alumina$^7$.

Here, we demonstrate the fabrication of quasi-random nanophotonic structures that have similar optical properties as black silicon and integrate them by both wet and dry processing. We also fabricate state-of-the-art light trapping structure, micron-sized pyramids and realize into silicon solar cell. We present a quantitative comparison of these nanophotonic structures both in the electrical and optical domain, evaluating the impact of plasma dry etching by comparing the same nanostructures made of wet chemical etching. Furthermore, it is an interesting study to understand whether the taper walls of the wet etched structure improves the antireflective (AR) property compared to the vertical walls realized by dry etching. Ultimately, we also show a detailed comparative study of micro vs nano, structures to address the question of whether nanostructuring to improve the optical performance of solar cell devices without compromising their electrical efficiency.

Here, a thermionic power converter fabricated from gold nanostructures is systematically tested. Periodic patterned gold nanostructures are fabricated through electron beam lithography. With laser excitation at different incident power and wavelength, the corresponding thermionic emission current is collected at a paired ITO anode. Short circuit current \( J_s \) and open circuit voltage \( V_{oc} \) provide a unique way to pinpoint the effective electronic temperature of the ‘hot electron’ distribution as well as its relative population compared to thermalized electrons. The wavelength and geometry dependence study reveal detailed insight into the light-matter interaction and electron-phonon coupling dynamics. Additionally, the experimentally observed electronic temperature of the non-thermal electron gas is also supported by anti-Stokes Raman thermometry recently developed in our group.

Nanoscale assembly coupled with competing anisotropic interactions can produce complex structures and provide additional degrees of freedom for tailoring their collective properties. However, the ongoing researches are highly limited by the poor quality of building blocks, inaccessibility of direct observation of crystal structures and lack of reliable numerical methods for analyzing their dynamic anisotropic interactions. In this presentation, we report magnetic assembly of super uniform magnetic nanorods into responsive body-centered tetragonal (hct) photonic crystals. The assembled structures are fixed during assembly by silica coating and directly characterized under electron microscopy, which suggests a body-centered tetragonal (hct) crystal structure. Finite-element calculations show that two magnetic nanorods approach thermodynamic equilibrium when the tangent components (orthogonal to the surface normal) of their magnetic forces is zero, showing good agreement with structures from TEM images of the assembled crystals. This method provides reliable analytical approach towards understanding the anisotropic interactions between building blocks. Thanks to the pretty good orders of the crystals, well-defined diffraction peaks are observed during SAXS measurements, which is consistent with the hct structures obtained by TEM images and provides detailed information about assembly kinetics. In combination with high packing density, the assembled photonic crystals exhibit extremely bright structural colors, whose intensity overwhelms our other tunable photonic crystals. In addition, the diffraction peaks and structural colors can be continuously tuned across visible range by varying the directions of magnetic field. We also extend the assembly strategy to other morphologies, like nanocubes and nanoplates. In the case of nanocubes, they tend to assemble along \([110]\) direction (edge to edge) as determined by the interplay of the shape and magnetic anisotropic interactions. In case of nanoplates, however, 2D photonic crystals are more favorable due to the symmetry breaking along the directions orthogonal to assembly axis (direction of external magnetic fields).

Anisotropically Shaped Cu Nanostructures as Emerging Plasmonic Materials

Jiansen Chen\(^1\), 2 and Yadong Yin\(^1\); 1University of California, Riverside, Riverside, California, United States; 2Soochow University, Suzhou, China.

Plasmonic materials have been extensively studied because of their broad applications in areas such as chemical and biological sensing, bioimaging, and solar energy conversion. So far major research efforts have been limited to noble metals particularly gold and silver due to their considerably large scattering and absorbance cross-sections as well as high chemical stability. However, these noble metals have limited earth abundance, making their large scale application impossible. Although much desired, little progress has been made to the development of non-noble-metal-based plasmonic materials due to their weak plasmonic response and/or low chemical stability against oxidation. In this presentation, we first analyze theoretically the plasmonic characteristics of copper using FDTD solution, and demonstrate that copper nanostructures can be made highly active in surface plasmon resonance if their resonance mode can be shifted to infrared to avoid the overlap with the intrinsic interband transition. Practically, this can be achieved by adopting an anisotropic shape such as plate and rod. The challenge however is the synthesis of copper nanostructures with well-defined anisotropic shapes using wet chemical approaches. In the second part of the present work, we report a seed-mediated templating growth method for the preparation of copper nanorods with highly controllable dimension and excellent size/shape uniformity. The resulting copper nanorods show surface plasmon resonance in infrared with intensity comparable to or better than silver and gold counterparts. With the protection of a crosslinked polymer layer, the nanorods also display considerably high stability against oxidation. Lastly, by taking advantage of their excellent photothermal conversion efficiency and high stability, we integrate the copper nanorods into the fabrication of shape-memory polymer nanocomposite and further demonstrate the construction of smart microrobots whose mechanical movement can be fully controlled by the illumination of light.
optical simulations, we show that these supercrystals exhibit Mie resonances both in scattering and absorption. This photonic behavior leads to absorption efficiencies of QD supercrystals greater than unity in a wide spectral range in the visible. Finally, we investigate QD coupling in supercrystals via ultrafast spectroscopy, finding that QD supercrystals feature a transition from bound to free biexciton as the interparticle distance decreases.

Plasmonic perfect absorbers can exhibit nearly 100% absorptivity at desired wavelengths, and also emit light at the same wavelengths when they are heated. It has been successfully demonstrated their use such as in wavelength-selective infrared thermal emitters and molecular vibrational sensors. In this seminar I will summarize some recent studies in our group on the perfect absorbers based on the metal-insulator-metal structures, Fabri Perot or other similar types of cavity structures as well as 2D patterned structures. Some of the fabricated mid-infrared perfect absorbers exhibit narrowband resonant absorption as narrow as 22 nm with efficiency higher than 97 %. We introduce some applications of these devices such as for selective thermal emitters operated above 1273K, selective surface-enhanced vibrational spectroscopy for high-sensitivity molecular sensing, and wavelength selective IR detectors in combination with pyroelectric, thermoelastic, and bolometer devices.

**Polarization Manipulation via Surface Phonon Polariton Nano-Resonators**  

The polarization of light is of interest in several technologically relevant fields ranging from chemical identification, where the differing handedness of a molecule can drastically alter its effects on the human body, to quantum computing, with the polarization of light serving as a qubit. Here, we report the polarization properties of L-shaped localized surface phonon polariton resonators etched into 6H-SiC, with modal Q-factors as high as 144. These high Q-factors allow us to identify three resonances and observe their evolution as a function of asymmetry, which would otherwise be muddled by the loss-induced broad linewidths in the comparable plasmonic structures. Full-wave electromagnetic simulations of the resonator reflection spectra and resonant charge distribution indicate that the low- and mid- energy modes are characterized by a longitudinal dipole and transverse dipole, respectively. This behavior is corroborated by polarization dependent reflectance measurements and simulations that reveal orthogonal excitation axes for these two modes for the symmetrical resonator. However, this orthogonality is broken as the relative leg length is increased. Interestingly, the simulated resonant charge distribution of the high-energy resonance suggests that it is associated with a higher order longitudinal mode. However, unlike the longitudinal dipole mode, the higher-order mode exhibits an anomalous polarization dependence that is characterized by a spectral weight that is only weakly dependent on the incident polarization. Furthermore, as this higher energy mode is tuned into resonance with the normally IR inactive zone folded longitudinal optical phonons, a coupling behavior is observed between the surface phonon polariton mode and the bulk phonons, with the resonant intensity of the phonon modes following the polarization dependence of the higher energy mode.

**Photonic Materials for Solar Sail Interstellar Missions**  
Artur R. Davoyan; University of California, Los Angeles, Pasadena, California, United States.

We discuss photonic material and design challenges facing future solar sail based interstellar missions. We discuss extreme conditions of solar radiation and corona that sails are exposed to during a solar gravity assist phase and outline designs that enable sustainable sail designs. At present deep space exploration is limited by transit time and overall mission costs. Conventional space transportation systems typically employ chemical or solar electric propulsion, which have effectively reached the limit of their maximum performance potential; further development activities focus mainly on improving reliability and reducing cost. Recent studies show that solar sails with high area-to-mass ratios and less than 0.1 AU perihelion approach (i.e., <20 solar radii) may enable missions with >30 AU/year propulsion, which have effectively reached the limit of their maximum performance potential; further development activities focus mainly on improving reliability and reducing cost. We show that with a proper photonic design polar resonances of the aforementioned materials may harnessed to obtain relatively large emissivity and achieve sustainable sail propulsion, which have effectively reached the limit of their maximum performance potential; further development activities focus mainly on improving reliability and reducing cost.

Next, we consider photonic designs that optimize reflectance and hence the radiation pressure force. We highlight the mass – reflectance tradeoff and show that sail materials with >20 AU/year are feasible. We show that conventional polymer based sails cannot withstand high solar flux and justify the need for novel sail materials. We discuss necessary criteria and show that sails based missions necessitate a very close pass near the sun, where the sail is exposed to extreme conditions of solar radiation and corona. Here, we study photonic properties of sail materials and discuss criteria needed for the design of such extreme solar sails.

Finally, with radiative cooling being the sole mechanism for thermal management, we study nanopatterning of the sail materials to increase their thermal emissivity in the infrared. We show that with a proper photonic design solar resonances of the aforementioned materials may harnessed to obtain relatively large emissivity and achieve sustainable sail temperatures, below the melting point of its constituent materials.

**Low-Loss Metasurface Optics Down to the Deep Ultraviolet**  
Cheng Zhang, Shawn Divitt, Qingbin Fan, Wenqi Zhu, Anam Agrawal, Ting Xu and Henri J. Lezec; 1National...
Institute of Standards and Technology, Gaithersburg, Maryland, United States; College of Engineering and Applied Science, Nanjing University, Nanjing, China.

Recent years have witnessed the rapid development of flat optical elements, known as metasurfaces. With properly designed and arranged sub-wavelength structures over its plane, a metasurface can impart arbitrary, spatially variant amplitude, phase and polarization modulations on an incident electromagnetic wave. The highly customizable nature of a metasurface allows it to accomplish a variety of functions that have traditionally been fulfilled by a combination of different optical elements, such as gratings, lenses, polarizers, wave-plates, beam splitters, and hologram plates, with a significantly reduced physical thickness compared to traditional optical elements. So far, researchers have demonstrated various types of high-performance metasurfaces operating in the infrared (IR) and visible regimes, paving the way towards high-efficiency, multi-functional and compact photonic systems.

However, there has been a conspicuous lack of work in the ultraviolet (UV) region, which is the spectral range hosting an array of important applications such as photolithography, spectroscopy, sterilization, astronomy, medical therapy, and high-resolution imaging. High-performance metasurfaces working at IR and visible frequencies employ dielectric materials such as Si, TiO\(_2\), and GaN. Direct scaling of operation frequencies of metasurfaces based on these material systems down into the UV is challenging because of the intrinsically lossy response of such materials at wavelengths below their bandgap, preventing high output efficiencies.

Here, we show how low-loss metasurface devices operating at UV wavelengths down to the deep-ultraviolet range can be implemented using Hafnium Oxide, an amorphous dielectric material most commonly exploited as a high-static dielectric constant (high-\(k\)) material in integrated circuit fabrication, that is characterized by a wide-bandgap (5.8 eV). We demonstrate a variety of polarization-independent metasurface devices, including lenses, holograms and self-accelerating beam generators, operating at two near-UV wavelengths (364 and 325 nm) with efficiencies as high as 75\%. Scaling down metasurface critical dimensions, we realize holograms operating with high efficiencies of 60\% at a record-short, deep-UV wavelength of 266 nm. Finally, we demonstrate spin-multiplexed holograms and self-accelerating beams at 364 nm, and spin-multiplexed holograms at 266 nm.

2:00 PM *EP12.02.02
Enhanced Hot Carrier Effects in Ultra-Thin Metallic Films on Index Near-Zero Substrates
Jeremy N. Munday; University of Maryland, College Park, Maryland, United States.

Bulk metals are generally reflective and are therefore commonly overlooked as efficient absorbers; however, the fields of plasmonics and metasurfaces have given new insights into methods for turning reflective surfaces into absorbing ones. Another recent approach has been the use of subwavelength Fabry-Perot-like resonances in ultra-thin films, which has been used to achieve absorption above 70\%, approaching the theoretical limit using traditional substrates. Here we take a different approach and show that near-perfect absorption is achievable provided that the ultra-thin metals are deposited on an index near zero (INZ) substrate. In this talk, I will present the various design considerations that allow for ultra-thin metal films on INZ substrates to obtain near-perfect absorption throughout the visible spectrum and into the near-infrared (NIR). We find that metals commonly used for plasmonics and hot carrier devices, such as Au and Ag, can obtain near-perfect absorption for near-ultraviolet and visible wavelengths, while metals such as Pd and Pt are efficient absorbers throughout the near-ultraviolet to near-infrared spectrum. Finally, I will present results where we use this mechanism to enhance the photocurrent of photodetectors based on hot carrier generation in thin metal films.

2:30 PM EP12.02.03
High Contrast Grating Metasurfaces as Wavelength Selective Reflectors
Haley Bauser, Colton Bukowsky, Megan E. Phelan, David R. Needell and Harry Atwater; California Institute of Technology, Pasadena, California, United States.

High contrast grating (HCG) metasurfaces are promising alternatives to Bragg filters as wavelength selective mirrors. HCG metasurfaces consist of a single material layer with a high index of refraction (\(n=3\)) patterned at a subwavelength thickness directly onto a lower index (\(n=1.5\)) substrate. Bragg filters are highly efficient in reflection, but suffer from a strong dependence on angle of incidence. Moreover, Bragg stacks use many layers of different indices to manipulate light, resulting in an expensive fabrication process. In HCG metasurfaces, the high contrast between the respective materials’ refractive indices enables scattering and mode interference that results in a sharp and tunable reflection peak. We explore the design and fabrication of HCG metasurface mirrors using three different materials: aluminum antimonide, silicon, and silicon carbide. We optimize our design for application in a planar luminescent solar concentrator comprising mirrors cladding a planar waveguide with embedded quantum dot luminesphores emitting at a peak wavelength of 635 nm design to reflect quantum dot luminescence emission that couples with the band edge of a III-V photovoltaic cell. We fabricated HCG mirrors on glass substrates via sputtering or PECVD and patterning via e-beam lithography and a dry etch. We find that the ideal HCG for a peak centered at 635 consists of a hexagonal array of cylindrical pillars with the radius and height approximately 100 nm and a pitch of roughly 495 nm. The reflectance peak of these materials ranges from 80\% to 95\% at 635 nm.

Exotic Light-Matter Interactions in 2D TMDC Materials
Linyou Cao; Department of Materials Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States.

Atomically thin two-dimensional (2D) transition metal dichalcogenide (TMDC) materials present a remarkable excitonic systems with exciton binding energy usually one order of magnitude higher than those in typical semiconductor materials. As a result, these materials bear great potential to enable the development novel optical and optoelectronic devices. Here we demonstrate some exotic light-matter interaction properties of 2D TMDC materials that result from the extraordinary strong exciton binding energy. This include: 1) giant gating tunability in the optical refractive index of 2D TMDC materials, in which a tunability > 60\% is achieved in the refractive index of 2D TMDC materials by electrical gating with a configuration compatible with CMOS devices; 2) room-temperature condensation, where the gas-like excitons may condense into a liquid-like state, electron-hole liquid (EHL). We will also demonstrate the magneto-optical properties enabled by magnetic TMDC materials.

3:45 PM *EP12.02.05
Robust and Scalable Meta-Surfaces for Powerful Lasers Applications
Eyal Feigenbaum, Jae H. Yoo, Hoang T. Nguyen, Michael A. Johnson, Salman H. Baxamusa, Selim Elhadj, Joseph T. Mckeown and Ibo Matthews; Lawrence Livermore National Laboratory, Livermore, California, United States.

The field of optical meta-surfaces is rapidly growing due to its great potential to enable thin optics implementation with relatively complex and flexible functions. In particular, high power laser systems could benefit from optical meta-surfaces that implement beam shaping, e.g., for wave-front aberration correction, but with the advantages of smaller accumulation of nonlinearity and lighter weight. Additionally, meta-surface technology could enable laser optics with improved anti-reflective layer designs. Current meta-surface technology is limited with respect to high power laser optics, which requires both scalability and laser intensity durability. The principal challenge arises from the necessity of patterning sub-wavelength features (to control the local optical properties by modifying geometrical properties) while being able to modify the structural parameters on the large optoelectronics scale used in high power laser systems (e.g., National Ignition Facility, Laser MegaJoule). The current patterning methods are either limited in scalability (e.g., FIB, e-beam lithography) or limited in robustness due to the usage of soft-materials (e.g., nanoimprint). We are developing novel technology capable of generating robust and scalable all-dielectric based meta-surfaces. In this talk we will describe the method, show results of fabricated meta-surfaces, and discuss the various levels of control that we have with this process. This method extends the current application field of interest for meta-surfaces to high power lasers, with the potential to stimulate meta-surface utilization in additional fields requiring large and robust optics.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-CONF-760584.

Highly Efficient Chiral Plasmonic Metasurfaces for Mid-Infrared Polarization Detection
Jing Bai, Chao Wang and Yu Yao; Arizona State University, Tempe, Arizona, United States.
Plasmonic metasurfaces provide great flexibility to control the amplitude, phase and polarization response of light in broad wavelength ranges from UV to THz, thus hold promise to realize ultra-compact chip-integrated photonic and optoelectronic devices for various applications. Chiral plasmonic metamaterial as artificial counterpart for the rare chiral material in nature enables generation, manipulation and detection of circularly polarized (CP) light. Plenty of works have demonstrated circular dichroism spectroscopy and circularly polarization detection based on chiral plasmonic metasurfaces. Besides, full Stokes parameters detector have been proposed based on phase gradient arrays, aperture antenna and in-line scatterers. Researchers are putting more efforts to develop new devices for high efficient and high performance polarization detection. Here we present our experimental demonstration of highly efficient (>85% transmission efficiency) chiral metasurface structures as circular polarization (CP) filters with extinction ratio over 50 (defined as the ratio between transmission of CP light with the desired handedness and that of the other handedness). The proposed structures are composed of rationally designed plasmonic antennas and nanowires, which are vertically intergraded with a subwavelength-thick dielectric spacer layer. This thickness of the device can be less than 1/10 of the operation wavelength. We investigated the design principle with anisotropic transfer matrix method and confirmed the design concepts with full wave simulation. According to our theoretical analysis, one can achieve CP filters with extinction ratio over 1000 and transmission efficiency over 90%. In experiment, we have achieved over 85% efficiency and extinction ratio ($r=T_{CP}/T_{CP}^*$) over 50 at 4 μm. We have also integrated the CP polarization filters with nanowire grating linear polarization filters on the same chip for full stokes polarization detection. The measurement errors of our devices are 2%, 4% and 5% for S1, S2 and S3, respectively. And the errors for DOLP and DOCP are 5.4% and 6.6%, respectively, which to our knowledge are the best among the metasurfaces based polarization detection techniques presented in literature so far. The operation wavelength of the device can be engineered from NIR to FIR (1 μm to 30 μm) by simply changing the design parameters. Our designs can be directly integrated onto various semiconductor-based photodetectors and imaging arrays; thus enable on-chip polarization detection and imaging for various applications such as circular dichroism (CD) spectroscopy, polarimetric imaging and sensing, and molecular spectroscopy.

4:30 PM EP12.02.07 Subwavelength Achromatic Metasurface Lens Over Whole Visible Bandwidths Ya Sha Yi, Yao Ye and Dachuan Wu; University of Michigan, Dearborn, Michigan, United States.

Metasurface lens is one of emerging planar nanophotonic devices that promises unprecedented control of the light at nano scale and have potential applications in highly multidisciplinary fields including imaging, sensing, spectroscopy and photovoltaics. Typically, for concentrating micro grating lens utilizing 0th diffraction mode, a high index contrast grating is used as individual phase shifter to satisfy the lens focusing requirements, as it can provide relatively large phase shift from 0 to 2π so that the light focusing condition can be met. However, the high index contrast gratings give rise to a significant chromatic behavior and achieving achromatic focusing over certain bandwidth turns out to be very challenging. The achromatic focusing capability is critical for a variety of applications, as light sources (e.g., light emitting diodes) or the signal (e.g., photoluminescence and fluorescence signals) has a substantial bandwidth, especially in the visible wavelength range. For refractive lens such as Fresnel lens, achromatic behavior requires hybrid design to compensate for chromatic loss, thus significantly increase the device’s complexity and cost. For emerging micro lens designed based on subwavelength phase shift units, metasurface based circularly polarized incidence is reported with achromatic behavior achieved through special dispersion control of Panchatramn-Berry phase elements. While for linearly polarized incidence, only several wavelengths can be achieved in telecommunication range, lens with a notable focal shift or very narrow bandwidth has been achieved.

In this work, we have demonstrated the achromatic all-dielectric metasurface lens covering the whole visible bandwidth based on relatively low index contrast gratings. Supported by the unique chromatic phase shift of polygonal polymer structure, we are able to design a broadband subwavelength achromatic micro lens which can cover 250 nm of visible bandwidths (from 435 nm to 685 nm) with focal shift less than 5% with linearly polarized incidence. Our work is a critical step further to achieve the promises made by the flat metasurface lens that is comparable with image qualities obtained by the commercial objective.

4:45 PM EP12.02.08 All-Dielectric Active Metasurfaces with III-V Multiple-Quantum-Well Mie Resonators Pin Chieh Wu,1,2, Ragip Pala,1 Ghazaleh Kafaie Shirmanesh,1 Wen-Hui Cheng,1 Ruzan Sokhoyan,1 Muhammad Alam1 and Harry Atwater1,2; 1California Institute of Technology, Pasadena, California, United States; 2Kavli Nanoscience Institute, California Institute of Technology, Pasadena, California, United States; Department of Photonics, National Cheng Kung University, Tainan, Taiwan.

Tunable metasurfaces enable active control of key constitute properties of light at a sub-wavelength scale. So far, electrically-tunable active metasurfaces in the near-infrared wavelength range have been typically achieved by incorporating active materials, such as tunable plasmonic structures or thermo-optically responsive media, into otherwise passive metasurface structures. To achieve a widely tunable response at low input power and high speeds in active metasurface structures, electro-optical modulation of resonantly excited quantum wells structures can enable strong light-matter interactions by couple of an optical field enhancement in an active material that can also undergo a large DC field modulation. Here, we report an all-dielectric active metasurface platform based on electro-optically tunable III-V multiple-quantum-well (MQW) Mie resonators. In this work, we design an epitaxial III-V compound heterostructure, comprising a distributed Bragg reflector (DBR) and a 1.23 μm-thick MQW layer grown on GaAs substrates. The DBR, which is used as a dielectric mirror, is comprised of 20 pairs of alternating layers of n-AlxGa1-xAs (76.5 nm) and n-GaAs (65 nm) with the n-AlxGa1-xAs as the topmost layer. We exploit the quantum-confined Stark effect in GaAs-based MQW Mie resonators to actively control the optical response of the metasurface phase and amplitude at near-infrared wavelengths. By applying a DC electric field across the Mie resonators, we dynamically modulate modes supported by the Mie-resonant metasurface elements. We experimentally observe a relative reflectance modulation of 270% accompanied with a continuous phase shift from 0° to 70°. In addition, we use our all-dielectric tunable metasurface to demonstrate a dynamically switchable diffraction grating. By selectively applying an electrical bias to metasurface elements, we can electronically modulate the metasurface period, enabling on-off switching of the first-order diffracted beam. We will also discuss how our tunable dielectric metasurface platform can be used for the realization of dynamically tunable ultrathin optical components, such as tunable metalenses, on-chip beam steering devices, active polarizers, and flat spatial light modulators.

References
Refractory nitride plasmonics offer the potential to realize enhanced light interactions for energy harvesting and photo-driven chemistry with materials systems that are thermally rugged, inexpensive, and potentially catalytic. Here, we have embedded commercial and in-house synthesized titanium nitride (TiN) nanoparticles into matrixes of titanium dioxide (TiO$_2$) and compared their ability to enhance electrochemical oxidation reactions to that of conventional gold (Au) nanoparticles. Although the photon-to-carrier conversion efficiencies were low (~10$^{-3}$%), the reaction rates were enhanced by a factor of 4 in the visible and near-infrared for Au and TiN, respectively, compared to a pure TiO$_2$ control. The spectral dependence of reaction rate enhancement followed the nanoparticle extinction spectra and a linear power-dependence identifies a photo-excited carrier mechanism (i.e., decaying plasmons excite carriers which participate in chemistry rather than heating of the system). Lastly, photo-induced transients of the electrochemical signal are found to be consistent with the band structures of these heterosystems. Specifically, the TiN/TiO$_2$ system, which has little or no Schottky barrier, exhibits a bias-dependent photoelectrochemical response rate while the Au/TiO$_2$ system, which naturally forms a Schottky barrier that immediately separates charged carriers, exhibits a near-instantaneous response.

Plasmon Effect Study in Lithium Borate Glasses Doped with Dy$^{3+}$ and Yb$^{3+}$ and Containing Silver Nanoparticles 

In this work, it was synthesized and characterized Lithium Borate Glasses doped with rare earths and containing Silver nanoparticles in different concentrations. The rare earths employed were Dy$^{3+}$ and Yb$^{3+}$. The Scanning Electron Microscope (SEM) show the formation of Silver nanoparticles, absorption spectra of the samples show the presence of bands in 420nm and 450nm associated with the SNP (Plasmon effect), and 750nm, 800nm, 875nm, 1098nm and 1278nm belonging to the Dy$^{3+}$ and one large peak in 976nm belonging to the Yb$^{3+}$. Emission spectra show two prominent bands in 480nm, 574nm, and one faint band in 665nm, all bands under 364nm pumping, and the fluorescence in the 550nm and 590nm spectral range enhanced two bands. It was studied the Plasmon Effect due to the increment of the SNP in the samples.

Colloidal Gold Nanoplate-Based Heterodimers for Charge Transfer Plasmon and Fano Resonances

The fascinating optical properties of noble metal nanocrystals are intriguingly offered by their localized surface plasmon resonances. Hybridized plasmon modes can be produced by placing two plasmonic nanocrystals close to each other. The electromagnetic interaction between the hybridized modes possesses unique plasmonic features, such as electromagnetically induced transparency, Fano resonance, magnetic plasmon resonance, and charge transfer plasmon (CTP). Plasmonic Fano resonance arises from the destructive interference between a broad, superradiant and a narrow, subradiant plasmon mode that overlap spatially with each other. It features an asymmetric non-Lorentzian spectral profile with a narrow transparent window corresponding to the energy of the subradiant plasmon mode. The unique properties of Fano resonance help in revealing the underlying physics in many intriguing phenomena and make it promising for many plasmonic-based applications, such as sensing, plasmonic switching, light slowing and stopping. However, most metal nanostructures cannot only support several Fano resonances with relatively shallow dips in the visible and near-infrared ranges. Second, when the air or vacuum gap between two metal nanoparticles is smaller than ~0.3 nm, the classical electromagnetic framework breaks down and the quantum tunneling effect alters the plasmon coupling behavior substantially. A new CTP mode emerges as a characteristic signature of the interparticle electron tunneling across the junction. However, it has still been challenging to fabricate plasmonic nanocavities with ultrasmall gaps. In this regard, bridging molecular junctions have been introduced to allow electrons to tunnel across the gap with a moderate distance. Nonetheless, the observed CTP has been limited with dipolar plasmon modes.

Colloidal Gold Nanoplate-Based Heterodimers for Charge Transfer Plasmon and Fano Resonances

We have fabricated gold nanoplate (NPL)-nanosphere (NS) heterodimers and observed Fano resonance with a deep dip (Nanoscale 2017, 9, 13222). When a gold NS is attached to one sharp vertex or one edge of a gold NPL on an indium tin oxide (ITO) substrate, a strong polarization-dependent Fano resonance with a deep dip is observed in the scattering spectrum. Under in-plane excitation that is polarized perpendicular to the connection axis between the NPL and NS, the Fano resonance can be “switched off”. In addition, by positioning a gold NS at the top facet of a gold NPL on a silicon substrate, the dipole–octupole interaction between the NS and NPL also gives rise to a deep Fano dip under out-of-plane excitation (Nanoscale 2016, 8, 17645). The dip depth and asymmetric line shape of the Fano resonance possessed in both structures can be well tailored by varying the sizes of the involved nanocrystals. When the gold NS and NPL are separated with a self-assembled monolayer of conductive molecules, electrons are allowed to transfer across the molecular junction. The electron tunneling effect largely modifies the Fano resonance feature in the scattering spectra, as well as the observation of a higher-order CTP. Taken together, these results will be helpful for deepening the understanding of Fano resonance and electron tunneling in plasmon-coupled systems, picturing a promising future in developing various potential applications, including nonlinear and switched metamaterials, displays, nanonanotransistors, optoelectronics, and new types of molecular-plasmonic devices.
resistive in the other directions. To explore the link between the non-local dielectric constant and the heterogeneous electron transfer rate, cyclic voltammetry has been used to observe the rate constant of the heterogeneous electron transfer from Fe$^{3+}$ to Fe$^{2+}$ on a Au surface.

In this report, the dependence of sweep rate on the electron transfer rate and potential on Au surfaces was measured to determine the carrier diffusivity and rate constant for the electron transfer reaction between an outer sphere redox reagent, ferricyanide, Fe(CN)$_6^{3-}$, and gold. Though the surface immediately adjacent to the ferricyanide ion are the same Au film, an enhancement in the electron transfer rate constant has been observed in the vicinity of the metamaterials. This rate constant was observed to six times faster than a single thin gold layer (~25 nm) from which the metamaterial is constructed. This enhanced electron transfer rate constant was also three times faster than thick gold (~200 nm) which is the thickness of the metamaterial stack. Future work will examine the effects of the dielectric constant on the rates of the forward and reverse rate constants.

Ultra-Sensitive microRNA Detection Using Vertically Coupled Plasmonic Nanoantennas Xiahui Chen$^1$, Zhi Zhao$^1$, Jiawei Zuo$^2$, Yu Yao$^2$ and Chao Wang$^2,1$.
$^1$School of Electrical, Computer and Energy Engineering, Arizona State University, Tempe, Arizona, United States; $^2$Center for Photonics Innovation, Arizona State University, Tempe, Arizona, United States.

Early and accurate diagnosis of cancer is extremely important for cancer treatment and improving patients’ survival rate. Liquid biopsy is an emerging approach that detects a panel of biomarkers that are available in bodily fluids, and potentially allows noninvasive diagnostics of a broad variety of cancers. Among the most studied biomarkers, microRNAs (miRNAs, single-stranded oligoribonucleotides) are viewed promising candidates, as they function as both oncogenes and tumor suppressors. The dysregulation of miRNAs has been shown to strongly correlate to the proliferation of cancer cells in various types of cancers. Current major approaches for miRNA detection rely heavily on enzymatic reactions that usually introduce biases, demand special instrument, and require long processing time. On the other hand, plasmonic nanoantennas have attracted considerable attentions due to its ultrahigh sensitivity, design flexibility, label-free detection and low instrument cost. However, miRNAs only have relatively small modulation of refractive index near the sensor surface due to their short sequence (~20 bp, or ~7 nm in length), and hence usually results in small optical signals that is insufficient to accurate diagnosis.

Here we present a vertically coupled complementary structure, consisting of a nanobar antenna and a perforated nanoslit aperture antenna separated by SiO$_2$ nanopillar. This structure has shown a high sensitivity of 1.36 nm shift in detecting assembled 1-octadecanethiol in the mid-IR range (ACS Nano, 2017, 11 (8), pp 8034–8046). In our ongoing work, we design nanoantennas at visible and near-IR wavelength range, and optimize its sensitivity through vertical coupling between the nanobar and aperture antennas and horizontal coupling between adjacent nanobar antennas. Our full-wave simulation shows that the captured miRNA on the sensor surface can lead to ~23-30 nm shift upon miRNA hybridization to DNA probes. In our preliminary experiment, we assembled thiolated single-stranded DNA probes to the sensor surface, and demonstrated 13 nm resonance shift upon miR-10b hybridization at 100 pM concentration, which is comparable to the state-of-the-art research (~8.5 nm at same concentration). Currently we are evaluating the detection limit of the miR-10b on our plasmonic nanoantennas and studying the specificity using different probe designs. We expect to update our results at the conference. Our concept of plasmonic nanosensing can be widely extended to more complex structures and used for multiplexed detection, which have broad applications in early, low-cost, and portable cancer diagnosis.

Hybrid Metal-Dielectric-Metal Structures of Controlled Geometry, Based on Large Area Colloidal Lithography with Metallic Spheres as a Patterning Mask Jusung Park, Sungjin In and Namkoo Park; Seoul National University, Seoul, Korea (the Republic of).

With the recent development of precision lithography such as EBL, FIB, and EUV technique, it now became possible to overcome the stringent requirements of nano-scale offset, high step-coverage and sub-wavelength resolution [1], in the fabrication of nano-photonic structures. These efforts, especially toward visible regimes, have also enabled promising applications such as display [2], antenna [3], color filter [4-5] and information encoding [6-7] over recent years. Nonetheless, in view of the costs, non-scalable, equipment dependent and time-consuming processes involved in the precision lithography techniques, the realization of cost effective, litho-free, and large-area fabrication of nano-photonic structures still remains as a challenge.

In this work, we present a colloidal lithography which uses metallic spheres as a patterning mask, to achieve hybrid metal-dielectric-metal (MDM) structures of controlled geometry in a large-scale. By adjusting the etching conditions between the metal- or dielectric preferential settings, the eccentricity of metal spherical and height of dielectric pillar are adjusted for the fine tuning of coupling strength between the residing hybridized modes, and therefore to deliver significant modulation of the reflection spectra in the visible regime (400nm – 800nm). Control of the full width at half-maximum (FWHM) bandwidth from 50nm to 250 nm, and near-perfect absorption (> 95%) at the resonance wavelength are demonstrated, for future applications in colored light harvestings, anti-counterfeittings and anti-reflecting coatings. As a simplest demonstration, we will present a large-area (> 4 inch) and full gamut color filter, with iridescent response. Our result of large-area, litho-free colloidal metal-particle mask technique will offer a new path in the fabrication of cost-effective and fabrication-friendly, precision nano-photonic devices.

Silicon Surface Nanotexturization with Diffraction Gratings via Metal-Assisted Chemical Imprinting Aliaksandr Sharshenous, Stanislau Niazuorazh, Michael Gregory, Vijay Pentapati, Jasmina Markovski and Bruno Azzeredo; Arizona State University, Mesa, Arizona, United States.

Metal-assisted chemical imprinting (MAC-imprinting) is a combination of metal-assisted chemical etching (MACE) and nanoimprint lithography (NIL) that can selectively etch arbitrary and complex 3D microscale features in silicon wafers such as parabolas, parabolic cylinders [1], inverted pyramids [2], rectangular grooves and holes [3]. The patterning resolution of this process can be controlled by varying etching parameters such as solution composition or external bias [4] down to the sub-5 nm range. Thus, this process can deliver mirror-finish surfaces suitable for manufacturing of optical elements such as lenses and gratings in which low surface roughness is critical. In this paper, we demonstrate MAC-imprinting of diffraction gratings onto Si wafers and examine the pattern fidelity and roughnesses across stamp and substrate. MAC-imprinting stamps consisting of patterned SU-8 with periodic linear grooves were prepared using UV-NIL. Patterned SU-8 was then coated with a Cr adhesive layer and an Au catalytic layer by magnetron sputtering, and used in MAC-imprinting of p-type low-doped (100) Si wafer. Visual examination of imprinted Si chips revealed surfaces exhibiting diffraction pattern similar to its corresponding stamps. Analysis of SEM data determined a width of 0.54 μm and period of 902 nm of the imprinted groove corresponding to the same values of stamp features. According to AFM-analysis surface roughness of the grooves was approximately 18 nm (RMS) matching the surface roughness of the MAC-imprinting stamp features. Thus, the origin of the roughness was attributed to the grain size of the sputtered Au layer rather than to the MAC-Imprint process itself. As a result, MAC-imprinting of diffraction gratings onto Si surface was successfully performed and the imprinted groove’s width, period and surface roughness was found to match the corresponding values of the imprinting stamp. This result serves to validate the use of MAC-imprinting to fabricate optical elements with superior quality.

Plasmon-Enhanced Emission and Quenching of Metallic Emitters Soheila Mashhadi1, Maxim Durach2, David Keene1 and Natalia Noginova1; 1Norfolk State University, 2Center for Nanoscale Materials, Argonne National Laboratory, 3Department of Physics and Astronomy, North Carolina State University.
Possibility to control spontaneous emission via modified optical environment provides new opportunities for magnetic dipole transitions, which are commonly very weak in comparison with electric transitions. We discuss various approaches for enhancing magnetic transitions. In particular, we concentrate on effect of propagating surface plasmon polaritons on emitters located in very close vicinity of plasmonic metal. In comparison with electric dipoles, magnetic emitters have lower quenching, and practically the same efficiency of SPP excitation. This prediction is confirmed by experiment using spontaneous emission of Eu³⁺ ions at magnetic dipole and electric dipole transitions.

EP12.03.13
Design of Ultrawide Bandwidth Electromagnetic Wave Absorbers Using Frequency Selective Surfaces with Different Patterns and Geometries

With the increased use of electronics over the broad frequency spectrum from microwaves to millimeter waves, high-performance absorbing and shielding materials are needed to ensure electromagnetic wave control and compatibility. Acquisition of wide bandwidth absorption with a planar layer and a small layer thickness has been a major challenge for commercial and military applications. Unfortunately, it is a difficult task to achieve both bandwidth enhancement and thickness reduction simultaneously because of an inverse proportional relationship among the bandwidth, thickness, and reflectance of the absorbers. In this study, the design of a thin and ultra wide-bandwidth microwave absorber has been conducted by layering two frequency selective surfaces (FSS) with different patterns (square loop, patch) and geometries on the grounded dielectric substrate. The circuit parameters of inductance and capacitance of the FSS are retrieved using the equivalent circuit model and utilized in the design of the wide-bandwidth absorber. Optimal design for the surface resistance of the FSS and spacer thickness of the double-layer absorber provides very large absorption bandwidth and small total thickness (for FSS of square-loop geometry, for instance, 10 dB bandwidth is 5.2 – 38.3 GHz and total thickness of the absorber is 6.3 mm, which is very close to the theoretical limit). Admittance analysis for substrate (layer thickness) and FSS (patterns, geometries) is made for the design scheme of the ultrawide bandwidth absorber. The free space measurement result with a test sample prepared by the screen printing method was in good agreement with the simulation result and strongly verified the validity of proposed design method. For these periodic array structures, however, the grating lobe or high frequency harmonics were observed in the high frequency region above which the unit cell periodicity is larger than the wavelength, and as the incidence angle increased, the grating lobe occurred at a lower frequency for both TE and TM polarization. The unit cell periodicity must be controlled in the periodic array structure, particularly for large oblique incidence angles.

SESSION EP12.04: Composites and Metastructures

Quantum Emission and Nonreciprocal Optical Transmission in Deeply Subwavelength Systems

A revolution in materials discovery has yielded a diverse portfolio of new classical and quantum photonic materials. In particular, a variety of two-dimensional layered architectures can be crafted with structural precision approaching the atomic scale. In parallel, advances in nanophotonics, plasmonics, and metamaterials have enabled precise control of light-matter interactions down to the nanoscale. By combining concepts from both of these young and rapidly developing fields, there is now an opportunity to create phononic matter where optical properties are tailored to attain thermodynamic limits. Here, we present our research exploring ultrathin nanostructured materials and metamaterials for bright quantum emission and nonreciprocal optical transmission. First, we correlate the local atomic structure of color centers in van der Waals materials with their optical emission at a single defect level. We use transmission electron microscopy and cathodoluminescence spectroscopy to investigate color centers in two-dimensional hexagonal boron nitride. This wide bandgap material is capable of room-temperature, high-brightness visible quantum emission, though the atomic structure of color centers remains unknown. Through high-resolution spatial maps, we find that multiple quantum emitters reside within a ~100nm region, each contributing slightly distinct spectral signatures. Defects are found in locations usually associated with regions of high strain and dislocations. Through correlation of cathodoluminescence to photoluminescence, we show that two classes of emitters exist, including charge neutral and charged emitters. Importantly, all are stable upon multiple exposures to the electron beam.

Next, we introduce nanophotonic designs that enable nonreciprocal transmission of visible and near infrared light within subwavelength optical paths. We show that the Kerr effect, in which the refractive index depends on the local light intensity, can produce passive directional transmission. In this case, slight structural asymmetries lead to a directionally dependent field enhancement and, consequently, a directional Kerr shift of the resonant dip. We achieve nonreciprocal transmission for silicon films as thin as 100nm with incident powers of a few kW/cm². We additionally show a nonreciprocal Kerr shift in a phase gradient metamaterial, making nonreciprocal beamsteering and lensing possible. This platform enables time-reversal-symmetry breaking for arbitrary free-space and modal optical inputs in a simple, robust materials platform, with potential for creating nanoscale optical diodes and photovoltaic devices that violate Kirchhoff’s law.

9:00 AM EP12.04.02
Towards Compact Infrared Adaptive Optics by Local Tuning of Nanophotonic Structures Enabled By Phase-Change Materials

Despite their nanometer thickness, metamaterials comprised of resonant metallic or dielectric nanostructures offer comprehensive control over light fields and allow for the creation, detection and transformation of light. Often, their optical functionality is only obtained at a fixed wavelength, determined by the geometric design and the material properties. For optimal functionality, they need to be freely programmable and have low optical losses. Phase-change materials (PCMs) provide a switchable dielectric environment for resonant nanostructures, altering their resonance frequencies in a non-volatile, reversible way. PCMs have a high optical contrast between their amorphous and crystalline phases, while only exhibiting low optical losses in the infrared [1,2]. Using PCMs for active metasurfaces offers adjustable, designed functionality for manipulation of light. Among recent examples are polarization filters [3], beam steers and lenses [4]. During crystallization of the PCM on a hot plate, intermediate states of the PCM have also been exploited to obtain gradual resonance shifts [5,6]. These shifts due to partial crystallization are uniform over the whole metamaterial and usually described by effective medium theory.

We now show how we can simultaneously control the size, position and crystallization depth of the switched phase-change volume within each meta-atom to selectively tune its optical properties. By using visible light for switching an infrared metamaterial, we could modify the PCM phase on length scales which are smaller than the size of a meta-atom. When combining this with present designs for infrared metamaterials, it will become possible to program the reflection amplitude and phase of each individual meta-atom. This goes beyond effective medium concepts, especially when accounting for the spatially localized electric near-fields of nanoantennas in the meta-atoms. With the proposed concept, it should be possible to actively impart multiple complex functionalities onto the same metasurfaces or to make small adaptations to correct external aberrations and fabrication errors.

Copper and Aluminum Island Films as Plasmonic Structures for Solar Energy Conversion

Chalcogenide Phase-Change materials (PCMs) exhibit high magnetic-optic contrast between their amorphous to crystalline states. The switching between such states can be quickly and reversibly controlled on demand, by making use of different heat stimuli such as electrical, thermal or optical pulses [1]. For the last couple of decades, PCM applications have been therefore focused on the development of non-volatile electrical and optical memories [2]. More recently, however, PCMs have attracted much interest as a tunable element in plasmonic optical metasurfaces [3, 4], due to the fact that PCMs have very different refractive indices when in amorphous and crystalline states, but can also provide intermediate crystallization levels having optical properties lying between those of the two structural phases. In this work, therefore, the potential of phase-change “meta-devices” is illustrated via the introduction of various device prototype concepts in which the state (fully-crystalline, partially crystalline or fully amorphous) of the PCM layer can be used to control device functionality.

As a first example, by appropriately combining plasmonic metasurfaces with the well-known phase-change alloy Ge2Sb2Te5, we have developed a dynamic beam steering meta-device working in the near infrared (specifically at λ = 1550 nm). As a second proof-of-concept, we demonstrate that thin films made of GeTe (another widely employed PCM), can be used to create broadband amplitude-only modulators in the visible regime. In such devices, the amount of light reflected can be controlled via changing the fraction of crystallization of the GeTe active layer, without introducing any optical phase shifts during the process (i.e. we can create an amplitude-only modulator). Finally, we show that optical phase manipulation is also possible over a 2π range, by combining novel low-loss PCMs (here Sb2S3) [5] with all-dielectric asymmetric Fabry-Perot cavity inspired metasurfaces [6]. Our approach here consists of arrays of geometrically identical elements (or meta-atoms) where the optical phase can be locally tuned between 0 and 2π at a wavelength of λ = 850 nm (commonly used in biomedical diagnostics) by changing the level of crystallization Sb2S3 in a pixelated device.

We believe that PCM-based metasurfaces and meta-films, such as the ones presented here, could be well-suited for many exciting applications, such as optical telecommunications, LIDAR scanning systems, autonomous vehicles, reflective displays, holography or wavefront shaping in biological tissues.

that Cu and Al metal island films can represent an efficient low-cost platform for certain plasmonic applications such as solar energy harvesting.

This talk will review our recent work on exploring functional plasmonics (i.e., switching, plasmonic Coulomb blockade) achieved in subnanometer gaps at the transition point towards tunneling. This is an ultra-sensitive plasmonic platform, akin to the metal-insulator transition achieved bulk materials like vanadium dioxide; however, subnanometer gaps provide a designer-based approach to switching.

I will also discuss our recent work on dual-wavelength upconversion and upconversion from single upconverting nanocrystals trapped optically within an aperture in a metal film. We demonstrate that tuning the aperture dimensions can have a massive impact on the upconversion detected.

**11:15 AM EP12.04.08 Inkjet-Printing of Plasmonic Reflective Displays** Samim Sardar, Pawel Wojciech and Magnus Jonsson; Laboratory of Organic Electronics, Linköping University, Norrköping, Sweden.

Plasmonic color generation have attracted tremendous interest in recent years as a solution for ink-free color printing. The prominent advantages of plasmonic coloration are better robustness compared with organic dyes while also providing high chromaticity and brightness. However, use of costly nanofabrication techniques to make reflective displays restricts potential applications and production of functional devices. Here, our aim is to generate plasmonic structural colors at high resolution using inkjet printing, which is scalable to large areas and avoids complicated fabrication steps. Our plasmonic metasurfaces contain three solid films on flexible plastic substrates. A silver film (~500 nm) was first inkjet-printed on the substrate to provide a high base reflection. Then an organic material was printed as a dielectric spacer layer with varying thicknesses to tune the reflective color by Fabry–Perot interference. A semi-transparent plasmonic top mirror completes the cavity and also improves color generation via wavelength-dependent plasmon absorption. Here, I will present our work towards facile fabrication of structural colors and discuss our results based on reflectivity measurements of red, green and blue pixels using micro-spectroscopy. We believe this inkjet printing process has the potential to generate reflective displays with high resolution, low cost, flexibility and compatible with large-scale production.

**11:30 AM EP12.04.10 Nonnegative Quadratic Programming Optimization of Focused Ion Beam Fabricated 3D Nanostuctures for Structural Colors** Vivek Garg1, 2, 3, Rakesh Mote2 and Jing Fu1;1 IITB Monash Research Academy, Mumbai, India; 2Indian Institute of Technology Bombay, Mumbai, India; 3Monash University, Melbourne, Victoria, Australia.

Structural colors, originated from interaction of visible light with subwavelength nanostructures, offer high spatial resolution color printing, beating fundamental resolution limit of a light field optical microscope. Such structural colors, arising from resonant scattering of light from subwavelength nanostructures, can be printed at resolutions as high as ~100,000 dots per inch (DPI). A variety of design, methods have evolved over the years for structural color generation and color printing at optical diffraction limit of light1. A novel approach, utilizing focused ion beam (FIB) direct fabrication of high-index silicon (Si) 3D photonic nanostructures for multicolor generation with enhanced color purity and high resolution color printing applications was recently developed2. Although successful, the systematic variation of geometrical parameters for tuning of color performance can be quite cumbersome sometime and require significant time and experiments, and does not necessarily allow tailoring the chromatic response in an optimal way prior fabrication. In this work, a general framework for optimization of photonic nanostructures for multicolor generation is presented. The design of photonic nanostructures for desired color printing is optimized numerically through the formulation of a nonnegative quadratic programming problem. This problem is solved by an iterative approach based on multiplicative updates algorithm3 for an optimal solution of ion beam dwell time maintaining high accuracy. The optimization algorithm is aimed at minimizing the deviation of a simulated geometry by FIB fabrication from the desired geometry of photonic nanostructures for color printing. The optimization algorithm for Si photonic nanostructures to develop structural color printing is further coupled with electromagnetic simulations based on finite-difference time-domain (FDTD) calculations. The chromatic response of periodic subwavelength nanostructures is calculated using FDTD simulations. The numerical results show that this hybrid approach is a versatile tool for the design of photonic structures for multicolour generation, which can be extended for different design and application perspectives. In summary, this work provides a general framework for design and optimization of photonic nanostructures for multicolor generation. This will enable automatic design of photonic nanostructures for high resolution structural color printing applications with ion beams. The possible ways to expand the color gamut and improve the color performance of such photonic color filters on CIE 1931 (Commission Internationale de l’Eclairage) color space will be further discussed. Finally, such optimization of photonic nanostructures is not just limited to structural color printing and has tremendous potential for future optics offering unique opportunities for optical security, polarimetry, spectral imaging applications etc.

(2) Garg, V.; Mote, R. G.; Fu, J. Focused Ion Beam Direct Fabrication of Subwavelength Nanostructures on Silicon for Multicolor Generation. Advanced Materials Technologies 2018, 3 (8), 1800100.

An idea “to marry” silicon as a semiconductor material with noble metals to fabricate a highly ordered plasmonic nanostructures has been an obsessive dream of specialists in metamaterials for photonics, surface enhanced vibrational spectroscopy, optoelectronics, etc. Porous silicon is one of the most favorable materials to achieve this objective as it can be used as a tool for integration with silicon technology. Metamaterials must have an ordered periodical structure. However porous silicon, which is traditionally formed by an electrochemical etching of monocryrstalline silicon, is typically characterized by a significant deviation of geometrical parameters of pores up to 50%. This leads to non-reproducibility of morphology of plasmonic nanostructures depositing on such porous material. In present paper, we developed a novel metal-assisted electrochemical method to obtain extremely ordered structure of mesoporous silicon with pore diameter deviation less than 10%. Following deposition of thin films of coinage metals was shown to provide a formation of so-called plasmonic nets composed of periodically crossing nanowires. Simulation of an electric field in the cavities of these nets showed its localization in the pore mouths due to strong rim component. It is proposed to use the profit of this component in the surface enhanced Raman-scattering (SERS) spectroscopy to detect and study analytes at submolar concentration down to the single molecule level. To place analyte species in the pore mouth we used sandwich film of graphene-test molecule-graphene covering the plasmonic net. Graphene was found to play a role of support for analyte molecules and a protection for heat sink induced by laser excitation. In addition to the improved plasmonic properties of the coinage metals organized into net on modified mesoporous silicon, the paper also presents a description of changes in magnetic and catalytic properties of other metals deposited on the developed template.

**2:00 PM EP12.05.02 Localized Surface Plasmon Modes in Nanoparticle Arrays and Dimers** Viktoria Babicheva, John Nehls, Jerome Molenoy, Aoxue Han and Colm Dinneen; College of Optical Sciences, The University of Arizona, Tucson, Arizona, United States.
Plasmonic nanostructures can significantly enhance electric and magnetic fields at nanoscale dimensions. Fields localized in the narrow gaps of plasmonic nanostructures can be several orders of magnitude higher than the incident light field, and this field enhancement strongly affects light-matter interaction processes in plasmonic nanostructures. Here, we study field enhancement in nanoparticle dimers and analyze surface plasmon amplification by stimulated emission (spaser) in the dimer gap. We consider both sphere and disk silver nanoparticles and employ finite-difference time-domain simulations for modeling field enhancement in the dimer.

Our in-house finite-difference time-domain (FDTD) method includes non-uniform, geometry-specific, semi-conformal meshing of the nanostructures and enables accurate resolution of electromagnetic ‘hot spots’ in the nanoparticle gap without parasitic staircasing. Our technique allows for FDTD simulation of fully-anisotropic permittivity and permeability material tensors. Semi-conformal meshing is enabled by placing grid boundaries along the surfaces of devices in critical areas and Maxwell’s equations encapsulating a coordinate transformation into the material tensors.

Using this approach, we numerically observe gap modes with even and odd field distributions within the 10-nm dimer gap and identify spatial regions with nodes and anti-nodes of the field enhancement. We use quantum density matrix (optical Bloch) equations for the spacer, calculate the plasmon amplification in the gap, and show its correspondence to the total mode characteristics. Because of the strong field enhancement in the gap, amplification of plasmons in a nanoparticle dimer is more efficient than ones in the proximity to a single nanoparticle and can be used as an ultra-compact light source in optical devices and medical applications.

3D Nanocrystal/Bulk Heterostructures with Giant Chiroptical Properties
Jaeck Guo1, Mingliang Zhang1, Ji-Young Kim1, Aaron Stein2, Nicholas Kotov3, Christopher Murray1 and Cherie R. Kagan4, 1Materials Science and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 2Electrical and Systems Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 3Materials Science and Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 4Brookhaven National Laboratory, Upton, New York, United States.

We report a novel fabrication method that exploits the differential chemical and mechanical properties of colloidal nanocrystals (NCs) and bulk materials to transform 2D bilayer heterostructures into 3D architectures by design. Colloidal NCs are hybrid systems, composed of inorganic cores and organic ligand shells, which make their surfaces chemically addressable and their assemblies mechanically soft. Using ligand exchange methods, bulky ligands that originally stabilize as-synthesized NCs are replaced by more compact ligands within a few minutes. Ligand exchange triggers a large volume shrinkage in NC assemblies, and in bilayer NC/bulk heterostructures generates a large misfit strain that drives bending. Following this strategy, we establish a set of design rules to create various 3D, cell-sized superstructures. These 3D structures may be harvested from surfaces and suspended in solvents or they can remain bound to surfaces. By choosing different colloidal NC building blocks, we demonstrate the versatility of this technique to create 3D structures with unique optical and magnetic physical properties. For example, we apply the design rules to construct 3D metasurfaces with giant chiroptical properties.

Spectroscopic Nanotransducers for Infrared Sensing Applications
Tadaaki Nagao1, 2; 1National Institute for Materials Science, Tsukuba-city, Japan; 2Department of Condensed Matter Physics, Hokkaido University, Sapporo, Japan.

Wavelength-selective light absorbers and emitters, or spectroscopic energy transducers for light, are expected to provide wide variety of applications in energy harvesting, remote sensing, and label free bio-sensing. By utilizing the strong near field of optical antennas and metamaterials, strong signal enhancement of molecules becomes operative to realize high sensitivity vibrational sensing. Recent developments in infrared plasmonic materials, nanostructure fabrication techniques, as well as their surface functionalization techniques have enabled us to propose and fabricate various types of advanced nano-sensing devices. In this talk, we exemplify the detection of tiny amount of molecules by surface-enhanced infrared absorption spectroscopy, using Au infrared antennas and metamaterials. We also introduce our new approach utilizing infrared surface plasmons in optical antenna array made of phosphonic acid-functionalized ITO nanorods to detect proteins with high specificity and sensitivity. In the latter half of the talk, we introduce some of our recently developed uncooled infrared sensors combined with spectroscopic perfect absorbers for wavelength-selective infrared ray detection. The MIM metamaterial IR sensors with pyroelectric detection as well as thermoelctric detection exhibit resolutions better than 1um with wide acceptance angles. By adopting Gires-Turnmois structure with plasmonic metals, the wavelength resolution goes lower than 50 nm at resonance wavelength of 3-4 um. Such structures also shows sharp thermal emission when it is fabricated with low-loss materials and heated at high temperatures. These devices will open a new avenue for potential applications in multiband temperature sensing, infrared-color imaging for material sensing, and NDIR gas sensors for security gas sensors and combustion analysis.

Spectroscopy, Characterisation and Applications of Plasmonic Sodium Tungsten Bronze Nanoparticles
Levi Tegg1, Dylan Cuskelly2 and Vicki J. Keast1; 1School of Mathematical and Physical Sciences, University of Newcastle, Callaghan, New South Wales, Australia; 2School of Engineering, University of Newcastle, Callaghan, New South Wales, Australia.

The noble metals, particularly Au and Ag, are widely used as plasmonic materials. Although Au offers terrific chemical stability and several options for nanofabrication, it suffers from relatively high plasmon damping losses. In contrast, Ag has very strong plasmon resonances but corrodres under ambient conditions, limiting device lifetimes. The limitations of Au and Ag has fuelled the search for alternative plasmonic materials.

The sodium tungsten bronzes (Na2WO4) are sub-stoichiometric metal oxides with variable Na content, 0 ≤ x ≤ 1. Above x > 0.3, the intercalated Na donates its 3s electron to the WOx conduction band, giving Na2WOx metallic electrical and optical properties which vary with the Na content. From electron energy-loss spectroscopy (EELS) studies, Na2WOx has been shown to support strong bulk plasmon resonances which blueshift with increasing x, from near-infrared to visible frequencies. However, characterisation of localised surface plasmon resonances (LSPRs) has been limited due to the lack of fabrication techniques for Na-rich (x > 0.5) nanoparticles.

Here, we demonstrate the synthesis of Na2WOx nanoparticles across 0.41 ≤ x ≤ 0.83 using a high-temperature method. Results from ex-situ and in-situ diffraction techniques provide insight into optimising the synthesis procedure to minimise the particle size of the products and to maximise phase-purity. Spectrophotometry and spatially-resolved EELS are used to investigate the plasmonic properties of Na2WOx. Strong LSPRs are observed which increase in frequency with x, similar to the variation in the bulk plasmon frequency. Experimental results are supported by simulated responses, which are calculated using the boundary element method (BEM).

Based on experimental and calculated responses, potential applications in solar control filtering, plasmon-assisted photovoltaics and plasmonic photocatalysis will be discussed. Given their high chemical stability, simple nanoparticle fabrication and tunable optical properties, we show that the sodium tungsten bronzes are promising alternative materials for plasmonics.

4:15 PM EP12.05.06
Non-Resonant Enhancement of Second-Harmonic Generation in a Dielectric Micro/Nano-Hybrid Particle with a Nonlinear Metamaterial Shell
Joong Hwan Bahng1, Douglas G. Monjoy2, Saman Jahani3, Nicholas Kotov4 and Alireza Marandi5; 1California Institute of Technology, Pasadena, California, United States; 2Chemical Engineering, University of Michigan, Ann Arbor, Michigan, United States;
Nanoscale particles are a promising class of materials for optical nonlinear conversion because of the strong field localization and the phase-matching-free conditions. While their utilities are envisioned in a spectrum of applications, a general layout to achieve and enhance nonlinear conversions is barren. The Mie and plasmonic resonances have been utilized in nano-scale particles to enhance the nonlinear response, especially the second-harmonic generation (SHG). While showing great promises, geometrical and bandwidth constraints in resonant enhancement, as well as loss and synthetic complexities in embedding plasmonic constituents impose challenges. In this study, we experimentally demonstrate an approach to achieve and enhance optical nonlinear conversion through a non-resonant dielectric particulate platform. The platform is based on a dielectric microsphere with a nonlinear nano-structured shell. The shell operates as a metamaterial-based impedance matching interface between the input light and a photonic jet and, at the same time, forms the material basis for the nonlinear wavelength conversion. We have adopted variants of the ‘hedgehog’ particles, which comprise an array of high-aspect ratio ZnO nano-spikes arranged orthogonally onto a silica microscope of 1 mm in diameter. The sub-wavelength arrangement of these nano-spikes forms a spherical metamaterial shell exhibiting a radically graded effective index. Such a configuration effectively confines the incident light into a strong photonic jet within the shell, which is made of a well-known ε0/3 material, thereby significantly enhancing the SHG signal compared to a flat array of similar nano-spikes. In addition, due to the non-resonant nature of the nonlinear conversion, following advantages are further conceived: 1) relaxation of the geometrical constraints in the construction of the metamaterial shell, 2) broadband wavelength tuning, 3) lower sensitivity to angle of incidence and polarization and 4) directional scattering of the SHG signal. We have experimentally observed strong enhancements of SHG in a variety of ‘hedgehog’ particles. Through the FDTD simulations, we observed strong enhancement of the SHG conversion efficiency in ‘hedgehog’ particles having 300 ZnO nanospikes whose geometrical features do not coincide within the resonant conditions. The simulations revealed 6×10^8-fold enhancement in the SHG efficiency compared to a single ZnO spike. The demonstrated concept of enhanced light to heat and enable highly specific drug delivery combining photothermal therapy with chemo and immunotherapy for enhanced treatment outcome in highly aggressive breast cancer.

8:00 AM *EP12.06.01
Exciton-Plasmon Coupling at Plasmonic Surfaces and Implications for Thin-Film Optoelectronics Deirdre O’Carroll1, 2, 3; 1Materials Science and Engineering, Rutgers University, Piscataway, New Jersey, United States; 2Chemistry and Chemical Biology, Rutgers University, Piscataway, New Jersey, United States; 3School of Physics, Trinity College Dublin, Dublin, Ireland.

Excitonic semiconductor thin films are emerging as next-generation active layer materials in optoelectronic devices used for display, solid-state lighting, laser and energy harvesting applications. However, active layer thicknesses in these devices are typically limited to 200 nm or less due to limited charge carrier diffusion lengths in excitonic semiconductor materials. Therefore, light management and localization in excitonic semiconductor thin films requires manipulation of light below the diffraction limit. As a result, to improve energy conversion efficiency in excitonic semiconductors, light manipulation using plasmonic structures integrated with the thin film excitonic material is of interest.

Here, our work on improving light trapping, light extraction and stimulated emission in excitonic organic semiconductor thin films using a variety of plasmonic metasurfaces will be presented. Numerous optical phenomena, such as absorption induced scattering, out-of-plane waveguiding and morphology-dependent surface plasmon outcoupling, are identified due to exciton-plasmon coupling between the organic semiconductor and the plasmonic metasurface. Interactions between localized and propagating surface plasmon polaritons and the excitonic transitions of a variety of organic conjugated polymer materials will be discussed and ways in which these interactions may be optimized for particular optoelectronic applications will be presented. Furthermore, our recent studies on the impact of exciton-plasmon coupling on stimulated emission from thin-film spasers will be presented.

Large Area Asymmetric Plasmonic Crystals Fabricated via Nanoimprint Lithography and Tilted Angle Metal Deposition Cristiano Matriardi, Juan Luis Garcia-Pomar, Maria Isabel Alonso and Agustín Mihí; Nanostructured Materials for Optoelectronics and Energy, Instituto de Ciencia de Materiales de Barcelona, Bellaterra, Spain.

Asymmetric and chiral plasmonic nanostructures have been widely used in the past to study the evolution of chirality as a function of geometrical parameters1, 2, 3. In particular, ordered arrays of asymmetric nanostructures can be designed to allow the interaction of surface plasmon polaritons (SPPs) with localized surface plasmons (LSPs) and increase the chiroptical effect4, 5. These emerging plasmonic architectures are pushing the limit of nanofabrication toward new approaches, such as multi-step e-beam lithography4 and colloidal nanohole lithography5. However, the development of low-cost, high throughput and large-area manufacturing techniques still remain a challenge in this field, especially for systems working at optical wavelengths.

We present a straightforward method to produce large area asymmetric plasmonic crystals with a sub-micrometer periodicity that shows intense polarization dependent resonant modes at optical wavelengths. Full control of the geometry allows us to fabricate different structures with gradual loss of symmetry along the 3D axis. The core fabrication process involves a first soft-lithographic nanoimprinting of photocurable resist followed by tilted metal deposition. Concretely, samples with a square array of holes with a pitch length of 500 nm were mounted on a tilted sample holder (0°, 20°, 45°). At a glancing angle, silver was deposited onto the pattern resulting in arrays of asymmetric plasmonic nanostructures. Reflectivity measurements, together with FDTD numerical simulations, unveil the degeneration of resonant modes due to the loss of symmetry and allow us to understand the physics underlying them. We demonstrate fine tunability of the resonant modes and polarization dependent photoluminescent enhancement of organic dyes.

Cancer Diagnosis and Response to Treatment with Plasmonic Nanoprobes Rizia Bardhan; Vanderbilt University, Nashville, Tennessee, United States.

In the past two decades, plasmonic nanostructures have gained tremendous interest as both diagnostic and therapeutic agents for cancer detection and treatment. In this talk I will show the utility of gold nanostar probes designed in my lab for rapid and noninvasive detection of multiple immunomarkers of cancer to enable patient selection for immunotherapies, as well as response to treatment after immunotherapy. We combined a clinical and pre-clinical imaging technique, positron emission tomography with surface-enhanced Raman spectroscopy (ImmunoPET-SERS) in vivo by labeling gold nanostars with radiolabels, Raman reporter molecules, and targeting antibodies. Multimodal ImmunoPET-SERS seamlessly integrates depth-resolved whole-body imaging and high sensitivity of PET with high spatiotemporal resolution and multiplexing of SERS providing dynamic immunomarker profiling in vivo. Further, we determined the immunomarker status of mice treated with combinatorial immunotherapy with ImmunoPET-SERS and demonstrated real-time feedback of CD8+ infiltration in tumors which was confirmed with IHC. Enhanced Raman spectroscopy (ImmunoPET-SERS) exhibits a radially graded effective index. Such a configuration effectively confines the incident light into a strong photonic jet within the shell, which is made of a well-known ε0/3 material, thereby significantly enhancing the SHG signal compared to a flat array of similar nano-spikes. In addition, due to the non-resonant nature of the nonlinear conversion, following advantages are further conceived: 1) relaxation of the geometrical constraints in the construction of the metamaterial shell, 2) broadband wavelength tuning, 3) lower sensitivity to angle of incidence and polarization and 4) directional scattering of the SHG signal. We have experimentally observed strong enhancements of SHG in a variety of ‘hedgehog’ particles. Through the FDTD simulations, we observed strong enhancement of the SHG conversion efficiency in ‘hedgehog’ particles having 300 ZnO nanospikes whose geometrical features do not coincide within the resonant conditions. The simulations revealed 6×10^8-fold enhancement in the SHG efficiency compared to a single ZnO spike. Metamaterials and Metasurfaces for Narrowband Rejection Filters

9:00 AM

Polycrystalline VN, NbN and TaN films and their plasmonic performance. In a final effort to generalize these results we extend this study to point defects have more crucial consequences to the plasmonic performance of TiN than the extended defects; as a result, an effective strategy to grow efficient plasmonic TiN is to use intense irradiation conditions that anneal the point defects out of the grains, albeit in expense of grain size. In a final effort to generalize these results we extend this study to polycrystalline VN, NbN and TaN films and their plasmonic performance.

We show that relying exclusively on XRD for the evaluation of crystalline quality of TiN may be misleading. Indeed, the combined XRD-XPS-Raman results clearly show that the Fermi level that trap electrons and enhance the dielectric losses, as shown by previous ab initio calculations. For some conductive nitrides, like TaN, MoN and WN, point defects were reported to form spontaneously as a mechanism of stabilization of epitaxial films. In order to identify the effects of point and extended defects we provide a detailed study of the optical properties and plasmonic behavior of a wide range of polycrystalline and heteroepitaxial TiN films as measured by ellipsometry in the broadband range of 190-40000 nm. These films have varying crystallographic features and chemical composition and were grown by reactive magnetron sputtering at various temperatures and irradiation conditions. The crystallographic features are studied by X-Ray diffraction (XRD) at various geometries (Bragg-Brentano, Phi-scans, Rocking Curves), the chemical composition by X-Ray Photoelectron Spectroscopy (XPS) core level spectra, the point defects by Raman spectroscopy, and the electron density of states (EDOS) by valence band XPS spectra. We show that relying exclusively on XRD for the evaluation of crystalline quality of TiN may be misleading. Indeed, the combined XRD-XPS-Raman results clearly show that the point defects have more crucial consequences to the plasmonic performance of TiN than the extended defects; as a result, an effective strategy to grow efficient plasmonic TiN is to use intense irradiation conditions that anneal the point defects out of the grains, albeit in expense of grain size. In a final effort to generalize these results we extend this study to polycrystalline VN, NbN and TaN films and their plasmonic performance.

9:30 AM

Hybridized Plasmonic Gap Mode in Gold Nanorod on Mirror NANOantenna for Spectrally Tailored Emission Enhancement

Hiroshi Sugimoto and Minoru Fujii; Kobe University, Nada Kobe, Japan.

Plasmonic nanoantenna offers the ultimate spatial control over electromagnetic waves by localizing the optical energy in the nanoscale and has significant potential for the nanophotonic applications utilizing enhanced light matter interactions. A nanogap structure in particular have an extremely small mode volume and a large field enhancement and a resultant large Purcell factor. However, formation of a sub-10 nm gap with an accuracy of ~1 nm is still challenging even by the state-of-the-art lithography techniques. Recently, plasmonic nanoparticle on mirror antennas in which a metal nanoparticle (NP) is placed on a metal film via dielectric spacer have shown the great potential in nanophotonic applications.[1,2] The structure can be fabricated by a bottom-up process using colloidal gold and silver NPs with a sub-10 nm gap. However, in spherical NP on mirror structure being studied experimentally, the degree of freedom of the antennas in terms of spectral and polarization control is limited. In this work, we report spectral shaping and polarization control of Purcell-enhanced fluorescence by the gap plasmon modes of an anisotropic gold (Au) nanorod on a mirror (NRoM) antenna.[3] We first simulate the property of the resonant modes under different excitation conditions. Systematic calculations demonstrate the richer resonance behaviors of a NRoM antenna than a spherical NPoM antenna due to the hybridization of the bright and dark modes driven by the structural anisotropy. We fabricate a NRoM antenna by placing a Au NR on an ultra-flat Au film via a mono- and multi-layers of light emitting quantum dots (QDs) (~3 nm in diameter). The experimentally measured resonance spectra of single NRoM antennas agree quite well with those of the numerical simulations. We demonstrate large enhancement (~900-fold) and shaping of the luminescence spectrum from QDs in the gap due to the coupling with the hybridized mode of a NRoM antenna. We also show that the polarization property of the emission is controlled by that of the mode coupled. These findings provide novel insights for the design of spectroscopy-based sensing and imaging at the single nanometer scale using the nanoantenna-enhanced emission enabled by hybridized plasmonic modes.

9:45 AM

Atomically- Thin Tunable Exciton Lens

Jorik Van de Groep, Jung-Hwan Song and Mark L. Brongersma; Geballe Laboratory for Advanced Materials, Stanford University, Stanford, California, United States.

Since the development of diffractive optical elements in the 1970s research has focused on replacing bulky optical elements such as lenses and gratings by thin counterparts. Over the last decade, nanoepitaxial metasurfaces rapidly advanced the development of flat optical elements based on the realization that resonant optical antenna elements enable local phase control. Present applications of metasurface flat optical elements include lenses, polarization control, and beam steering.

Next-generation applications of flat optics require dynamic control over optical functionalities, e.g. the focal position or efficiency of optical elements. However, most nanoepitaxial structures are static after design and fabrication. Current approaches for dynamic control like electrical gating exhibit limited tunability due to the finite few-nm extent of the depletion and accumulation layers as result of coulombic screening.

Here, we demonstrate actively-tunable and atomically-thin optical lenses by carving them directly out of monolayer transition-metal dichalcogenides (TMDs) like WS2 with a strong excitonic resonance in the visible spectral range. This turns the 2D material into the antenna or metamat material and incorporation of active materials into larger antenna structures will no longer be needed. Due to their sub-nm thickness, these materials are highly tunable through external control. We demonstrate dynamic electrical tuning of the focusing efficiency through manipulating of the excitonic material resonance properties as opposed to tuning of antenna resonances.

10:30 AM

Metamaterial Absorber with Nanofluidic Channel for Attomole Nanoconfined Molecular Detection

Takuo Tanaka,1,2,3,4 Metamaterials Laboratory, RIKEN Cluster for Pioneering Research, Wako, Japan; 1Innovative Photon Manipulation Research Team, RIKEN Center for Advanced Photonics, Wako, Japan; 2School of Materials and Chemical Technology, Tokyo Institute of Technology, Meguro-ku, Japan.

In bioanalysis, especially in single cell analysis, label-free detections and recognitions for molecular analysis are highly demanded. IR spectroscopy is one of label-free methods and it gives us chemical specificity and molecular information, yet its application in bioanalysis is limited due to its low sensitivity. Recently, plasmonic nanostructures were intensively studied to improve the sensitivity of IR spectroscopy by several orders of magnitude, however positioning analytes exactly at the hot-spots is still challenging [1]. We propose a device that utilizes nanofluidics to manipulate analytes into the hot-spots of metamaterials, consequently an ultra-high sensitivity of IR absorption detection can be achieved.

The structure consists of metal square-disks array and metal mirror separated by a nano fluidic channel. The interaction between top square nanostructure and bottom mirror forms the quadruple resonance, and it suppresses the light reflection from the device. When the molecule whose absorption is overlapped with this mode is introduced, strong interaction between molecules and metamaterials is excited and it creates the reflection light within the absorption band of the metamaterial. The sensitivity was achieved at molecule density of ~10⁴ molecules/Å², which is improved by 2 orders compared to reported plasmonic induced IR detection methods [2]. We also succeeded in the quantitative determination of absolute number of molecules by precise fluidic operation. Moreover, the device allows the confinement of both molecules and plasmonic energy inside the nanocavities. We confirmed the presence of a strong H-bond network and the
scaling behavior of water confined in 10-100 nm regime. Our method can provide the capability for in-situ probing molecules and chemical reactions under nanoconfinement [3]. When we make the size of unit cell of metamaterial absorber down to several hundreds nanometers, the absorption bands move to the visible light region. We present a simple yet efficient approach for ink-free color printing employing sub-micrometer scale plasmonic pixels of single constituent metal structure that supports near unity broadband light absorption at two distinct wavelengths, facilitating the creation of saturated colors [4]. The dependence of these resonances on two different parameters of the same pixel enables controllable color attributes such as hue, brightness and saturation across the visible spectrum. Here we present an up scalable color printing scheme using plasmonic pixels of single constituent metal structure, enabling the design of full colors with controllable color attributes.

11:00 AM EP12.06.08

Ultra-Flat, Transparent and Rainbow-Free Guided Mode Resonance for Diffractive Optical Eye Tracking Glass

Jung-Hwan Song, Jorik Van de Groep and Mark L. Brongersma; Stanford University, Stanford, California, United States.

Over several decades, eye tracking has been providing indispensable analysis tool in wide range of research fields including Ophthalmology, Psychology, and Neurology. Recently, augmented reality is pushing its demands on more compact, transparent optical eye trackers, which are compatible to head-mounted display or heads-up display. The requirement augmented reality imposes on the optical eye trackers is tracking human eyes while it does not perturb human vision. The optical eye trackers should have acceptable power efficiency as well as maintain optical transparency. The two requirements—power efficiency and high-transparency to human vision—are typically conflict to each other.

Many of proposed optical eye tracking systems, such as oblique half-mirror and holographic waveguide are suffering from either severe human vision interference or poor operation efficiency. In addition, these are bulky, poorly transparent, and producing rainbow images due to non-zero diffraction in the visible spectrum. Here, we demonstrate ultra-flat, transparent, and rainbow-free diffractive eye tracking glass based on guided mode resonance which supports near-unity transmission. It is based on a 200-nm-thick SiNx slab dielectric optical waveguide between a quartz substrate and a 100-nm-thick SiO2 capping layer. The vertical feature is designed for high transmission (>90%) over the whole visible spectrum. We insert 3-mm-thick Si grating layer between the SiNx slab dielectric waveguide and SiO2 capping layer which launches high-quality (Q=2,000) guided mode resonances in the slab waveguide. We rigorously characterize the resonantly diffractive, dispersive properties of the fabricated structures through angle-resolved confocal spectroscopy. The guided mode resonance is excited when light of resonant wavelength (870 nm) in near-infrared spectrum is normally incident on the structure. The scattered light components at individual the Si gratings constructively interfere to be fanned into quasi-guided waves in the SiNx slab dielectric waveguide. During long (2,000 optical cycles) travelling time inside the SiNx slab before re-radiation into the free space, the light is building up its intensity and coming out with high diffraction efficiency (13%) into the desired direction which is useful for eye tracking. When the incident light is in the visible spectrum, on the other hand, the guided mode resonance becomes weak due to Si absorption, resulting in suppressed rainbow-producing diffractions with negligible (0.1%) efficiency. We also demonstrate the imaging of artificial eye by a single webcam located at the 60 degree from the surface-normal direction of fabricated 2 cm by 2 cm sample. The full anterior images of an artificial eye are obtained at the oblique direction and we hope that this opens a promising route toward ultra-compact, transparent, and non-obtrusive imaging for displays and optical switching applications.

11:15 AM EP12.06.09

Active Tuning of Plasmons and Surface-Phonon Polariton Resonances

Adam Dunkelberger1, Chase Ellis1, Daniel Ratchford1, Alexander Giles1, Scott Katzer1, Roderick Davidson1, Andrea Grafton1,2, Mijin Kim1, Chul Soo Kim1, Igor Vurgaftman1, Joseph Tischler1, Joshua Caldwell2 and Jeffrey C. Owstsky3; 1U.S. Naval Research Laboratory, Washington, District of Columbia, United States; 2NRC/RAP Postdoctoral Fellow, Washington, District of Columbia, United States; 3KeyW, Inc., Hanover, Maryland, United States; 4Vanderbilt University, Nashville, Tennessee, United States.

The infrared spectra of many polar semiconductors are dominated by highly reflective reststrahlen bands that occur between the transverse and longitudinal optical phonons. We have previously shown that photoinjected carriers transiently and reversibly modify the reststrahlen bands through carrier-induced charge modulation. Here, we report on the active control of the reststrahlen bands in high-quality SiGe/SiGeI strained-layer optical structures using a surface-phonon polariton (SPP) resonant cavity. We use time-resolved infrared reflection spectroscopy to identify the frequency tuning of the SPP resonance in the presence of photoexcited carriers, with electro-optical measurement of the change in cavity permittivity. The active control of the SPP resonance is demonstrated for SiGe/SiGeI strained-layer mirror cavities using a range of optical materials and device structures, including high-quality strained-layer mirrors. The results demonstrate the potential for active control of SPP resonances in a variety of device applications, including optical frequency conversion, optical phase conjugation, and optical switching.

11:30 AM *EP12.06.10

Thin Films andMetasurfaces for Optical Information Processing

Ann Roberts; School of Physics, University of Melbourne, Melbourne, Victoria, Australia.

Extraction of the properties of optical wavefields, such as wavelength, polarization and phase, is widely employed in a range of applications including optical communications, sensing and imaging. These attributes of light are, however, not directly sensed by photodetectors and additional optical components or computational post-processing of intensity images is required to extract this information. Similarly, optical information processing is widely used for enhancing images and the visualization of transparent objects such as live unstained cells. Various well-known computational and all-optical strategies have also been developed to perform image manipulation. To sense properties of light other than its amplitude or to selectively modify optical images, therefore, either real-time approaches requiring bulky and expensive optical components, or methods utilizing potentially time-consuming computational strategies are employed. Here we discuss the use of plasmonic thin films and metasurfaces to directly convert amplitude and phase gradient information in an optical field into enhanced intensity images and the incorporation of plasmonic antennas into photodetectors to sense polarization, phase gradients and color. These devices provide an avenue for the development of ultra-compact systems that will perform on-chip, real-time, single-shot conversion of wavefield information to readily measured and enhanced intensity distributions or a measurable photocurrent.

There have been several recent demonstrations of the use of metasurfaces and plasmonic thin films to perform mathematical operations. For example, a metasurface can be used as a tailorable spatial filter in a conventional optical spatial filtering system where optical differentiation or integration can be performed using independent tuning of the amplitude and phase of scattered light at different spatial locations on the filter. Alternatively, and the method to be discussed here, the angular sensitivity of certain plasmonic resonances permits direct access to the Fourier (or angular) spectrum of a reflected or transmitted field establishing the possibility of ultra-compact approaches to optical information processing. The angular dependence of prism coupling to surface plasmons on a thin metal has been previously used to demonstrate differentiation of images both amplitude and phase. Here we will discuss the use of<br>

2:00 PM EP12.07.02 Effects of Nanostructured Plasmonic Environment on Electrochromic Polymer Switching Mohammad Shahabuddin, Carl Bonner, Natalia Noginova and Sohelia Mashhadi; Center for Materials Research, Norfolk State University, Norfolk, Virginia, United States.

Strong modification of local environment associated with plasmonic nanostructures provides possibilities to control various processes, including charge transfer processes and chemical reactions. In this work, we explore opportunities to enhance electrochromic polymer performance using plasmonic metamaterials, and study the origin of this enhancement. Electrochromic polyaniline (PANI) films deposited onto gold metasurfaces demonstrate non-monotonous coloration behavior at low voltages, step-like color-change and much faster saturation in color change compared with polyaniline films deposited on flat gold. The additional small voltage peak in the cyclic voltammogram in nanomesh/PANI cell and the asymmetric and nonlinear I-V characteristics of the sandwich nanomesh/PANI/flat gold structure indicate a possible formation of Schottky-like interface between polyaniline and nanogold structured, whereas the Ohmic contact is observed for the flat gold-polyaniline system. The results are discussed in terms of the modified work-function of nanogold structured, interface charging and threshold-like charge transport. Possibility to engineer optical and charge transport properties of electrochromic materials via nanostructured interfaces can bring various optoelectronic applications.

2:15 PM EP12.07.03 Enhanced Reflection at Glancing Angles from a Pt/SiN Metamaterial Perfect Absorber Nicole Pfister and Thomas E. Vandervelde; Tufts University, Medford, Massachusetts, United States.

Many metamaterial devices are designed to operate at a wide range of angles of incidence. However, the ability to control reflection at an angle is useful for 3-D imaging and detection, as well as controlling light for photonic circuits. We have demonstrated a metal-dielectric-metal metamaterial perfect absorber that can be either angle-dependent or angle-independent based on the dielectric material chosen for the spacer layer. Use of platinum and silicon nitride produced increased selectivity of the near infrared perfect absorber at wide angles of incidence under p-polarized light. This enhanced selectivity came from increased reflection at wavelengths smaller than the target wavelength for absorption.

Variable angle spectroscopic ellipsometry was used to explore the enhanced reflection. Based on the Mueller matrix, the sample exhibited a small amount of anisotropy, though to what degree depended on the angle of incidence and orientation of the sample. When the long elliptical axis was perpendicular to the plane of incidence, the sample appeared more anisotropic, particularly at wider angles of incidence. Depolarization and scattering measurements showed that the anomalous behavior is not a function of scattering or cross-polarization, indicating that a resonant mode within the metamaterial is being induced. FEM simulations confirmed that anti-parallel electric field curls are only present in the cases where enhanced reflection occurs, generating a magnetic dipole that contributes to the metamaterial’s response. To determine if this behavior is specific to this combination of materials and device design, additional simulations were conducting with varying material parameters and ellipsoidal axes.

To explore the design space where the enhanced reflection occurs, the permittivity of the dielectric layer and the long elliptical axis were varied. From these simulations, three regions appeared. The first, with high permittivities and long elliptical axes near the size of the unit cell, showed angles of incidence independent behavior with no enhanced reflection, which was consistent with devices found in literature. The second region, where the nanostructure approached a circle as the elliptical axes became equal and the permittivity of the low, showed extreme increasing in reflection, though with losses to the designed absorption peak. In this region, many designs did not exhibit a metamaterial response at all as the permittivity of the dielectric layer was too low to support the resonant modes.

Finally, in region three, a range of permittivity values and elliptical column sizes resulted in the reported enhanced reflection but with high levels of absorption at the target wavelength. Therefore, this behavior is more common than previously thought. Obtaining a thorough understanding of the design space like this will lead to better informed device decisions for other applications.

2:30 PM EP12.07.04 Plasmonic Nanovoids in Silicon—Simulation and Experiment Hanna Bandarenka1, Sergey Redko2, Aliaksand Shapel1, Aliaksa Shkarshniou1, Stanislau Niauzorau1 and Bruno Azeredo2; 1 Applied Plasmonics Laboratory, Belarusian State University of Informatics and Radioelectronics, Minsk, Belarus; 2 Laboratory of Materials and Structures of Nanoelectronics, Belarusian State University of Informatics and Radioelectronics, Minsk, Belarus; 3 The Polytechnic School, Ira A. Fulton Schools of Engineering, Arizona State University, Mesa, Arizona, United States.

Ordered arrays of plasmonic nanovoids (antinanoparticles) provide unconventional plasmonic platforms for detection and study of organic molecules at ultralow concentrations by surface enhanced Raman scattering (SERS) spectroscopy. They are especially attractive for analysis of large molecules that cannot be objectively studied with traditional plasmonic nanoparticle. This is caused by the small areas of localization of electromagnetic field (hot spots) that is induced by surface plasmon resonance in nanoparticles. As a result, Raman signal from particular bonds of large molecules, which are located beyond hot spots, is not enhanced. Electromagnetic field of nanovoids is mostly localized inside cavities due to multiple bounces of excitation light. If an analyte molecule appears in nanovoid, Raman signal of all bonds will be increased nearly equally. To promote significant enhancement plasmonic nanovoids should have depth and diameter more than 0.5 microns. Such structures are usually fabricated by nanosphere lithography, which main drawbacks are (i) limited area of plasmonic sample and (ii) high consumption of noble metals. Here we propose to fabricate plasmonic nanovoids by sculpturing the silicon template and following electrochemical/electroless deposition of silver film. Arrays of voids with proper dimensions in silicon can be fabricated by electrochemical anodic etching [1] or direct electrochemical imprinting with dotted stamp [2]. Using the first approach, we were able to form arrays of macropores in lightly doped p-type silicon, which have sizes deviating from 0.5 to 1.5 microns and slightly variable profile causing partial non-repeatability of the substrate’s optical and electromagnetic properties. On the other hand, the second method leads to etching the voids with well-reproducible periodical structure and related properties. Effectiveness of nanovoids was estimated by simulation of electric field distribution under different excitation wavelengths for the cavity in silicon coated with continuous silver film with 100 nm thickness. The distance between nanovoids was 10 nm. The depth and diameter of simulated nanovoids were 0.5 microns. We solved a 3D frequency-domain wave equation for electric field with a finite element method (FEM). To simulate the excitation light we used a plane wave with a normal incidence. Simulations showed electric field enhancement in the void volume due to internal reflections. It was found that the electric field in nanovoids is 2-3 orders of magnitude higher than the field in the silicon slab. The maximal electric field shifts from the bottom to the mouth of nanovoid according to increase of excitation wavelength from 473 to 980 nm. Localization of electric field maximum in the center of nanovoid was typical for 785 nm. Experimental SERS measurements of peptides and proteins at micromolar concentration showed that the most number (80%) of full-view spectra were obtained at 785 nm. Considering simulation results this can be explained by uniform overlapping the analyte molecules with the centered electric field. In future work, fabrication of films of other metals and optimization of their deposition process on the template formed by direct electrochemical imprinting with stamp is needed. This would enable to analyze large molecules at lower concentrations and achieve reproducibility of their SERS-spectra for 90 – 95% of nanovoids.

2:45 PM EP12.07.05 Compact a-Si Nanopillar Arrays for Spectral Filtering via Guided Mode Resonances Ryan C. Ngi1, Julia Green2 and Katherine T. Fountaine3; 1 California Institute of Technology, Pasadena, California, United States; 2 NGI Next, Northrop Grumman Corporation, Redondo Beach, California, United States.
Sub-wavelength periodic structures have potential in many various applications due to their unique spectral characteristics. These arrays exhibit near-unity reflectivity resonances that arise from the coupling of an incident wave into a leaky waveguide mode via a grating vector that is subsequently re-radiated, a phenomenon commonly known as a guided mode resonance (GMR). Such spectral characteristics are well-suited for multi- and hyper-spectral filtering applications in the infrared. We designed an all-dielectric platform consisting of amorphous silicon (a-Si) (n \approx 3.5) nanopillar arrays embedded in SiO_{2} (n \approx 1.4) with a ratio of radius, r, and a center-to-center distance, d, of r/d \approx 0.2 in simulation and experiment for application as narrow stopband filters. These filters are ultra-thin (<0.1μ), polarization-independent, relatively straightforward to fabricate compared to conventional Bragg stack reflectors, and possess greater efficiencies relative to their plasmonic-based counterparts due to low material absorption. The choice of a-Si as the nanopillar material stems from its low cost, high index of refraction, and a band gap of 1.55 eV near the edge of the visible.

We present the tunability of the spectral characteristics of the GMR in these arrays through variation of array geometric parameters in simulation and experiment and validate the GMR formulation with photonic crystal slab band diagram calculations. The GMRs are observed experimentally in fabricated arrays with an amplitude >85% with FWHM values ranging from 20-50 nm. We further extend our analysis to periodic arrays of finite size, which are required for high resolution snapshot imaging. GMR designs often consider only the case of an infinite array, where the leaky waveguide mode can propagate laterally for hundreds of periods, allowing for this mode to eventually scatter out of the array giving rise to the characteristic narrow near-unity rapid spectral variations of a GMR. With an insufficient number of periods, the quality factor and thus the optical filtering performance is greatly diminished. We present arrays that operate under finite size limitations optimized for spectral imaging applications in the near-infrared.

3:00 PM BREAK

3:30 PM *EP12.07.06 On-Chip Free Electron Light Source Fang Liu1,2; Tsinghua University, Beijing, China; 2Beijing National Research Center for Information Science and Technology, Beijing, China.

To generate Cherenkov radiation (CR) in natural medium, the electron energy threshold is higher than hundreds of keV. Even though various approaches were adopted, the high-energy electrons as high as tens of keV is still required in experiment. Here we proposed to eliminate the threshold of electron energy to generate CR with the help of hyperbolic metamaterial (HMM). The analytical and simulation results indicate that, even though electron energy is lower than 0.1keV, the CR could be obtained in HMM in a visible and near-infrared frequency region. Furthermore, the on-chip integrated threshold-less CR source has been realized. It is demonstrated that the electron energy generating CR experimentally is two-three orders of magnitude lower than that in natural medium and the first on-chip integrated free electron light source is realized. Moreover, having free electrons interact with surface plasmon polariton (SPP) cavity mode, the surface plasmon amplification by stimulated emission of radiation (SPASER) is discovered and used for realizing lasers at nanometer scale. The conventional gain media applied in SPASER are solid materials such as organic dye or semiconductor, which limits the frequency range of SPASER. Actually, the free electrons could be considered as a kind of gain medium for emitting radiation. Here, we investigate theoretically the SPASER excited by free electrons and demonstrate numerically the tunable, deep-ultraviolet, and ultracompact laser by having free electrons interact with surface plasmon polariton mode supported on metal surface. The wavelength in deep ultraviolet could be widely tuned by varying the electron energy. Our work opens up the possibility of exploring high performance on-chip integrated free electron light source and optoelectronic devices, and provides a way for realizing integrated free electron laser in ultraviolet frequency region.

4:00 PM EP12.07.07 Coupling of Boron Dipyromethene Dye Excitons to Plasmonic Surface Lattice Resonances in Aluminum Nanodisk Arrays Robert Collison1, Jacob Trevino2, Vinod Menon2 and O’Brien Stephen3; 1The Graduate Center, CUNY, New York, New York, United States; 2Chemeloon Inc., New York, New York, United States; 3City University of New York, New York, New York, United States.

When plasmonic metal nanoparticles are arranged in extended, one- or two-dimensional periodic arrays, the localized surface plasmon resonances (LSPRs) of the individual particles will couple radiatively to form a collective, propagating photonic-plasmonic mode known as a surface lattice resonance (SLR). Currently, SLRs and their potential applications in photonic devices, such as solar cells and light-emitting diodes, are growing topics of interest in the literature. In particular, the interaction of propagating, delocalized SLRs with the highly localized excitons of organic dye molecules is being investigated, and exotic phenomena such as the Bose-Einstein condensation of polaritons composed of dye excitons coupled to SLRs was recently reported. We report on the fabrication of SLR-supporting arrays of aluminum nanodisks on glass, and the coupling of these SLRs to dye excitons via coating of the arrays with dye-doped poly(methyl methacrylate). In particular, the interaction of the SLRs with boron dipyromethene (BODIPY) dye is examined, and the resulting effects, including angle-dependent fluorescent emission and enhancement of energy transfer between two different BODIPY dyes, are reported.

4:15 PM EP12.07.08 Tailoring UV Circular Dichroism with Semiconducting Metamaterials Sunam Sarkar and John Gibbs; Northern Arizona University, Flagstaff, Arizona, United States.

Chiral electromagnetic metamaterials that have chiroptical activity, have attracted attention due to their suitability for many potential photonic and biological applications including lasers, molecular sensing, structural studies of organic molecules such as proteins and DNA. Despite the recent advances in chiral metamaterials, to date, very little attention has focused upon artificially large optical activity in the UV range, where molecular circular dichroism (CD) bands are most frequently encountered. In this work, a systematic investigation is made into CD behavior in the UV range with respect to geometry and critical dimensions with a semiconducting metamaterial. The glancing angle deposition (GLAD) method was used as it provides a means of experimentally investigating the relationship between morphology and optical activity, which is critical to optimizing design. We also explore more complex, multi-material and multi-functional hybrid metamaterials that are active across the UV and visible spectrum. This technique allows us to tailor optical activity making it possible to achieve chiroptical activity over a wider range of wavelengths.

4:30 PM EP12.07.09 Leveraging Momentum to Dictate Spectral Tuning of Infrared Phonon-Polaritonic Thomas Beechem1, Christopher Saltonstall1, Tristan Gilbert2, Joseph Matson2, Fabian Ugwu3, Rachel Kasica3, Francisco Bezare3, Jason Valentine4 and Joshua Caldwell2; 1Sandia National Laboratories, Albuquerque, New Mexico, United States; 2Vanderbilt University, Nashville, Tennessee, United States; 3National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 4University of Puerto Rico, Cayey, Puerto Rico, United States.

The nanophotonics field has long sought to identify mechanisms to realize dynamical control of optical modes. In most approaches, the magnitude of tuning is dependent upon the multi- and hyper-spectral filtering applications in the infrared. We designed an all-dielectric platform consisting of amorphous silicon (a-Si) (n \approx 3.5) nanopillar arrays embedded in SiO_{2} (n \approx 1.4) with a ratio of radius, r, and a center-to-center distance, d, of r/d \approx 0.2 in simulation and experiment for application as narrow stopband filters. These filters are ultra-thin (<0.1μ), polarization-independent, relatively straightforward to fabricate compared to conventional Bragg stack reflectors, and possess greater efficiencies relative to their plasmonic-based counterparts due to low material absorption. The choice of a-Si as the nanopillar material stems from its low cost, high index of refraction, and a band gap of 1.55 eV near the edge of the visible.

We present the tunability of the spectral characteristics of the GMR in these arrays through variation of array geometric parameters in simulation and experiment and validate the GMR formulation with photonic crystal slab band diagram calculations. The GMRs are observed experimentally in fabricated arrays with an amplitude >85% with FWHM values ranging from 20-50 nm. We further extend our analysis to periodic arrays of finite size, which are required for high resolution snapshot imaging. GMR designs often consider only the case of an infinite array, where the leaky waveguide mode can propagate laterally for hundreds of periods, allowing for this mode to eventually scatter out of the array giving rise to the characteristic narrow near-unity rapid spectral variations of a GMR. With an insufficient number of periods, the quality factor and thus the optical filtering performance is greatly diminished. We present arrays that operate under finite size limitations optimized for spectral imaging applications in the near-infrared.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia LLC, a wholly owned subsidiary of Honeywell International Inc. for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.
Plasmonic nanostructures have gained prominence thanks to their ability to confine electromagnetic fields far below the wavelength. By virtue of the collective resonant oscillations of free electrons in metallic structures, extremely high field enhancements can be achieved [1]. These resonances are strongly related to the shape, size as well as the material properties of the nanostructures. While till date, in most cases, the spectral properties have been determined by the shape and size, the ability to tune the material properties, provides additional advantages and offers a new degree of freedom for designing plasmonic nanostructures. Alloying is an attractive way of tuning the properties of metals since it alters the permittivity and, consequently, changes the resonance wavelength [2]. In our work, we employed gold and silver alloys (Au/Ag alloy) of different composition to fabricate nanostructures of different shapes and sizes including complex structures exhibiting Fano resonances. To this end, a very original low-temperature process has been developed, which allows the nanostructures to retain their shape.

Our work aims to fabricate alloyed plasmonic nanostructures using standard techniques of e-beam lithography and lift-off. We deposit consecutive metal layers, where the thickness, hence the volume, of each layer determines the desired composition, using e-beam evaporation technique, in contrast, to often used co-sputtering [4]. Here, we demonstrate the performance of a newly developed low-temperature annealing process using three different Au/Ag alloys, namely, Au0.2Ag0.8, Au0.5Ag0.5, and Au0.8Ag0.2. A uniform alloy is achieved by annealing the previously deposited metal layers at temperatures of 300°C for 8 h and 450°C for 30 mins under N2 atmosphere. The experiments reveal that using such low temperatures, far below the Tammann temperature, at which the mobility of the molecules in a solid sets in, the shape of the nanostructures are perfectly conserved! EDX and XPS measurements carried out on 150 nm thin films of the Au/Ag alloys confirm a homogeneous alloy. Ellipsometric studies carried out on thin films confirm further that the permittivity of alloys can be tuned. After successful fabrication of alloyed thin films, 50 nm high equilateral nanotriangles of 300 nm side length and nanorods of 400 nm and 50 nm length and width, respectively, and periodicity of 4 μm were fabricated by e-beam lithography. Shape and size of the structures are perfectly retained after annealing and EDX measurements confirm fully homogeneous alloys. We also fabricated more complex Au/Ag Fano-resonant plasmonic nanostructures using this technique. The optical response of a 4 rod Fano resonant structure excited with light polarised along its long axis [4] has been simulated for five different compositions, namely, pure Ag, Au0.2Ag0.8, Au0.5Ag0.5, and Au0.8Ag0.2, and pure Au. The simulations clearly show a variation of the spectrum by altering the composition. These nanostructures were successfully fabricated, and experimental spectra confirmed the variation of resonances by varying the composition.

To conclude, we successfully demonstrated a novel fabrication technique where plasmonic nanostructures of different shapes and compositions retain their shape after low-temperature annealing of consecutively deposited Au and Ag layers. This result opens up the opportunity of fabricating plasmonic nanostructures of different material compositions, which offers a new degree of freedom for tailoring the optical properties of plasmonic nanostructures.

10:30 AM *EP13.01.01
Advances in the Understanding and Performance of High Performance Thermoelectrics Mercouri G. Kanatzidis; Northwestern University, Evanston, Illinois, United States.

Thermoelectric solid-state energy conversion technology can provide a reliable and clean way to generate operative electricity from waste heat, which is a promising strategy for addressing energy conservation and management. Thus, there is a broad based push from the science and technology community to develop highly efficient thermoelectric materials as a possible route to address the worldwide power generation problem from heat. Today there is a variety of effective strategies to improve the properties of these narrow gap semiconductors such as achieving extremely low thermal conductivity and raising the power factors. The so-called nanostructuring and mesoscale approach has led to a new era of investigation for bulk thermoelectrics. Currently lead chalcogenides incorporating second phases hold the record in figure of merit for high temperature power generation applications. Nanostructures enable effective phonon scattering of a significant portion of the phonon spectrum while mesostructures tend to scatter phonons with long mean free paths remain. By combining all relevant length-scales in a hierarchical fashion, from atomic-scale disorder and nanoscale endotaxial precipitates to mesoscale phonon scattering a large enhancement in the thermoelectric performance of bulk materials can be achieved. Progress on device and module assembly is excellent and modules with conversion efficiency of ~11% for a delta T of 590 K have been demonstrated using nanostructured PbTe-based materials. Interestingly, nanostructuring is not necessary to obtain record high thermoelectric performance. Several systems based on PbTe and PbSe will be described that lack nanostructuring but feature complex structures and point defects, which can also achieve very low thermal conductivity. Comparisons with nanostructured materials will be made. Finally, SnSe is a new striking example of a single-phase two-dimensional material which has shed new light in thermal transport and charge transport properties both in p-type and n-type doping. The state of the art in the understanding of this system will be presented.

11:00 AM *EP13.01.02
First-Principles Simulation of Electron and Phonon Transport in Thermoelectric Materials with Alloys and Defects Jiawei Zhou, Te-Huan Liu, Qian Xu, Qichen Song, Zhiwei Ding and Gang Chen; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.
This talk will discuss our recent work to simulate electron and phonon thermoelectric properties based on the density-functional theory, in particular focusing on materials with alloys and defects. Intrinsic electron transport properties are governed by carrier scatterings by phonons, but practical materials often involve alloys or have defects, that can significantly change the transport properties. The main challenge is how we can take these into account in first principles simulations and obtain more reasonable estimation for materials' thermoelectric performance. In this talk, building upon our previous experience in understanding the electron transport in semiconductors (EPL, 109, 57006, 2015; PRL, 114, 115001, 2015; PNAS, 112, 14777, 2015; PRB, 95, 075206, 2017; Nat Comm, 9, 1721, 2018; PNAS, 115, 879, 2018), I will discuss how we can extend the simulation to include alloys and defects. First, I will use two alloy systems (ZrNiSn/ZrNiPb, and Si/Ge) to illustrate what are the general effects of alloying on electron transport in comparison to phonon transport. The latter material system also gives us the opportunity to utilize the phonon drag effect to enhance the thermoelectric performance. In the second part, I will discuss how local defects (e.g. dopants, interstitials) impacts the electron transport in half-Heuslers and Zintl compounds. The ability to quantify the defect scattering not only helps to explain the discrepancy between experiment and simulation results assuming only intrinsic scattering mechanisms, but also provides guidelines for selecting optimal dopants for thermoelectric materials. This work is partially supported by S-TEC, an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences (Award No. DE-SC0001299/DE-FG02-09ER46577), and partially by DARPA MATRIX program (Grant No. HR0011-16-2-0041).

11:30 AM EP13.01.03
High-Throughput Screening for Thermoelectric Material and Transport Descriptors D V M. Repaka,1 Ady Suvardi,1 Zekun Ren1,2, Tonio Buonassisi1,3 and Kedar Hippalgaonkar1,4 1Institute of Materials Research and Engineering, Singapore, Singapore; 2MSE, Nanyang Technological University, Singapore, Singapore; 3ME, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4National University of Singapore, Singapore, Singapore.

In the field of functional materials, there has been a lot of development in piezoelectrics, thermoelectrics and photovoltaics using Bayesian inference with a forward model to accurately determine material descriptors. So far, machine learning approaches have only been used to predict promising new thermoelectric compositions from density functional theory calculations, building upon open-source databases towards the discovery of high performance materials. Further, high-throughput materials screening approaches are still rudimentary, limited by the lack of universally defined material and thermoelectric transport descriptors. Finally, rapid and accurate materials characterization that can directly measure these descriptors are arduous (for example, method of four coefficients) or do not exist. In this work, we disclose a rapid and accurate way to determine the material and transport descriptors of thermoelectric performance by feeding simple single-leg power-load experimental data to a Bayesian machine learning algorithm using Boltzmann transport theory. Employing only two input parameters (temperature gradient and external load resistance) and the observed power output, the Bayesian inference algorithm is able to extract thermoelectric parameters ranging from material-layer properties (Seebeck coefficient, electrical resistivity) to transport-layer characteristics (energy-dependent scattering parameter, band gap offset, etc.) as well as extrinsic contributions such as parasitic contact resistance. In addition, systematic error from measurement can also be identified and corrected. Hence, we are able to predict band and transport descriptors that can be measured directly using experiments for the first time. While these reveal the complex dynamics of scattering in thermoelectric materials, we envision that they will also provide universal screening criteria for high performance thermoelectrics in the near future.

11:45 AM EP13.01.04
Integrated Micro-Thermoelectric Coolers with Free-Standing Design and Robust Device Performance Guodong Li1, Javier Garcia1, David Alberto Lara Ramos2,3, Vida Barati1,2, Nicolas Perez1, Ivan Soldatov1, Heiko Reith1, Gabi Schiering1 and Kornelius Nielsch1,2 1Leibniz Institute for Solid State and Materials Research Dresden, Dresden, Germany; 2Institute for Materials Science, Dresden University of Technology, Dresden, Germany; 3Consejo Nacional de Ciencia y Tecnologia, Ciudad de Mexico, Mexico.

Fabrication of micro-thermoelectric modules is needed in order to realize on-chip integrated power generation as a solid-state thermoelectric generator (TEG) and local heat management as a Peltier cooler (TEC). The main challenges lie in the development of a feasible and cost-effective technology, which needs to be compatible with the modern semiconductor fabrication technology. In this work, integrated micro-thermoelectric coolers (μ-TECs) based on the telluride compounds, with a packing density over 5500 leg pairs per cm² and an optimized net cooling around 6 K near room temperature, have been successfully fabricated by combining conventional techniques of photolithography and electro-chemical deposition (ECD). Systematical device characterizations, including current and temperature dependent cooling performances, transient cooling response, cycling reliability, and long-term stability under constant current, have been examined and demonstrated. Particularly, the as-fabricated μ-TECs show a reliability up to 10 million cycles and cooling stability under constant current for more than 1 month under ambient environment. Further, a transient cooling response time of 1 ms outperforms that of devices reported in the literatures by at least one order of magnitude. Model simulations based on the finite-element method (FEM) and analytical calculations both show consistency with the experimental results, indicating high quality thermoelectric materials (for both n and p legs) and negligible contact resistances in the as-fabricated μ-TECs.

Tuning the Electrical Transport in Rashba Spin-Split BiTel Lihua Wu and Jihui Yang; University of Washington, Seattle, Washington, United States.

Crystal structure inversion asymmetry and strong spin-orbital coupling can induce a Rashba-type spin-split effect on the electronic band structures of materials, which has been intensively studied in diverse fields of condensed matter physics and materials science. Bulk BiTel compound possesses a giant Rashba spin-split band dispersion with a unique Fermi surface topology evolution across the Dirac point. The dimensionality reduction in the density of states can lead to beneficial thermoelectric responses in bulk and few-layer-thick BiTel, when the Fermi level is below the band-crossing point. In this talk I will present our recent data and analysis of the Shubnikov de Haas oscillations to distinguish electrons of the inner and outer Fermi surfaces. We also studied topological phase transitions and changes in the electrical transport properties by applying uniaxial strain on micro-size samples. Our data suggest that from bulk to few-layers, BiTel offers an interesting platform for exploring new degrees of control for quantum materials.

2:00 PM • EP13.02.02
Electric and Thermal Conduction Behavior of Layered-Oxide Thermoelectric Ceramics Yuhanhua Lin, Guangkun Ren, Xin Tan and Cewen Nan; School of Materials Science and Engineering, Tsinghua University, Beijing, China.

In comparison with thermoelectric alloys, oxide semiconductors, which are thermally and chemically stable in air at high temperature, are regarded as the promising candidates for high-temperature thermoelectric applications in waste-heat recovery and power generation, such as solar energy harvesting through solar concentrators. However, the ZT values of the oxide ceramics still remain rather low in comparison with their alloy counterparts due to the medium electrical conductivity and high thermal conductivity. In this talk, we focus mainly on our works on layered BiCuSeO, Bi2SeO and Cu2O-CuO ceramics. The special layered structure can effectively scatter the phonons, resulting in an obvious reduction of thermal conductivity. Further by engineering the band structure and nanostructures, the thermoelectric properties can be significantly improved, and a high performance oxyselenide BiCuSeO ceramic with ZT>1.5 at 823 K was developed.

Antiferromagnetic MnTe:Li has shown a benevolent strong spin effect on thermoelectric properties across a broad range of temperature leading to $ZT>1$ at 900K [1,2]. Strong spin contribution to the heat capacity and spin disorder scattering effect on carrier mobility is observed near the Neel temperature, $T_N=307K$. However, the spin contribution to the thermopower continues above $T_S$ and extends up to 900K. Spin contribution to those properties below $T_S$ has been attributed to the magnon-drag effect [3], while spin effects on thermopower above $T_S$ are associated to the paramagnon-drag originated from the mid or short-range magnetic ordering [2]. Neutron inelastic spectroscopy and specific heat data showed an agreement to that theory to some extent while some competing theories such as the spin-fluctuations and spin entropy can also explain thermopower enhancement in magnetic materials [1,4]. To investigate the validity of those theories, we synthesized MnTe with different dopants to modify the magnetic properties and study their effects on the thermoelectric characteristics. In particular, Cr-doping was introduced to the MnTe system to break the antiferromagnetic ordering intentionally. MnTe doped with 5% and 14% Cr showed ferromagnetic properties with Curie temperature of ~100K with the magnetic moments reducing monotonically at above 100K. The specific heat, however, still showed the strong contribution from the magnon heat capacity near 300K despite lack of obvious magnetic phase transition at or near that temperature. The presence of ferromagnetic ordering in MnTe:Cr observed in the magnetic measurement is attributed to the spin-polarized hole-mediated magnetic interaction, while magnons observed in specific heat measurement can be associated to the presence of remnant short-range antiferromagnetic ordering. The breaking of the antiferromagnetic ordering suppresses the magnon and paramagnon contributions to the thermopower in MnTe:Cr. Cr-doping overall exhibited detrimental effects on the thermoelectric behavior of MnTe due to the modifications in magnon hole interactions. We will discuss the results obtained on thermoelectric properties and compare them with those of Li-doped MnTe.

Paramagnetic Dragan as a Route to High ZT
Joseph P. Heremans,1 Yu-Nhua Zheng,1 Tianqi Lu1, Md Mobarak Hossain Polash1, Morteza Rasoulihanboroujeni1, Ning Liu1, Michael Manley2, Yuan Deng6, Peijie Sun6, Xiaolong Chen5, Raphael Hermann3, Dariohosh Vashe3, and Huaizhou Zhao4; The Ohio State University, Columbus, Ohio, United States; 1North Carolina State University, Raleigh, North Carolina, United States; 2Marquette University, Milwaukee, Wisconsin, United States; 3Institute of Physics, Chinese Academy of Sciences, Beijing, China; 4Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 5University of the Negev, Be'er Sheva, Israel.

Thermal spin transport can be used as a new, independent variable that alleviates the counter-indicated nature of the parameters that enter ZT. Fermi-Dirac statistics impose an inverse relation between the thermopower and the carrier concentration, and thus, the electrical conductivity. However, this condition does not exist for bosons, like magnons, whose magnonic thermopower is the entropy per particle [1]. For example, magnon drag can boost the thermopower of ferromagnetic metals [2]. In this talk, we will first outline how magnon drag also increases the thermopower of the antiferromagnetic (AFM) semiconductor MnTe doped with the aliovalent acceptor Li by about a factor of 3 near the ordering temperature $T_N=307K$. Surprisingly, the boost in thermopower persists in the paramagnetic (PM) regime up to above 900 K. This enables optimally doped MnTe to reach ZT values in excess of 1 at $T>850K$. We ascribe the increase in thermopower to the drag (transfer of linear momentum) of electrons by the local thermal fluctuations of the magnetization in the paramagnetic state, paramagnons. Neutron scattering identifies the magnon density of states in the AFM regime. An excess density of states remains visible up to the maximum temperature of the measurements, 450 K. From the energy width of this line, a paramagnons lifetime of $3x10^{-14}s$, is derived. The spin-spin correlation length in the PM state is then further derived to be about 2.5 nm from this and the momentum linewidth. The energy scattering time of electrons derived from the mobility is 2-to-5 x $10^{-14}s$, about 10 times smaller than the paramagnons’ lifetime. The de Broglie wavelength and the effective Bohr radius of the electrons are both shorter than the spin-spin correlation length. Consequently, from the electron point of view, paramagnons behave like magnons in the ordered state and contribute a drag thermopower that is the main mechanism behind the high ZT. This is the first example of a spin-based effect that is much larger than a charge-based effect, and leads to a technologically significant thermoelectric performance. If this observation can be verified in other classes of paramagnetic semiconductors, of which there may be many, it could open a new direction for thermoelectrics research.

The work is supported by then ARO MURI “Materials with extraordinary spin/heat coupling, grant W911NF-14-1-0016

Chiral Fermion Transport and Their Thermoelectric Properties
Qiang Li; Brookhaven National Laboratory, Upton, New York, United States.

Chiral fermions exist in the expanding class of quantum materials that display some unique transport properties, including negative longitudinal magnetoresistance via chiral magnetic effect, anomalous Hall effect, and anomalous Nernst effect that may be exploited for thermomagnetic cooling. Among the contributing factors to these unique properties are linear electronic band dispersion, chirality, and Berry curvature in chiral fermion systems. Interesting, many chiral materials were discovered in the compounds that are normally investigated for their superior thermoelectric performance. In this presentation, we will present our studies attempting to capture the fundamental difference in seemingly similar behavior in the transport properties of chiral materials and trivial thermoelectric materials. I will also discuss how to experimentally identify which mechanism is the result of chiral fermions.

First-Principles Defect Calculations to Dopability Predictions in Thermoelectric Materials
Anuj Goyal, Prashun Gorai and Vladan Stevanovic; Colorado School of Mines, Golden, Colorado, United States.
Dopability is important for thermoelectrics as it represents the ability to control carrier concentration of a semiconductor material. However, general understanding of factors governing dopability is largely missing which makes dopability predictions very difficult. To address this problem we aim to develop a predictive model that allows rapid computational assessment of the dopability of materials. As a first step, we have build a training set of accurate point defect calculations obtained using our robust ab initio computational framework to calculate point defect energetics using modern defect theory. Automation tool has thus enabled us to build a large dataset of first-principles defect calculations on a diverse set of thermoelectric-relevant materials. As a second step, we use this training set to develop dopability prediction model that can effectively correlate set of easily accessible bulk-derived properties to defect formation energies and carrier concentrations. Our analysis focuses on structural as well as compositional properties, bulk formation enthalpy, chemical potentials, and details of the electronic structure such as band dispersion, band gap, absolute band edge position, etc. Ultimately, this procedure allows us to parameterize dominant bulk properties that will be important in achieving reliable dopability predictions.

SESSION EP13.04: Layered Structures
Session Chairs: Theodora Kyratsi and G. Snyder

Engineering Thermal and Electrical Interfaces and Grain Boundaries in Thermoelectric Materials G. J. Snyder; Northwestern University, Evanston, Illinois, United States.

To devise strategies for improving the thermoelectric performance of materials, it is essential to understand the coupled charge and thermal transport mechanisms. In heavily doped semiconductors for example we often expect ionized impurity scattering to dominate electrical transport especially when mobility increasing with temperature is observed. However, the inadequacy of this description in thermoelectric materials such as the new high-performance n-type MgSb2, becomes apparent when trying to consistently explain various experimental observations like the enhanced mobilities in larger grain samples and sharp crossovers to metal-like mobilities that decrease with temperature. The underlying cause of such complications is largely associated with the conventional Mathiessen’s rule that interprets or models all of the charge carrier scattering as homogeneous events. The inhomogeneous nature of materials, such as that caused by grain boundaries, must be taken into account to rethink engineering strategies and further improve thermoelectric materials. Prevailing models for thermal transport treat interfaces and grain boundaries as structureless even though at the atomic scale they are better described as arrays of linear defects of various types. Allowing for this inherent structure, several fundamental characteristics of heat transport arise, such as diffraction conditions when heat carrying phonons scatter off the periodic, linear defect arrays that should be present in grain boundaries. Furthermore, a dimensionality crossover is observed in diffusive heat transport where phonons with a wavelength longer than the linear defect spacing see the interface simply as a structureless planar defect, and phonons with see with the interface as a collection of independently scattering linear defects.

8:30 AM *EP13.04.02
Layered Thermoelectric Materials Bo B. Iversen, Department of Chemistry, Aarhus University, Aarhus, Denmark.

Layered (2D) materials exhibit a variety of extraordinary properties, and recent focus has included topological insulators, electrode materials, monolayers, hetero structures – and thermoelectrics. The physical properties such as band gap or thermal and electrical conductivity are related to the detailed structural characteristics as well as the specific chemical bonding both within the covalent layers and across the van der Waal gap. It is generally assumed that layered materials exhibit anisotropic properties, but the properties are rarely discussed in direct relation to the specific chemical bonding characteristics of the solid. Using advanced crystallographic analysis including charge density modelling as well as ab initio theoretical calculations, we have studied the crystal structures and chemical bonding of a range of important layered thermoelectric materials including Cu2Se [1], MgSb2 [2], SnS2 [3], TiS2 [4] and SnSe [5]

9:00 AM EP13.04.03
Improved Stability and High Thermoelectric Performance Through Cation Site Doping in N-Type La-Doped MgSb2,Bi4S2 Max Wood, Kazuki Imasato, Jimmy J. Kuo and G. J. Snyder; Northwestern University, Chicago, Illinois, United States.

Until Recently only chalcogen (S, Se, Te) anion site dopants had been considered tested for n-type MgSb2 type materials. Herein is showed how n-Type conduction in a MgSb2, Bi4S2 system is achieved with La-doping at cation sites with a peak $zT > 1$. La-doped samples exhibit much higher doping efficiency and dopability compared to other chalcogen-doped samples, which allows for greater tunability of the electronic properties. La-doping also significantly improves the thermal stability of n-type MgSb2, Bi4S2 measured via a long-term Seebeck and Hall carrier concentration measurements. This increased stability in La doped material suggests new pathways to engineer around the degradation of electronic properties witnessed in this and other thermoelectric materials.

The Effect of Mn Doping and Porosity on the Transport Properties of Thermoelectric Alloys in the MgSb2 Family Yuanhua Zheng1, Siyi Chang2, Joseph P. Heremans1 and Haizhou Zhou1, 1The Ohio State University, Columbus, Ohio, United States; 2Institute of Physics, Chinese Academy of Sciences, Beijing, China.

Considering the cost of tellurium, it is technologically important to find alternatives to the well-known Bi2Te3-based tetradymite family of thermoelectric materials for cooling applications near room temperature, and power generation applications below 300 °C. The MgSb2 family of materials is a promising candidate [1], specifically MgS1-xMnxSb2. We investigate here the effect of Mn doping of this material by the method of the four coefficients [2]. In this method, the four transport coefficients, resistivity, and Hall, Seebeck and Nernst effects are measured, and used to calculate the charge carrier concentration, mobility, density of states effective mass $m^*$, and scattering exponent $\lambda$ (defined by the energy (E) dependence of the relaxation time, $\tau(E) \propto E^{\lambda-\alpha}$). We then further study the effects of making the samples porous. Thus resonance or Kondo effects are separated from the effects of changes in scattering mechanisms.

9:30 AM EP13.04.05
Nano-Structuring of Bi2Te3-Se: Toward High Thermoelectric Performance Sang-Soon Lim1, Kwang-Chon Kim1, Hyung-Go Park2, Seung-Hyub Baek1, Seong Keun Kim1 and Jin-Sang Kim1, 1Center for Electronic Materials, Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2Department of Materials Science and Engineering, Yonsei University, Seoul, Korea (the Republic of).
Thermoelectric materials should have a high electrical conductivity and a low thermal conductivity simultaneously to realize high thermoelectric figure-of-merit ($ZT$). However, the intimate coupling between electrical conductivity and thermal conductivity renders the enhancement of thermoelectric performance difficult. Nano-structuring of thermoelectric materials has been a major strategy to improve the thermoelectric performance because the phonon scattering at nano-grain boundaries effectively reduces the thermal conductivity without significant loss of electronic carrier.

Here, we propose a novel strategy with atomic layer deposition (ALD) for nano-structuring of Bi$_2$Te$_3$-Se, thermoelectric element to achieve a low thermal conductivity. The ALD technique is known to allow a precise thickness control at a sub-nm scale and have excellent conformality even on complex shaped substrate. Conformal ZnO layers were grown on the very fine Bi$_2$Te$_3$-Se powders. The Bi$_2$Te$_3$-Se/ZnO core-shell structured powders were sintered by a spark plasma sintering process and a hot-extrusion process. The ZnO-coated Bi$_2$Te$_3$-Se thermoelectric element shows small grains compared to the uncoated Bi$_2$Te$_3$-Se$_x$. The thermal conductivity is significantly decreased by the small grains and the thin ZnO layer at the grain boundaries. Consequently, the figure-of-merit of the n-type Bi$_2$Te$_3$-Se$_x$ is improved. Furthermore, the mechanical strength of the materials is enhanced by the ZnO ALD coating. Therefore, we believe that the nano-structuring of the Bi$_2$Te$_3$-Se$_x$ with ALD contributes to enhance thermoelectric performance of Bi$_2$Te$_3$-related materials.

Rapid Solid-State Reaction and Simultaneous Sintering of Nanostructured Thermoelectric Materials Using Microwave Radiation
Abhishek Malhotra$^1$ and Daryoosh Vashaee$^{1,2}$
$^1$Electrical and Computer Engineering, North Carolina State University, Raleigh, North Carolina, United States; $^2$Material Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States.

Nanostructuring in some materials can reduce the thermal conductivity more than cutting the thermoelectric power factor leading to $ZT$ improvement. With the quest to make and test the nanostructured forms of a variety of the known good thermoelectric materials, efficient material synthesis methods become highly desired. The conventional method of synthesis is based on a multi-step process involving ball milling, melt-quenching, and sintering, which requires a significant amount of time and energy. We introduce an alternatively faster approach based on electromagnetic field induced reaction and sintering using microwave (MW) radiation that can produce nanostructured bulk compounds with excellent properties compared to the conventional methods. This is a two-step process involving the uniform mixing of the elements and followed by MW radiation. The synthesis happens at a temperature lower than the melting point with the energy heating only the material (and not the entire furnace), which lowers the overall power requirement. MW radiation has been shown to enhance diffusion rates[i] and results in an accelerated solid-state reaction. Compared to other rapid alloying methods, such as self-propagating high-temperature synthesis, there is no limit to the type of compounds that can be synthesized. Furthermore, the consolidation happens simultaneously during the reaction and does not require additional densification steps.

Achieving crystallite sizes less than 20 nm is often difficult in bulk structures using conventional sintering methods such as hot pressing and spark plasma sintering. The main obstacle is that during the sintering, the grains grow, and nanoscale features broaden or diminish. Reducing the sintering time does not help either, as the material would not be adequately sintered resulting in low carrier mobility. Therefore, the sintered materials often have average crystallites larger than 20-30 nm in size at best. Interestingly, MW radiation has also shown decrystallization effects which further reduces the requirement of other nanostructuring steps. MW synthesis can generate structures with sub-10nm crystallites appropriate to achieve high ZTs in some materials.[ii]

This study has focused on the synthesis of nanostructured Bi-Sb-Te-Se alloys. The elemental powders were mixed in the required stoichiometry and sintered under MW radiation. No other source of heating was used. Materials used for this study were Bi-Sb-Te, Bi-Te and Sb-Te alloys, which are known for their thermoelectric properties near room temperature. The elemental powders were mixed for 15 minutes, cold-pressed, loaded into a die, and sintered in a MW cavity. Samples were consolidated at different temperatures ranging from 325 °C to 425 °C in steps of 25 °C. The x-ray diffraction (XRD) analysis of the mixed powder before MW sintering showed diffraction lines of the elemental materials with no sign of solid-state reaction after the short mixing time. However, the XRD analysis of the microwave processed samples showed a complete solid-state reaction with no trace of the elements. It was observed that the alloy entirely formed at 325 °C. Differential Scanning Calorimetry analysis was performed on these samples which further confirmed the formation of the alloy after the MW sintering. We will discuss the processing steps of MW sintering, material characteristics, and the thermoelectric properties of the synthesized materials.

Revealing Heat Transport and Phonon Scattering Using Electron Probes—Challenges and Opportunities
Yimei Zhu; Condensed Matter Physics and Materials Science, Brookhaven National Laboratory, Upton, New York, United States.

Modern electron microscopy, especially combined with the aberration correction and monochrometization technologies, has changed the way we visualize materials across a wide range of length scales. Nevertheless, revealing thermal transport and phonon scattering mechanisms in materials with electrons still poses a major challenge. In this talk, I will first describe the electron microscopy method we developed to understand the role of lattice disorder on phonon scattering by accurately measuring local static displacement and thermal vibration via simultaneous acquisition of multiple annular-dark-field images at different electron-scattering-angles. Layered caborlates, which exhibits unusually large thermoelectric power, will be used as an example. The system consists of a soft-rigid layered crystal structure with incommensurate displacive-modulation and local atomic vibrations. Through structure determination and refinement using electron microscopy and quantum field theory we show the specific combination of highly crystalline and strongly distorted layers is essential for enabling large electronic-conductivity and low thermoconductivity that is associated with efficient phonon scattering. We further demonstrate besides the well-known Umklapp, Rayleigh and displacement phonon scattering mechanisms, additional resonance and anharmonic scattering play an extremely important role in layered materials. As for future opportunities, I will give an overview on the RF-gun-based 2.8MeV ultrafast electron microscope we recently developed at BNL that has achieved 120fs resolution with 10$^6$ electrons per pulse. Brief examples will be given on how we probe the time-resolved interactions between charge, orbital and lattice and separate the roles of various phonon modes as well as thermal transport in function materials using ultrafast pump-probe approach.

The author would like to thank the members of the Electron Microscopy and Nannstrucure Group at BNL, the work at BNL is supported by US DOE, Basic Energy Sciences, Materials Sciences and Engineering Division under Contract No. DE-SC0012704.

11:00 AM EP13.05.02
Thermoelectric Properties and Topology of Phosphides
Claudia Felsen$^1$, Johannes Gooth$^2$, Satya N. Guin$^2$, Chenguang Fu$^2$ and Sarah J. Watzman$^1$
$^1$Department of Mechanical and Materials Engineering, University of Cincinnati, Cincinnati, Ohio, United States; $^2$Solid State Chemistry, Max Planck Institute Chemical Physics of Solids, Dresden, Germany.

Topology, a mathematical concept, became recently a hot topic in condensed matter physics and materials science. The topology of the electronic structure of a material determines the electronic, thermal and magnetic properties of solids. All known materials can be reclassified through the lens of topology [1]. Beside of Weyl and Dirac fermions, new
fermions can be identified via linear and quadratic 3-, 6- and 8-band crossings stabilized by space group symmetries [2]. Weyl semimetals, a new class of topological phases were found in NbP, NbAs, TaP, MoP and WP [3-13]. In NbP nano wires we have observed the chiral and a mixed gravitational anomaly [9, 10]. Additionally, NbP [10] and WP [11] show evidence for a hydrodynamic flow of electrons, which violated strongly the Wiemann-Franz law. MoP and WP show exceptional transport properties such as high conductivity (better than copper), high mobilities and a large magneto-resistance [6, 7]. In WP2 a transition from a hydrodynamic electron fluid below 15 K into a conventional metallic state at higher temperatures is observed in thermal and magneto-electric transport experiments [11]. The hydrodynamic regime is characterized by a viscosity-induced dependence of the electrical resistivity on the square of the channel width that coincides with as strong violation of the Wiedemann-Franz law. Single crystalline NbP shows an exceptional high Nernst-effect with a strong magnetic field dependence [12, 13]. Even polycrystalline, spark plasma sintered samples of NbP show still a large Nernst thermopower value of ~90 μV/K and power factor of ~35×10−4 W mK−2 at 9 Tesla. Also in magnetic samples, such as Co2MnAl and Co2MnSe2, we can design giant Nernst effects due to an strongly enhanced Berry curvature [14, 15]. In general, the concept of topology might enable us to design more energy efficient materials for thermoelectric applications and beyond.

11:30 AM EP13.05.03
Slow Diffusion-Fast Vibration Model in Superionic Conductor Thermoelectric AgCrSe2
Lin Xie, Di Wu, Hongliang Yang, Yong Yu, Yifan Wang and Jiaping He;
Department of Physics, Southern University of Science and Technology, Shenzhen, China.

Phonon Liquid-Electron Crystal (PLEC) thermoelectric materials based on superionic conductors have attracted a number of research interest for their ultralow lattice thermal conductivity. It is proposed that the mobile ions are liquid-like, which either gives rise to a reduction of specific heat from the solid limit to the liquid limit, or the vanish of mean potential for transverse waves. However, it is debated if the timescale of the mobile ions is fast enough to interrupt phonon and the low is instead attributed to anharmonicity. In this talk, we will report the study of superionic conductor AgCrSe2, from the low temperature metallic phase to the high temperature superionic phase by in-situ scanning transmission electron microscopy (STEM) and ab-initio molecular dynamics simulation. We discovered that the mobile Ag+ ions in the “liquid-like” superionic phase are not randomly distributed in between neighboring CrSe2 layers as in liquids, but on average still tend to dwell at lattice sites as in a positional disorder solid. The preferential occupation of mobile ions at lattice sites indicates that the diffusing ions are weakly bonded to a potential and thus they cannot move freely as in liquids. According to our theoretical calculations, it is revealed that the characteristic timescale for Ag+ diffusion is relatively slower than phonon vibrations. The calculated probability distribution of Ag+ atoms also demonstrates the same preferential occupation at lattice sites feature as observed experimentally. Therefore, the ion diffusion and vibrations are decoupled in a slow diffusion-fast vibrations way and we suggest that diffusion is not able to strongly interrupt phonon vibrations. Instead, phonon vibrations are significantly affected by the cation disorder, just as in phonon glass thermoelectric materials. The ultralow of AgCrSe2 at its superionic phase can be explained by disorder according to the lattice gas model or Cahill’s model for disordered solids.

11:45 AM EP13.05.04
Thermoelectric Transport Properties of Iodine Doped Phthalocyanine Copper (CuPc)
Yanling Chen and Lidong Chen; Shanghai Institute of Ceramics, Chinese Academy of Science, Shanghai, China.

Metal phthalocyanine compounds are considered as the potential thermoelectric materials because of their good heat and chemical stability. But the poor electrical transport properties greatly impede their application. Chemical doping is an efficient method to optimize the electrical transport properties of organic semiconductors. In this work, we systematically studied the effect of iodine doping on the thermoelectric properties of copper phthalocyanine (CuPc). A series of CuPcI (x=0, 0.5, 0.75, 1.0, 1.25, 1.5, 1.6 and 1.75) were prepared by heating in an iodine ambient at 400 K. The microstructure and charge carrier transport process of the CuPcI were characterized by XRD, SEM, XPS, c-AFM and PPMS. The results suggested that CuPc could be successully doped by iodine and formed two phases CuPc and CuPcI. The amount of the two phases could be detected by the XRD refinement and ion chromatography. The electrical conductivity of iodine doped CuPc samples significantly increased in comparison to the pristine sample, which was due to formation of the three dimension percolation path of the conductive CuPcI. Moreover, it was noticed that the electrical conductivity and Seebeck coefficient of these iodine samples were decoupled, which was ascribed to the low electron energy filtration effect introduced by the CuPc/CuPcI interface. As a result, the highest electrical conductivity of iodine doped CuPc was up to 914 Sm−1, about 11 orders of magnitude of the undoped sample, and the maximum seebeck coefficient of 65 μV K−1 was obtained. Finally the optimum ZT value reached 0.038 at 300 K.
of each atom using Zintl chemistry that offsets the energy penalty of forming defects in nearly all cases. Thus, we propose a valence balanced rule to understand the ground state stability of half-Heuslers irrespective of stoichiometry and nominal electron count (8, 18 or 19). Using this generalized rule we (a) predict 16 previously unreported nominal 19-electron XYZ half-Heuslers, (b) rationalize the reports of giant off-stoichiometries in compounds such as Ti₇₅₅NiSb which has been known for over 50 years and (c) discover a new class of low thermal conductivity quaternary half-Heuslers. Of the new compounds predicted here, new ternary (Ti₅₁₅PbSb) and quaternary compounds were synthesized and the half-Heusler phase confirmed through X-ray studies. Thermoelectric performance of typical defect-free half-Heuslers based on equiatomic XYZ stoichiometry are limited by their intrinsically high thermal conductivity. Flexibility in stoichiometric control of the half-Heusler systems to attain a stable valence balanced composition by accommodating large defect concentrations opens up new dimensions of low thermal conductivity defective half-Heuslers.

2:15 PM EP13.06.03

The high demand on cost-effective renewable power generation has led to intensified research interest in thermoelectric (TE) materials. Filled skutterudite alloys have attracted the greatest interest due to their suitable band gap, high carrier mobility, low-cost and benign constituent elements. In order to further lower the thermal conductivity and improve figure of merit, multi-fillers, e.g. Yb, Eu, La, Ba, Na etc., have been considered to maximize the phonon resonant scattering resulting from varying vibrational frequencies of fillers. However, the correlated behavior of electrical conductivity, Seebeck coefficient and thermal conductivity has limited the gain in figure of merit (ZT). Bulk heterojunction structure in organic solar cells offers a good mechanism for optimized electron transport. In the present study, mixed alloy comprising of (Ba, Yb, Ca₃,Co₃Sb₄, and In₃,Co₃Sb₂, was obtained by high energy ball milling and characterized for TE performance. High ZT values of 1.3 at 700 K have been achieved. The mixture of two different compounds induces an isotype heterojunction structure, which results in enhanced carrier mobility. A DFT calculation on the mixed materials band structure is conducted to understand the formation of heterojunction. Nano-grains achieved by high energy ball milling enhances the phonon scattering on mesoscale level and decreases thermal conductivity due to the decrease of thermal diffusivity and heat capacity. Quantum effect on electron transport based on both theoretical calculation and Hall measurement have been discussed.

Intrinsically Low Thermal Conductivity in Metal Chalcogenides for High Performance Thermoelectric Energy Conversion Kanishka Biswas; New Chemistry Unit, Jawaharlal Nehru Centre for Advanced Scientific Research (JNCASR), Bangalore, India.

One of the fundamental challenges in developing high-performance thermoelectric materials has been to achieve low lattice thermal conductivity (κ_L). The exploration of new materials with intrinsically low κ_L along with a microscopic understanding of the underlying correlations among bonding, lattice dynamics and phonon transport is fundamentally important towards designing promising thermoelectric materials. InTe [i.e. In²⁺Te⁻], a mixed valent compound, exhibit an ultralow κ_L, which manifests an intrinsic bonding asymmetry with coexistent cationic and anionic substructures. The phonon dispersion of InTe exhibits, in addition to low-energy flat branches, weak instabilities associated with the rattling vibrations of In⁺ atoms along the columnar ionic substructure. These weakly unstable phonons originate from the 5s lone pairs of adjacent In⁺ atoms and are strongly anharmonic, which scatter the heat-carrying acoustic phonons through phonon-phonon interactions. Similarly, a Zintl compound, TlInTe, also exhibit ultralow κ_L due to low energy rattling modes of weakly bound Tl⁺. Soft phonon modes and optical-acoustic phonon coupling cause an ultralow lattice thermal conductivity in the room-temperature hexagonal phase of AgCuTe, while the dynamic disorder of Ag/Cu cations leads to reduced phonon frequencies and mean free paths in the high-temperature rocksalt phase. A high thermoelectric figure of merit (ZT) of 1.6 is achieved in the p-type AgCuTe at ~670 K. Recently, we have shown that the localized vibrations of Bi bilayer leading to ultralow lattice thermal conductivity and high thermoelectric performance in weak topological insulator n-type BiSe near room temperature.

4:00 PM EP13.07.02
N-Type Cubic GeSe Stabilized by Entropy Driven Alloying of AgBiSe₃ Leads to Ultralow Thermal Conductivity and Promising Thermoelectric Performance Subhajit Roychowdhury, Tanmoy Ghosh, Raaga Arora, Umesh V Waghmare and Kanishka Biswas; JNCASR, Bangalore, India.

n-type Ge-chalcogenides with promising thermoelectric performance is urgently needed to match their p-type counterparts. However, their realization remains elusive due to intrinsic Ge vacancies which make them p-type semiconductors. GeSe crystallizes into a layered orthorhombic structure similar to the SnSe at ambient conditions. High symmetry cubic phase of GeSe is predicted to be stabilized either by applying external pressure of 7 GPa or by enhancing the entropy through solid solution mixing. The interplay of positive and negative chemical pressure anomalously changes the band gap of GeSe with increasing the AgBiSe₃ concentration. The band gap of n-type cubic (GeSe)ₙ(1-x)(AgBiSe₃)ₓ possesses a value in the 0.3-0.4 eV range, which is significantly lower than orthorhombic GeSe (1.1 eV). Cubic (GeSe)ₙ(1-x)(AgBiSe₃)ₓ exhibits an ultralow lattice thermal conductivity (κ_L ~ 0.43 Wm⁻¹K⁻¹) in the 300-723 K temperature range. The low κ_L is attributed to significant phonon scattering by entropy driven enhanced solid solution point defects.

4:15 PM EP13.07.03
Study of Thermoelectric Properties of Mixed Phase Bi₂Se₃ Films Made by Electrodeposition Md Golam Rosul, 1 Rasim Ahmed,2 Mona Zebarjadi,1, 2 and Giovanni Zangari; 1Electrical and Computer Engineering, University of Virginia, Charlottesville, Virginia, United States; 2Materials Science and Engineering, University of Virginia, Charlottesville, Virginia, United States.

Polymorphism in Bi₂Se₃ allows it to be tuned for unique electrical, thermal and optical properties. The commonly reported rhombohedral structure exhibits semi-metallic properties corresponding to a band gap of 0.32 eV and has been widely studied for thermoelectric applications and as topological insulators. The alternative orthorhombic structure is more semiconducting and has been reported to have a band gap close to 1.2 eV. The opportunity to fabricate a mixture of these orthorhombic and rhombohedral structures provides a chance for materials engineering with the aim of optimizing its electrical and thermal properties. Here we report the room temperature Seebeck coefficient and electrical resistance of mixed phase n-type Bi₂Se₃ films. Bi₂Se₃ films with Bi:Se atomic fraction of 38:62 was prepared by electrodeposition using an acidic bath. The XRD pattern of the electrodeposited Bi₂Se₃ films confirmed the existence of a mixed phase structure where the orthorhombic phase was found to be improved upon emergence and subsequent
Thermoelectric materials enable direct conversion between electricity and thermal energy. Therefore, most of previous studies on thermoelectric materials focus on the electrical and thermal properties. Herein we will explore the interesting optical properties of thermoelectric materials. First, we demonstrate the promising ultra-broadband phonon-enhanced optical properties. Precise control of carrier density is essential to synthesize high-performance thermoelectric materials. Doping by impurities is often frustrated in n-type Bi2Te3 alloys by incomplete activation, bipolar doping, the formation of secondary phases, and prevailing intrinsic point defects such as vacancies. This weakens the reproducibility of synthesis processes and reduces the long-term reliability of material performance. Hence, aging. Here, we explore an impurity-free doping technique to synthesize n-type bismuth tellurium selenides, combining a cold deformation and a hot extrusion. The cold deformation enables controlling the electron density in the range of \( \sim 10^{19} \text{ cm}^{-3} \). Consequently, the development of innovative technology for energy conservation in the cement industry is urgently needed. The large amount of energy from exhaust gases could potentially be used for waste heat energy recovery to generate other forms of energy. Thermoelectric power generators (TEG) could be used for such recovering of waste heat. In this work, the performance assessment of an exhaust thermoelectric generator for cement sector application is investigated with emphasis on the heat exchanger and the optimization of its geometric characteristics. A pin-fin array was considered into the exhaust duct to form the heat absorber, which could increase the heat-exchange surface area and time. This is expected to increase the temperature on the hot side of the thermoelectric module, leading to higher energy conversion and efficiency of the device. Moreover, the influence on the efficiency of the height, length and spacing of the fins is analysed for the fixed width and length of the TEG. The influence of geometric parameters of the fins on the TEG efficiency was carried out using a standard orthogonal array of the Taguchi method. An L27 orthogonal array with four controlling factors at three levels was employed in this design of experiments method. The proposed design, through the Taguchi method, leads to a significant increase of output power and increased energy recovery of the thermoelectric generator.

Theoretical Analysis of Evaporative Cooling to Enhance the Performance of Thermoelectric Device

Due to the increasing environmental awareness and rising cost of energy, there is a growing demand to develop renewable energy systems that reduce our reliance on fossil fuels [1]. Thermoelectric generator is a promising technology that cleanly converts temperature difference to electricity on the basis of Seebeck effect. Therefore, to maximize power-generation efficiency of thermoelectric generator, except the figure of merit, ZT, should be as high as possible, the temperature differential between the hot and cold sides also should be as large as possible [2]. In this work, we utilize evaporative cooling technology as opposed to the traditional heat sink to cooling the thermoelectric generator cold side. By combining thermodynamics and heat & mass transfer theory, the numerical model of thermoelectric generator with film water evaporative cooling is established in this study. And the numerical model has been constructed to consider temperature-dependent thermoelectric material properties, heat loss due to radiation and conduction, and Thomson effect. Based on the numerical model, the performances of a typical thermoelectric generator are simulated. Here, the thermoelectric generator hot side temperature is fixed into 50-150 Celsius degree, the thermoelectric generator cold side is covered by thin film water. The ambient temperature is 25 Celsius degree, the relative humidity of the air is set from 25 to 75%. The results show that when fixed the relative humidity, the higher hot side temperature, the higher output power and efficiency; when fixed the hot side temperature, the lower relative humidity, the higher output power and efficiency. Therefore, the maximum power output of 0.272 W and the maximum efficiency of 2.25% are available when the temperature of the hot side is 150 Celsius degree and the relative humidity is 25%. The theoretical model and calculation method may be applied to the prediction and
conducting polymers (CPs) have attracted extensive attention due to the advantages of mechanical flexibility, abundant elements, nontoxicity, as well as intrinsically low thermal conductivity (k) and high electrical conductivity (σ). Among them, Poly(3,4-ethylenedioxythiophene)poly-(styrenesulfonate) (PEDOT:PSS) is a promising candidate as the next-generation thermoelectric (TE) material arising from the advantages of excellent thermal stability, high transparency, and solution preparation. In this work, the TE properties of PEDOT:PSS films were effectively improved by a sequential treatment with a binary secondary doping and solution of hydrazine in DMSO at the optimized the oxidation level. Initially, doping with formic acid and then further treated with formamide improved the σ from 0.3 to ~2604 S/cm while the Seebeck coefficient (S) decreases from 17.5 to 14.5 μV/K resulting a power factor (PF) of 54.8 μW/Km at the optimum concentration of the dopants. Then, the formic acid-formamide doped PEDOT:PSS films were further doped with a solution of DMSO and hydrazine with different hydrazine concentrations. During the DMSO-hydrazine solution doping, the σ of the films decreased from 2604 to 661.3 S/m whereas the S increased from 14.5 to 41.3 μV/K due to a decrease in the carrier concentration (n), resulting in a PF of 112.8 μW/Km at the optimum oxidation level. The obtained maximum PF is almost 11280 times higher than that shown by untreated PEDOT:PSS films. Besides the k of the pristine PEDOT:PSS films decreased from 0.59 to 0.29 W/Km due to the removal of PSS after treatment. At this lowest k value, a ZT value of ~0.12 was obtained at 300K.

There is a recent interest in semiconducting superlattice films because their low dimensionality can increase the thermal power and phonon scattering at the interface in superlattice films. However, experimental studies in all cross-plane TE properties, including thermal conductivity, Seebeck coefficient, and electrical conductivity, has not been performed from these semiconducting superlattice films, because of substantial difficulties in the direct measurement of the Seebeck coefficient and electrical conductivity. Unlike the conventional measurement method, we present technique a structure of sandwiched superlattice films between two embedded heaters as heating source, and electrodes with two Cu plates, which directly enables the investigation of the Seebeck coefficient and electrical conductivity across the AO/ZnO superlattice films, prepared by atomic layer deposition (ALD) method. Used in combination with the promising cross-plane four-point-probe 3-α method, our measurements and analysis demonstrate all cross-plane TE properties of AO/ZnO superlattice films in the temperature range from 80 to 500 K. Our experimental methodology and the obtaining results represent a significant advancement in the understating of phonon and electrical transports in nanostructured materials, especially in semiconducting superlattice films in various temperature ranges.

Metal dichalcogenide thin films, such as bismuth telluride and molybdenum disulfide were successfully deposited on different substrates using radio-frequency magnetron sputtering technique. The structural, morphological, and thermoelectric transport properties of bismuth telluride and molybdenum disulfide thin films have been investigated systematically to develop a high-efficient thermal energy harvesting thermoelectric device. The magnitude of the Seebeck coefficient of bismuth telluride thin films decreases with increase in film thickness. Bismuth telluride grown at 350°C displays a maximum Seebeck coefficient of -126 μV/K at 435 K. The performance of the device shows a very strong dependence on the different growth temperature of the film. The power factor increases from 0.009 W/mK² at Room temperature to 0.014 W/mK² at 350°C. Molybdenum disulfide films show the positive Seebeck coefficient values and their Seebeck coefficient increases with film thickness. The AFM images of bismuth telluride thin films display a root-mean-square (rms) roughness of 32.3 nanometer and molybdenum disulfide thin films show an rms roughness of 6.99 nanometer when both films were deposited at 350°C. The open-circuit voltage of 130 mV shown by the pn-junction thermoelectric generator (TEG) device at 393 K. We have demonstrated a highly efficient pn-junction TEG device for waste heat recovery applications.

The thermoelectric dream is one in which thermoelectric materials can be used for energy generation and harvesting in a commercial sense at high efficiency and low cost. Efficiency is hard to achieve for most thermoelectric as electrical and thermal conductivity are closely related and correlated. The efficiency of any thermoelectric device is given by a quantity which called the figure of merit ZT. For thermoelectric devices to be viable alternative energy source they should achieve a ZT greater than 2. Here we report on a thermoelectric device based on Bi₂Te₃/W₃S superlattice structure created through radio frequency (RF) magnetron sputtering deposition. Quantum confinement in these low dimensional layers creates a high density of carriers near the Fermi level thereby enhancing the electrical conductivity and ZT. The ZT is increased by increasing these layers through the scattering of short wavelength phonons by picking layer thicknesses less than the phonon free mean path. This makes the structure a good electrical conductor while limiting the thermal conductivity thus beginning to decouple these two material properties.

A System for Thermomagnetic Transport Properties Measurement from 80 K to 400 K Roger Dorris, Randy Sterbentz, Juan P. Tolento, Dominic Gallelli and Matt Beekman; California Polytechnic State University, San Luis Obispo, California, United States.

Experimental determination of material quantities such as the charge carrier density of states effective mass and dominant charge carrier scattering mechanism can provide important insight into the performance of thermoelectric materials, and plays a central role in contemporary thermoelectric materials research. In this context, measurement of the Nernst coefficient, which is sensitive to the scattering mechanism, provides useful additional information that complements the traditional measurement of electrical resistivity, Seebeck coefficient, and Hall coefficient. Here we describe a custom measurement system capable of measuring all four of these galvanomagnetic and thermomagnetic transport coefficients as a function of temperature from 80 K to 400 K, in magnetic fields from ~1 T to 1 T, on both bulk and thin films samples. In addition to data on the system’s
Synthesis and Thermoelectric Performance of Ceramic Composites Julius F. Rodriguez, Adam Sebastian Gutierrez and Luis Carlos Moreno; Univ Nacional de Colombia, Bogota DC, Colombia.

\[ \text{La}_{0.5}\text{Ca}_{0.5}\text{CoO}_3 \] polycrystalline thermoelectric ceramics with small amounts of metallic \( \text{La}_1 \text{Sr}_2\text{CuO}_4 \) have been fabricated by solid-state reaction method. The effects of introducing metallic ceramics on the thermoelectric and transport properties of \( \text{La}_{0.5}\text{Ca}_{0.5}\text{CoO}_3 \) have been studied. The transport properties were studied in the temperature range between 85 and 300K. The thermoelectric performance of \( \text{LaCoO}_3 \) ceramics was improved as a consequence of the Ca doping and metallic \( \text{La}_1 \text{Sr}_2\text{CuO}_4 \) adding. The composite exhibits maximum values for the thermoelectric power factor, PF, and the dimensionless figure of merit, ZT close to 28 mW/K²·cm and 0.5, respectively. Thus, the observed behavior in the transport properties become these composites promising materials for use in thermoelectric devices for low-temperature applications.

Relationship Between Thermoelectric Properties and Morphology of Doped P3HT Thin Films for Potential Thermoelectric Applications Jonathan J. Montes and Harold O. Lee; Norfolk State University, Norfolk, Virginia, United States.

Polymeric conjugated materials are very promising for developing future soft material-based semiconductors, conductors, electronic and optoelectronic devices due to their inherent advantages such as lightweight, flexible shape, low-cost, ease of processability, ease of scalability, etc. There are numerous ways to tune material properties via post-processing treatments. One way to enhance device performance is through the process of thermal annealing. Annealing allows for polymer thin films to self-assemble into a lower energy conformation which typically leads to better morphology and higher charge mobility. What is yet to be fully understood is how film morphology is related to the Seebeck coefficient of a material. In this study, we observed the relationship between the Seebeck coefficient, various annealing times and temperatures, and doping concentration with doped P3HT thin films. Our results can provide insight into how can develop high performance organic thermoelectric materials post-processing techniques.

Ultralow Thermal Conductivity and High Thermoelectric Figure of Merit in Polycrystalline SnSe Yong Kye Lee1,2 and In Chung3,4; Chemical and Biological Engineering, Seoul National University, Seoul, Korea (the Republic of); 3Center for Nanoparticle Research, Institute for Basic Science, Seoul, Korea (the Republic of).

A remarkably high thermoelectric figure of merit \( ZT \) of ~2.6 at 923 K was recently reported in p-type SnSe single crystals along the crystallographic b-axis. Afterward, realizing comparable thermoelectric performance in the polycrystalline counterparts have been intensively investigated. However, polycrystalline SnSe-based materials unexpectedly exhibit much higher thermal conductivity than the single crystals, resulting in far poorer thermoelectric performance in the former. In this presentation, we hypothesize that surface oxidation would be the main origin of their high thermal conductivity. To solve this issue, we introduce an oxygen-removal process under mildly reductive atmosphere. As a result, we are able to achieve the ultralow lattice thermal conductivity and thereby markedly enhanced \( ZT \) in polycrystalline SnSe-based materials, which are comparable to those in their single crystals.

Rapid Synthesis and Fabrication of Thermoelectric Materials Using Advanced Manufacturing Technique Jianxu Shi, Hualing Chen and Wnajian Wang; 1Louisiana State University, Baton Rouge, Louisiana, United States; 2Mechanical Engineering, Xian Jiaotong University, Xian, China.

The conventional forming processes for thermoelectric bulk materials, such as hot press, cold press, spark plasma sintering, plasma activated sintering and others, require thermoelectric alloyed powders as raw materials. While the conventional synthetic methods of thermoelectric alloyed materials require very long time of combination reaction due to slow heating and cooling processes. It typically needs a heat preservation of several hours to achieve uniformity of reaction using lower energy density of heat source. Consequently, the balance between performance and fabrication costs plays a vital role in thermoelectric application.

We report a rapid and scalable synthetic method of thermoelectric materials using selective laser melting (SLM) of powder bed with a thickness of 2mm. The mixed powders of thermoelectric element granule in stoichiometric ratio are used as starting materials. Alloy was then formed using SLM method with very high energy density. \( \text{Sb}_2\text{Te}_3 \) bulk with the merit number \( ZT \) at 0.4 was SLM-synthesized. This is comparable with that of the \( \text{Sb}_2\text{Te}_3 \) bulk obtained using conventional melting technology. \( \text{Bi}_2\text{Sb}_3\text{Te}_5 \) bulk was also SLM-synthesized with its \( ZT \) at 0.64. The SLM-synthesized time of thermoelectric materials processed is less than 30 min, compared to tens of hours for conventional melting process. SLM-synthesized method therefore opens up a novel way for rapid, scalable and low-cost manufacturing thermoelectric materials.

Positive and Negative Thermopower by Compositional Tuning of Hybrid Halide Perovskites Md Azimul Haque, Mohammad Insan Nugraha, Sri Harish Kumar Paleti and Derya Baran; KAUST, Jeddah, Saudi Arabia.

Hybrid halide perovskites have recently received exponential interest due to their extraordinary photovoltaic performances.[1] Apart from solar cells, multitude of other applications such as photodetectors, lasers, LEDs, and memory devices have been already demonstrated underpinning the versatile nature of halide perovskites.[2] Despite the unprecedented performance of other hybrid perovskid, their other crucial physical properties such as thermal transports have received limited attention. The majority of the works on thermal transport of hybrid perovskides are accomplished using single crystals or polycrystalline pellets with limited information on seebeck coefficient.[3] Furthermore, in-plane thermal conductivity and seebeck coefficient of \( \text{CH}_3\text{NH}_3\text{PbI}_3 \) films remains largely unexplored. Thermal transport behaviors strongly correlate with material structure and its meticulous understanding is imperative for thermal management of efficient and high performance devices. In this work, we systematically investigate the thermal conductivity and thermopower of sequential vapor deposited \( \text{CH}_3\text{NH}_3\text{PbI}_3 \) films. An ultralow in-plane thermal conductivity of 0.3 Wm⁻¹K⁻¹ at room temperature was recorded for \( \text{CH}_3\text{NH}_3\text{PbI}_3 \) using a chip-based \( S \)-method. Temperature-dependent thermal conductivity measurement of a series of \( \text{CH}_3\text{NH}_3\text{PbI}_3 \) films with different degree of methylammonium treatment reveal that the thermal conductivity value is governed by \( \text{PbI}_2 \) octahedron framework. Furthermore, \( n- \) and \( p- \) type \( \text{CH}_3\text{NH}_3\text{PbI}_3 \) films were achieved by compositional tuning of the precursors (\( \text{CH}_3\text{NH}_3 \) and \( \text{PbI}_3 \)) resulting in high positive and negative thermopower. The effect of self-doping and defects on the thermopower along with the implications of the present work on future thermoelectrics based on hybrid perovskides will be discussed.

Performance of an Active Peltier Cooler for Electronics/Batteries Michael J. Adams1, Mark A. Verosky1, Mona Zebjarjadi2 and Joseph P. Heremans1; 1The Ohio State University, Columbus, Ohio, United States; 2University of Virginia, Charlottesville, Virginia, United States.

The design rules for active cooling systems of electronic devices or batteries are quite different from those for Peltier refrigeration. Peltier modules made from tetradymite materials [1] are used commercially for refrigeration, pumping heat opposite the natural direction, but have yet to compete in active cooling where the heat flux from a hot source to a cold sink is the parameter that must be optimized. In particular, a high thermal conductivity is beneficial in the materials used for active cooling, since it allows a higher heat load to be carried away from the device to be cooled, whereas it is obviously detrimental to the \( ZT \) of a Peltier element used in refrigeration mode. The real objective of active cooling is to maximize the effective total thermal conductance, due to both the Fourier and the Peltier heat fluxes, rather than the \( ZT \), which determines the minimum reachable cold temperature in a refrigeration application. Optimal materials for maximum active cooling are those with high thermoelectric power factor and high thermal conductivity [2]. Metals with large thermopower due to magnon drag offer such a prospect. A cooling module is constructed from several possible \( n \) and \( p \)-type metals with high thermoelectric power factor. It is connected so as to pump heat from a variable-power heater into a heat sink. The thermal conductance is first characterized against the temperature gradient in the
absence of a Peltier current (passive cooling mode). It is then characterized again in the presence of an electrical current that maximizes the Peltier heat flux (active mode). The ratio of the thermal conductance of the cooler in active and passive mode is shown as a function of temperature drop and background temperature. The dynamic response is further analyzed and compared to the time constant predicted by thermal resistance and capacitance.

**Developing and Testing of an Experimental Concept of a Hybrid Solar Thermoelectric (HSTE) System**

Paulina V. Escobar, Andrea Arias, Diego I. Oyarzun, Tomas Salinger and Amador M. Guzman; Pontificia Universidad Catolica de Chile, Santiago, Chile; Stanford University, Stanford, California, United States.

In this study, for the first time, we fabricate the thermoelectric mushroom geometry. The model includes Peltier heating at material interfaces and Thomson heating within materials using experimentally measured Seebeck coefficients. The mushroom does not need to be completely amorphized to achieve good memory windows. However, it takes significantly longer times to achieve these operations. Additionally, grain boundary amorphization drastically reduces reset and set times in nanocrystalline GST (down to ~1 ns) as the mushrooms do not need to be completely amorphized to achieve good memory windows.

We measure voltage, current, and temperatures to demonstrate the technical feasibility and performance of the HSTE. Three working fluids were used: deionized water, 10% ethylene glycol and 20% ethylene glycol. The operating characteristic curves are presented under different flow rates in the condensation zone and input powers in the cartridge heater. We found that the best performance occurs for a supplied heat of ~120 W and deionized water as the working fluid. Under this condition, we achieve a maximum of 187.69 mW of electrical power and a maximum of 80.49 W extracted heat in the condenser zone. In general, among the working fluids used deionized water presented the best heat recovery and electricity generation.

In brief, we demonstrate the coupling of a thermosyphon and TE module for heat extraction and electricity generation in a HSTE concept. Future work includes modifications to the system to decrease the energy losses and increase the electricity generation. We also work towards a device that could generate energy for domestic and industrial applications.

**EPI.13.08.17**

**Thermoelectric Properties of Printed Oxide pn Modules**

Yooboon Park, Kyoungah Cho and Sangsik Kim; Korea University, Seoul, Korea (the Republic of).

Oxide materials as thermoelectric materials have been recently researched since they are eco-friendly materials unlike conventional thermoelectric materials such as lead selenide and bismuth antimony telluride. On the other hand, screen printing technique has been widely used for printed electronics. In order to extend the application of oxide thermoelectric devices, it needs to explore the possibility of screen printing process as fabrication technology for oxide thermoelectric pn modules. Hence, we attempt to fabricate square printed oxide pn modules and investigate the thermoelectric characteristics. Herein, we chose n-ZnO and p-Cu2O as representative oxide materials. The ZnO paste was printed on a Si substrate and annealed at 400 °C for 30 minutes before Cu2O paste was printed on the substrate and annealed at 200 °C for 30 minutes. And two Au electrodes (Ea and Ecold) were deposited with an interval of 1 cm. Then the Seebeck coefficients of the n-ZnO and p-Cu2O films were measured.

We use a finite-element PCM model which captures stochastic nucleation, growth, and grain boundary melting to demonstrate thermoelectric effects in a cell with a “double mushroom” geometry. The model includes Peltier heating at material interfaces and Thomson heating within materials using experimentally measured Seebeck coefficients for fcc and amorphous GST (Ge85Sb15), TiN, and SiO2. The double mushroom cell consists of two phase change layers sandwiching an insulating layer which contains a conductive filament. The switching region of the device is in the hearth of the geometry, thermally isolated from the top and bottom contacts by GST layers. This geometry is symmetric and serves as a suitable platform to demonstrate the impact of thermoelectric effects on cell behavior.

Our simulation results show that it is possible to amorphize a single mushroom with lower reset currents (above or below the filament depending on polarity) or two mushrooms both below and above the filament with higher reset currents. Our analysis includes the polarity dependence of both set and reset operations, resistance ratios and the necessary time to achieve these operations. Additionally, grain boundary amorphization drastically reduces set and reset times in nanocrystalline GST (down to ~1 ns) as the mushrooms do not need to be completely amorphized to achieve good memory windows. The crystal grains embedded in the amorphous regions eliminate the need for nucleation, allowing for very fast set but increasing cell-to-cell and cycle-to-cycle variability.

**Thermal Conductivity of Organic-Inorganic Hybrid Perovskite Single Crystals**

Kotaro Matsuyama, Thai Mai H. Doung and Hirokazu Tada; Osaka University, Toyonaka, Japan.

Thermoelectric conversion devices directly convert thermal energy into electricity. In recent years, these devices have received significant attention for their potential to convert waste heat into electricity. Metallic materials like Bi2Te3 with a ZT (figure of merit) value around 1 and a high thermoelectric conversion efficiency, and have been target of research since the 1950s. Despite these efforts, thermoelectric devices are yet to be utilized on a large scale due to their low thermoelectric conversion efficiency and high cost. Hybrid materials utilizing the properties of both organic and inorganic materials have been the subject of many recent studies. Organic-inorganic perovskites have been reported to
have low thermal conductivity and high Seebeck coefficients and are an appealing candidate for use in thermoelectric materials [1],[2]. Various structure of organic-inorganic prepared perovskite. We measured thermal conductivity (k) of these crystals using the steady-state method. We prepared various structures of 1D and 2D single crystals of hybrid perovskites by turning the preparation conditions and organic molecules inserted between the perovskite layer [3]. It was found that a 1D crystal with methyl pyridine showed k of 0.14 (W/mK) while that with pyridine-thiol showed k of 3.3(W/mK). In my presentation, the relationship between the crystal structure and the thermoelectric parameters, and determine the combination that optimizes the thermoelectric conversion efficiency.

The Role of α- and β- FeSi2 Interfaces on Thermoelectric Properties of Si Rajasekar Parasuraman and Arjun M. Umarij; Materials Research Centre, Indian Institute of Science, Bengaluru, India.

Thermoelectric power generation is a reliable and environmentally friendly technology to convert waste heat into a useful form of energy, which does not involve any moving parts or toxic gas emissions. However, practical application of this technology needs the exploration and development of materials which can be designed, cost-effective and mass produced. Si-based composite materials have been extensively studied for thermoelectric applications because they are cheap, abundant, non-toxic and environmentally friendly. In literature, thermoelectric properties of Si/Ni/Si, Si/β-FeSi2 and Si/CoSi2 composites are studied [1][2].

Si/α-FeSi2 composite has not been studied widely due to metallic nature and the structural transition of α-FeSi2 at 1210 K. However, it is shown in the literature that α-FeSi2 is stable even near room temperatures at Si-rich conditions [3]. Hence, the composite samples of Si/α-FeSi2 and Si/β-FeSi2 have been synthesized by controlling Fe incorporation during mechanical milling. Thermoelectric properties of the samples with α- and β- interfaces have been studied. Si/α-FeSi2 shows higher electrical conductivity and low thermal conductivity, due to the coherency with Si in ‘c’ direction and presence of ‘Fe’ vacancies. This intrinsic ‘Fe’ vacancies act as phonon scattering centers to lower the thermal conductivity. Increased electrical conduction and the reduction in thermal conductivity enhanced the thermoelectric performance of Si/α-FeSi2 composite. Further, Si/α-FeSi2 composites with varying ‘Fe’ vacancy concentration and chemical dopings can be employed to improve the thermoelectric performance.

EP13.08.22
Superior Performance Bi2Te3/PEDOT:PSS Composite for Three-Dimensionally Printed Flexible Thermoelectric Generators Shuping Lin, Wei Zeng, Lisha Zhang and Xiaoming Tao; Hong Kong Polytechnic University, Hong Kong, Hong Kong.

Flexible, lightweight, solution-processible thermoelectric (TE) generators with high room- or low-temperature performance are much desirable in energy harvesting for wearable microelectronics, active microclimate controlling systems and waste heat utilization.[1-3] However, the thermoelectric generators (TEGs) are facing decades of transformation. Up-to-date, there has been a shortage of thermoelectric materials that can be used for such applications. Hooking up these rigid semiconductors to flexible device technology won’t be straightforward.[1-5] To address the problems of the limitation of flexible TE materials, we develop a superior room-temperature performance of Bi2Te3/PEDOT:PSS inorganic-organic thermoelectric composites, which are suitable for printed three-dimensionally flexible thermoelectric generators.[5] For the materials, the Seebeck coefficient of the optimized TE composite is 273.3 μV/K at room temperature, reaching that of pure Bi2Te3, representing the highest value for Bi2Te3/PEDOT:PSS composites reported so far. The corresponding power factor and ZT is 473.5 μW/mK²and 0.4, respectively. Furthermore, the flexible TEGs were fabricated by three-dimensionally 3D printing on aramid paper and PDMS substrates, respectively. The paper-based thermoelectric generator can produce a higher output power of 30.8 mW, specific power density of 12.3 mW/g and areal power density of 20.5 mW/cm²working at under 70 K temperature difference. More importantly, the variation in electric resistance of the PDMS-based flexible TEG is negligible even after 100,000 bending cycles up to 2.5 cm curvature, demonstrating the excellent flexibility and durability of the resultant flexible thermoelectric generator. Therefore, these solution-processible, soft and flexible inorganic-organic composites offer unique advantages that are not available to their rigid counterparts. The methods and findings in this work pave a way to produce high-performance flexible thermoelectric generators for wearable electronic systems, waste heat harvesting and active microclimate control systems.

Substitutional Effects of Bivalent Zn and Ni Cations on Spin Thermoelectric Properties of Co3O4 Nolan W. Hines1, Gustavo Dans Resende1, Anweeksh Koneru1 and Terence Musho2; 1University of Texas Permian Basin, Odessa, Texas, United States; 2West Virginia University, Morgantown, West Virginia, United States.

Thermoelectric materials show promise in converting waste heat energy in combustion processes to useful energy like electricity. The current low operational efficiencies of thermoelectric materials create difficulties in implementation of these materials for real time applications. Current methodologies such as grain boundary scattering, substitutional effects, band structure engineering, etc., have been utilized to improve the thermoelectric performance, yet have not attained the desired level. An innovative technique is to incorporate these methodologies to semiconducting magnetic thermoelectric materials and extract additional voltage using spin-Seebeck effect, which yields a higher Seebeck coefficient by combining the conversion from conventional charge and spin currents and thus resulting in a higher ZT. Co3O4 is an interesting material with spinel configuration that can allow substitutions with transition metal cations having divalent and trivalent oxidation states. First-principles based density functional theory (DFT) calculations were performed on Zn and Ni substituted Cobalt spinel oxides. The Zn substitution in Co2+ sites resulted in normal spinel structures with no resultant spin polarization, while substituting Cobalt cations with Zn2+ and Ni2+ resulted in a partially inverse spinel configuration with a net resultant spin polarization varying from 0 μB to 4 μB depending on the amount of substitutions. Varying these substitutions alters the spin current due to magnetization fluctuations in the configurational space. DFT calculations executed in quantum espresso were performed on a 56 atom unit cell to find band gap, lattice parameter, effective mass of conduction electrons and spin polarization of each configuration formed with various substitutions of Zn2+ and Ni3+ cations. These fundamental properties were used to perform conventional charge and spin transport calculations by combining non-equilibrium Green’s function approach with spin transport theory to produce a spin transport model. The formalism developed in this research may also be applied to other interesting thermoelectric materials with semiconducting and magnetic properties.

EP13.08.24
Silicides as High Temperature Thermoelectrics for Industry Quansheng Guo, David Berthebaud and Takao Mori; National Institute for Material Science, Tsukuba, Japan.

Thermoelectric power generators are composed of n-type and p-type thermoelectric couples that are connected electrically in series and thermally in parallel and capable of converting heat directly into electricity.[1] The efficiency (h) of thermoelectric power generation technology can be expressed as

\[ h = \frac{\sigma T_c (1 + \alpha T_f)}{\sigma T_c (1 + \alpha T_f) + \sigma T_c (1 + \alpha T_f) T_c / T} \]

where \( T_f \) is hot side temperature, \( T_c \) is cold side temperature and \( z = \alpha a^2 / k \) is the materials’ dimensionless figure-of-merit, where \( a, \alpha, k, T \) refer to the electrical conductivity, Seebeck coefficient, thermal conductivity and the absolute temperature, respectively.[2] Decent performance requires both high electrical transport and low thermal conduction. In addition, thermal stability, machinability, cost and non-toxicity also constitute major issues in thermoelectric devices development.
Considering around 50% of the energy gets lost during its production process and to harvest and convert it into electricity, we focus on materials with potential applications at intermediate-high temperatures. Higher manganese silicides (MnSi2) and iron disilicide (β-FeSi2) are selected as candidates for the p- and n-type legs since both are made of environmentally-friendly and abundant elements. Here we will show the fabrication of thermoelectric devices from silicides with striking thermal stability and attempt to improve the efficiency via reducing contact resistance.

EP13.08.25
Reinvestment of the Point Defects in N-Type Bismuth Telluride Based Thermoelectric Materials Qi Zhang, Yehao Wu, Teng Fang, Tiejun Zhu and Xinbing Zhao; Zhejiang University, Hangzhou, China.

The relatively low properties of n-type polycrystalline bismuth telluride based thermoelectric materials, compared to p-type ones, restrict their application in solid state refrigeration. It is the highly random grain orientation and extremely high electron concentration originated from donor-like effect that attributes to the relatively low properties. The former can be realized by applying pressure, while p-type doping and the manipulation of intrinsic point defects are the solution to the latter. For the manipulation of intrinsic point defects, it is well known that the interaction of vacancies with antisite defects, i.e. the donor-like effect, can explain the sharp increase of electron concentration after grinding, pressing and sintering. However, the evolution of the point defects in preparation process remains elusive. In this study, by changing the particle size and hot press temperature, we reinvestigate the intrinsic point defects in n-type bismuth telluride materials. The results show that not only the mechanical deformation, but also the sintering process is vital to the donor-like effect, which is helpful for understanding the nature and evolution of the point defects.

EP13.08.27

Recently, wearable electronic devices are utilized for sensor, heath monitoring and smart gear, etc. However, self-powered supply modules are required for sustainable and battery-free wearable electronics. Therefore, the demand for self-powered supplies for these devices is urgent, and energy-harvesting modules represent a promising method to achieve self-powered electronic systems. Source of renewable energies such as sunlight, wind or human being from human motion and body heat are being studied for the self-power technology. Among these, the human body can be stable and sustained natural heat energy source and temperature difference (ΔT) can be driven between the body heat and ambient atmosphere. Therefore, Thermoelectric (TE) technology, in which energy is harvested from waste body heat, is one of the most suitable candidate technology to operate wearable electronic device. Wearable thermoelectric modules (WTG) is fast becoming a new platform for powering wireless and portable devices. However, we realized that body heat has a limit to obtain a high temperature difference. In previous our study, we obtained a novel cross-plane type of wearable solar TEG (W-STEG) having not only high flexibility but also high performance by integrating solar absorbers on PI substrates. 500nm thick of five-period Ti/MgF2 super-lattice thin film absorbs 96.3% of sunlight in visible light spectrum and ΔT between the hot and cold sides is up to 20.9 °C. The TE legs are prepared by integrating printable BiTe-based TE ink by dispersing mechanically alloy BiTe-based powder and sintering Sb2Te3 and Te in a high viscosity glycerol solvent. In this study, furthermore, we simulated the heat transfer mechanism from the W-STEG module hot side and we proposed the optimal module design to maximize the temperature difference between the hot side and the cold side. We maximize temperature difference between hot side and cold side integrating PDMS cover on solar absorber to block heat convection transfer and attaching flexible copper foam with large surface area which acted as a heat sink. As a result, when exposed to Sunlight, temperature difference between the hot and cold sides was 33.4 °C. The open circuit voltage of the TEG comprising 10 p-n leg pairs is 74.4 mV and the output power is 11.4 μW.

Non-Equilibrium Thermal Transport and Thermoelectric Effects at the Melt-Solid Interfaces in Semiconductors Sadid Muneer1, Gokhan Bakanc2, Helena Silva2 and Ali Gokirmak1, 1Electrical and Computer Engineering, University of Connecticut, Storrs, Connecticut, United States; 2Electrical and Electronics Engineering, Atılım University, Ankara, Turkey.

Emergence of phase change memory as a viable non-volatile memory technology intensified the interest in high temperature non-equilibrium electro-thermal phenomena at small scales. Phase change memory devices typically operate under large thermal gradients (up to ~50 K/nm) and electrical stresses (up to ~107 A/cm²). The phase change materials transition between the solid and the liquid phases. The general behavior of the phase change devices can be captured by electro-thermal models using temperature-dependent equilibrium values for thermal conductivities, electrical conductivities and Seebeck coefficients1,2. However, as we have observed in our self-heating experiments of silicon microwires, the non-equilibrium processes at the melt-solid interfaces can significantly alter the thermal profiles, hence melting and crystallization dynamics.3 Large number of free electrons and holes are expected to diffuse into the solid material at the liquid-solid interfaces. This injection drastically increases electrical and thermal conductivity due to increased carrier concentrations. Thermal conductivity across the interface is further increased due to heat released by the recombining carriers in the solid. This generation (G) - transport (T) – recombination (R) process (GTR) can be more significant than the electronic convective heat flow by the carriers across the interface. In presence of an electric field at the interfaces, GTR process introduces an asymmetry since minority carriers recombine to release heat if they are drifted into the solid. In a self-heated microwire, this leads to an asymmetric thermal profile that continuously shifts in the direction of the minority carrier flow until a steady state is reached.1,3

Large Valley Degeneracy and High Thermoelectric Performance in P-Type BaCu₄Ge₄₀₆₈-Based Clathrates Hiroki K. Sato, Hiromasa Tamaki and Tsutomu Kanno; Technology Innovation Division, Panasonic Corporation, Seika-cho, Japan.

There is an increasing interest in high-throughput computational screenings of thermoelectric (TE) materials. A representative example is that valley degeneracy and band effective mass have been demonstrated to be relatively easy to calculate, yet strong descriptors for good electronic properties [1,2]. In this study, we have predicted a high TE performance of p-type BaCu₄Ge₄₀₆₈ based on these descriptors, and experimentally confirmed the prediction. Density functional theory calculations for BaCu₄Ge₄₀₆₈ have found that the stoichiometric compound is a naturally p-doped semiconductor with 6-fold degenerated valleys with light band effective masses. It has also been indicated that introduction of Ge substitutions on the Cu site is effective in controlling the chemical potential. Motivated by these calculation results, a series of Ba₅₋ₓCuₓ₅₋ₓGe₄₀₆₈ samples with different Ge substitution amount x were fabricated by arc-melting and spark plasma sintering, and the transport properties were characterized. It has been observed that the carrier type is effectively controlled with x. The p-type sample with x=0.3 shows a high power factor of ~1 mW/mK², and the thermal conductivity is found to be as low as ~1 W/mK. The resulting TE figure of merit ZT is 0.26 near room temperature, and the peak ZT is 0.62 at 615 K. These ZT values are, although somewhat inferior compared to the record of single-crystalline clathrates (ZT~1.5 at around 500 K [3]), one of the highest among polycrystalline samples (ZT~0.5 at the same temperature range [4]). Therefore, this study further emphasizes the strength of the computational screening in search of high-performance TE materials.

Highly Improved Thermoelectric Performance Through Oxygen Manipulation in BiCuTeO
Huiching Chang¹,², Ramon Sankar³, Ying-Jay Yang³, Li-Chyong Chen¹ and Kuei-Hsien Chen².¹Center for Condensed Matter Sciences, National Taiwan University, Taipei, Taiwan; ²Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei, Taiwan; ³National Taiwan University, Graduate Institute of Electronics Engineering, Taipei, Taiwan.

BiCuTeO is one of the potential thermoelectric materials owing to its low thermal conductivity and high carrier concentration. However, the thermoelectric performance of BiCuTeO is still below average and has a large room for improvement. In this study, we manipulated the nominal oxygen content in BiCuTeO and synthesized BiCuTeO$_{x}$ (x=0.94–1.06) bulk by a solid-state reaction and pelletized them by the cold-press method. The power factor was enhanced via the nominal oxygen deficiency due to the increased Seebeck coefficient. In addition, the thermal conductivity was reduced due to the decrease in lattice thermal conductivity owing to the small grain size that was generated by the deficiency in the nominal oxygen content. Consequently, the ZT value enhanced to around 1.1 at 523 K for the stoichiometric BiCuTeO$_{0.94}$ compared to BiCuTeO. Thus, optimal manipulation of oxygen in BiCuTeO can enhance the thermoelectric performance. This study can be applied to developing the oxides with high thermoelectric performance.

EP13.08.31
High-Throughput Screening of Efficient Bulk and Monolayer Thermoelectric Materials
Kamal Choudhary,
National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

While bulk materials are widely used for making thermoelectric devices to convert heat into electricity and vice versa, 2D-monolayers have shown significant potential because of the unique low-dimensional electronic properties. Additionally, although there has been an intensive work in systematic high-throughput discovery of new bulk thermoelectric materials, similar investigations for monolayer and their comparison to bulk materials is still in the developing phase. In this work, we identify both bulk and monolayer thermoelectric materials using semiclassical transport method with density functional theory. We emphasize on inclusion of proper units of thermoelectric properties especially for monolayer materials because of their surface nature rather than bulk 3D nature. We establish the correlations in thermoelectric properties of monolayer materials and their bulk counterparts. We find the density of state at the Fermi-level to be correlated with Seebeck coefficient behavior for both bulk and monolayers. We also show the periodic trends, crystallographic and compositional trends for the whole dataset. After screening a few candidate bulk and monolayer materials, we carry out higher-level Green function based approaches to calculate more reliable thermoelectric properties of the screened materials. We made our results publicly available through NIST’s JARVIS-DFT database (http://jarsv.nist.gov) consisting of more than 3000 bulk and 700 monolayer materials.

EP13.08.32
High Thermoelectric Efficiency in Monolayer PbI$_2$ from 300 K to 900 K
Bo Peng, Hao Zhang and Heyuan Zha; Fudan University, Shanghai, China.

By using a first-principles approach, monolayer PbI$_2$ is found to have great potential in thermoelectric applications. The linear Boltzmann transport equation is applied to obtain the perturbation to the electron distribution by different scattering mechanisms. The mobility is mainly limited by the deformation-potential interaction with long-wavelength acoustic vibrations at low carrier concentrations. At high concentrations, ionized impurity scattering becomes stronger. The electrical conductivity and Seebeck coefficient are calculated accurately over various ranges of temperature and carrier concentration. The lattice thermal conductivity of PbI$_2$, 0.065 W/mK at 300 K, is the lowest among other 2D thermoelectric materials. Such ultrathin thermal conductivity is attributed to large atomic weight, weak interatomic bonding, strong anharmonicity, and localized vibrations in which the vast majority of heat is trapped. These electrical and phonon transport properties enable high thermoelectric figure of merit over 1 for both p-type and n-type doping from 300 K to 900 K. A maximum ZT of 4.9 is achieved at 900 K with an electron concentration of 1.9×10$^{13}$ cm$^{-2}$. Our work shows exceptionally good thermoelectric energy conversion efficiency in monolayer PbI$_2$, which can be integrated to the existing photovoltaic devices.

EP13.08.33
Fabrication of Thermoelectric Devices with High Aspect Ratio Pillars by Using Patterned Electro-Chemical Deposition in Multi-Channel Glass Template
Ning Su¹, Bo Li¹ and Fu Li¹;
¹Tsinghua University, Shenzhen, China; ²Shenzhen University, Shenzhen, China.

Thermoelectric (TE) devices, which can realize the mutual transformation between heat and electricity directly both in “Seebeck effect” and “Peltier effect”, have attracted worldwide interest because of their promising widely applications in electronics, for example airspace part, local refrigeration, accurate temperature controlling and telecommunications components. Compared with traditional energy conversion components, TE devices are superiorly applicable to the applications where weight and size are limited because they could be operated under small temperature difference produced by small energy sources and could apply well to low power levels. Therefore, the integration and miniaturization of the thermoelectric devices is becoming a top issue to promote its materialization combining with micro-electromechnanical systems(MEMS) and integrated circuit (IC) technology. The thermoelectric couples of the TEG fabricated by mechanical cutting and array configuration is difficult to reach micron scale for it is limited by processing technology. To solve this problem, template forming method was used in fabricating thermoelectric device in order to achieve high integration and aspect ratio in finite area for it’s unique advantage that it can utilize chemical self-assembly technology combing with MEMS technology. After manufacturing some vertical hole arrays in the template, TE materials were filled in the micro-pores by electrodeposition. This work demonstrates that micro thermoelectric generators (TEGs) with large output power of 218 μW and output voltage of 34.7 mV under a larger temperature difference of 98 K can be fabricated using electro-deposition based on the multi-channel glass template, which is much higher than the reported works. The micro-TEGs was consisted of four pair of thermocouples. And each thermocouple was composed by about two hundred p-type legs of Sb2Te3 and two hundred n-type legs of Bi2Te3 with 60 μm in diameter and 200 μm in height, which are well filled in the glass template by impulse voltage deposition.

EP13.08.36
Enhanced Thermoelectric Properties of N-Type Bi$_2$Te$_3$-Based Materials
Joeun Cha¹ and Chung¹,²,³Center for Nanoparticle Research, Institute for Basic Science (IBS), Seoul, Korea (the Republic of); ²School of Chemical and Biological Engineering, Seoul National University, Seoul, Korea (the Republic of).

A thermoelectric figure of merit ZT has been mainly improved by reducing thermal conductivity, resulting record high performance in several important thermoelectric (TE) systems. Their thermal conductivity rapidly approaches to the amorphous limit. In contrast, power factor (PF) does not have the theoretical upper bound, and it directly determines the output power of TE modules. However, enhancing PF is highly challenging, especially for Bi$_2$Te$_3$-based compounds that are representative TE materials near ambient temperature. Here we report ultrahigh power factor and carrier mobility in new n-type Bi$_2$Te$_3$-based materials, which are stabilized under excess Cu and Te conditions. The enhanced power factor is attributed to markedly high carrier mobility and electrical conductivity, which increase with the higher extent of Cu.

EP13.08.37
Enhanced Thermoelectric Performance of Highly Crystalline Ge$_{1-x}$Sb$_x$Te Crystals
Tianwey Lan, Min-Nan Ou, V.K. Ranganayakulu, Shih-Hsun Yu and Yang-Yuan Chen; Academia Sinica, Taipei, Taiwan.

Pristine GeTe is a highly degenerate semiconductor shows very low thermoelectric properties due to its large carrier concentration induced by the presence of Ge vacancy. In this work, we report a promising thermoelectric figure of merit (zT) of ~1.8 at 700–740 K was obtained on high-quality Ge$_{1-x}$Sb$_x$Te crystals grown by the Bridgman method. The substitution of Sb into Ge sub-lattice significantly reduces the excess hole concentration due to the donor dopant nature of Sb. The zT enhancement can be attributed to the reduction of carrier density due to Sb doping, as well as optimizes the electrical conductivity which subsequently enhances the Seebeck coefficient in Ge$_{1-x}$Sb$_x$Te compared to the pristine GeTe crystal. Reduction of thermal conductivity arises from enhancing phonon scattering by Sb doping effect, which results indicate that Sb doping is effective for enhancing the thermoelectric performance in p-Type GeTe Compound. With the inelastic neutron scattering investigation of selected Ge$_{1-x}$Sb$_x$Te crystals, the significant difference on phonon dispersion relation is investigating.
EP13.08.38

Electron-Phonon Interactions in Normal and Inverse Nickel Substituted Cobalt Spinel Oxides
Gustavo Damis Resende¹, Nolan W. Hines¹, Anveeksh Koneru² and Terence Musho²; ¹University of Texas at the Permian Basin, Odessa, Texas, United States; ²West Virginia University, Morgantown, West Virginia, United States.

Harvesting waste heat from power plants and other sources has proven to be a great challenge. Though thermoelectric technology has the capability to directly convert waste heat energy to electricity, the strong association of electrons and phonons in thermoelectric materials is greatly hampering the field. This research studied the electron-phonon interactions in spin-polarized materials formed by substitutions of Ni⁰ in Co₃O₄ spinel matrix. The preferential substitution of Ni⁺ in the octahedral sites changes to tetrahedral interactions with the increasing concentration of Ni⁺ resulting in the transition from inverse spinel to a partially inverse spinel. This change in the preferential substitution also accompanied a sudden change in spin-polarization, band gap, effective mass and lattice parameter. Thorough ab-initio studies were performed on a 56 atom unit cell of three configurations: inverse spinel \([\text{Co}_3\text{Ni}_x\text{O}_4 (0<x<0.5)]\), normal spinel \([\text{Co}_3\text{Ni}_x\text{O}_4 (0<x<1)]\) and partially inverse spinel \([\text{Co}_3\text{Ni}_x\text{O}_4 (0<x<0.5)+\text{Ni}_y\text{O}_2 \text{Co}_{2-y} \text{O}_3 (0<y<0.5)]\). These interactions were tuned by substitutions to attain optimal thermoelectric performance while extracting additional voltage associated to the spin of electrons in the spin-polarized materials. When the spin-polarization of the material is maximized, the spin thermoelectric module takes advantage of the spin Seebeck effect to generate extra voltage even when the electronic and thermal conductivities are not at their respective optimum levels. In an ep spin thermoelectric material configuration, the contributions of conventional and spin thermoelectric modules were combined to yield a higher operational thermoelectric efficiency.

EP13.08.39

Effect of Annealing on Thermoelectric Characteristics of Ag₃Te Nanoparticle Thin Films
Seunggeen Yang, Kyongha Cho and Sangsig Kim; Electrical Engineering, Korea University, Seoul, Korea (the Republic of).

Recently, energy conversion from heat to electricity has emerged in the field of energy devices. Solution-processable thermoelectric nanoparticles (NPs) have been considered as promising materials for high efficient thermoelectric devices on flexible plastic substrate. Nevertheless, the low electrical conductivity of NPs acts as a barrier to the development of high efficient NPs-based thermoelectric devices. Hence, in this study, we attempt to increase the electrical conductivity of Ag₃Te NPs thin films through annealing below plastic deformation temperature and investigate the effect on the thermoelectric characteristics. Ag₃Te NPs were synthesized in an aqueous solution by the colloidal method. To examine the thermoelectric characteristics of the Ag₃Te NPs thin films, a platform consisting of a meander line patterned heater and two electrodes at a distance of 40 μm was prepared on a plastic substrate by a photolithography and sputtering method. A heater and two electrodes were made of Pt, and the Ag₃Te NPs thin film was formed between the two electrodes by spin-coating. The Ag₃Te NPs thin film was annealed at 150 °C by rapid thermal annealing in vacuum. Irrespective of whether an Ag₃Te NPs thin film is annealed or not, the thermoelectric characteristics show p-type behavior. The Seebeck coefficients of non-annealed and annealed Ag₃Te NPs thin films are 1740 and 1260 μV/K, respectively. On the other hand, the electrical conductivities of non-annealed and annealed Ag₃Te NPs thin films are 0.16 and 11 S/m, respectively. Owing to annealing, the electrical conductivity of the Ag₃Te NPs thin films increases by about 100 times. Considering that low electrical conductivity of the NPs thin films results from poorly connected NPs in the thin film, it implies that annealing process makes strong connection between NPs in the thin film. With the Seebeck voltage and the electrical conductivity, we calculate the output power of non-annealed and annealed Ag₃Te NPs thin films. The values of non-annealed and annealed of the Ag₃Te NPs thin films are calculated to be 0.69 and 79.1 μW/cm² at a temperature difference of 7.5 K, respectively.

EP13.08.40

Development of Novel Eutectic Thermoelectric Alloy Systems and the Effect of Directional Solidification
Srisaha P; Indian Institute of Science, Bangalore, India.

Conversion of dissipated heat into electricity is the basic principle of thermoelectricity. It has wide variety of applications in the areas such as automobile engineering, refrigerating coolants, satellite etc. In search of such materials thermoelectric has gone wide scope to complex materials like Tellurides, Clathrates, Zinc compounds, Half Heusler alloys, Si, Ge, Skutterudite etc. The defining factor for thermoelectric materials is ZT, thermoelectric figure of merit. This attributes to the power factor \(P=\sigma S\), the electrical and thermal conductivities, and the absolute temperature, respectively. The thermal conductivity is a combination of thermal conductivity via electrons, \(\lambda_e\), and phonons, \(\lambda_p\), i.e., \(k=\lambda_e+\lambda_p\). The main difficulty in improvement of the efficiency of a thermoelectric device is due to the complex relation between \(\sigma, \alpha\) and \(k\). Improving the transport properties correlation will be presented.

EP13.08.41

Developing an Optimized Preparation Process for Bi₂Te₃-Se₅ Based Alloys for Thermoelectric Power Generation Applications
Omer Meroz and Yaniv Gelbstein; Ben Gurion University of the Negev, Beer Sheva, Israel.

The thermoelectric method of directly converting thermal into electrical energy is attracting increased attention for such applications and thus enhancing its efficiency is of great importance. The performance of thermoelectric devices is assessed by the dimensionless figure of merit \(ZT\) of the material, defined as \(ZT=\alpha^2\sigma/k\), where \(\sigma\), \(\alpha\) and \(k\) are the Seebeck coefficient, the electrical and thermal conductivities, and the absolute temperature, respectively. The thermal conductivity is a combination of thermal conductivity via electrons, \(\lambda_e\), and via phonons, \(\lambda_p\). The main difficulty in improvement of the efficiency of a thermoelectric device is due to the complex relation between \(\sigma\), \(\alpha\) and \(k\). Improving the performance of thermoelectric materials is usually done either by improving the power factor, \(P=\sigma S\), or by applying phonon scattering methods in order to lower the thermal conductivity. The most efficient n-type thermoelectric materials for temperatures up to 300°C are currently Bi₂Te₃-Se₅ based. By optimizing the preparation process while considering the inherent characteristics, an even more dramatic, the efficiency of such materials can be further improved. In this study the Bi₂Te₃-Se₅ composition was optimized by CH₂ doping, preferred alignment of the crystallographic orientation, and lattice thermal conductivity minimization. The synthesis route included rocking furnace melting, ball-milling or melt spinning, and hot pressing with optimal parameters for enhancement of the thermoelectric figure of merit, \(ZT\), at temperatures higher than 200°C, commonly applied in low temperature power generation applications. The transport properties in the directions parallel and perpendicular to the pressing direction were examined. In the direction perpendicular to the pressing axis, a maximal \(ZT\) of ~0.9 was obtained at ~175°C and at ~210°C, which is as far as we know among the highest ever reported for n-type Bi₂Te₃-Se₅ based alloys.

EP13.08.42

Conduction Band Engineering and Phonon Softening for High Performance N-Type PbSe Thermoelectrics
Chongjian Zhou¹,² and In Chung¹,²; ¹Center for Nanoparticle Research, Institute for Basic Science (IBS), Seoul, Korea (the Republic of); ²School of Chemical and Biological Engineering, Seoul, Korea (the Republic of).

PbSe is an attractive tellurium-free thermoelectric material for the intermediate temperature power generation. However, the performance of PbSe is much poorer than its more expensive isostructural analogue of PbTe. Here we present that PbSeSnₓBrx0.002-2xCuxSe exhibits peak ZT 1.8 at 723 K and average ZT 1.1 between 300 and 823 K, which are the highest values to date for all previously reported n- and p-type PbSe-based materials as well as for tellurium-free n-type polycrystalline materials. Cu:Se doping simultaneously flattens the conduction band edge of PbSe, increasing the effective mass of charge carriers, and band gap, which substantially improves the Seebeck coefficient. It also raises the carrier concentration with a negligible damage in carrier mobility, thereby even improving the electrical conductivity above ~423 K. These induced factors synergistically result in
ultrahigh power factor, reaching $\sim 21 - 26 \mu W cm^{-1}K^{-2}$ over a wide range of temperature from $\sim 423$ to $723$ K. Cu$_2$Se doping markedly depresses the lattice thermal conductivity to $\sim 0.4$ W m$^{-1}K^{-1}$ at $773$ K, which is close to its theoretical amorphous limit. First-principles calculations show that the obtained ultralow value originates from the remarkable softening of acoustic phonon at the low-frequency region.

Solid-state thermoelectric technology uses electrons or holes as the working fluid for heat pumping and power generation and offers the prospect for novel thermal-to-electrical energy conversion technology that could lead to significant energy savings by generating electricity from waste industrial heat. The key to the development of advanced TE technologies is to find highly efficient TE materials. Recently, several novel concepts have been proposed to enhance the efficiency of TE materials and laboratory results suggest that high $zT$ values can be realized in several families of bulk materials. In this presentation, we will show the study on the thermoelectric properties of liquid-like materials. We will show these materials possess interesting thermoelectric properties with ultralow thermal conductivity and good thermoelectric figure of merit. The physical mechanisms behind these abnormal thermoelectric properties will also be discussed. Finally, the stability of these compounds will also be presented and discussed.

In this presentation, the results and outcome of a 3-year project aiming at discovering new TE materials will be discussed, shown and critically analyzed.

Among the emerging promising thermoelectric materials is AgBiSe$_2$. This class of materials shows an intrinsically low lattice thermal conductivity stemming from a strong anharmonicity of the Bi$^{5+}$ lone pair. AgBiSe$_2$ crystallizes in a trigonal structure at room temperature. At 460 K the structure changes into a rhombohedral structure and at 580 K to a cubic rock salt structure. At the same time, AgSbSe$_2$ crystallizes in a rock salt cubic structure without any phase transitions.

In this work, we show the influence of the vacancy and Sb substitution on the structure and thermoelectric properties in Ag$_{1-x}$Bi$_x$Se$_2$ and Ag$_{1-x}$Sb$_x$Se$_2$. Synchrotron Bragg and pair distribution function analyses show the existence of site-disorder between Bi and Ag at room temperature, induced by the phase transitions during cooling. While the site-disorder leads to enhanced point defect scattering, the vacancy doping shows that the site-disorder can be mitigated. Furthermore, we will show how the substitution using Sb influences the phase transition temperature, local and with it the thermal transport. These studies show the direct effect of defects and the local structure on the transport in thermoelectric materials.

Prior ultralow thermal conductivity materials are not suitable for thermoelectric applications due to the limited electronic transport in the materials. Here, we present a new class of ultralow thermal conductivity materials with substantial electronic heat transport. Our samples are graphene/metal heterostructures of transferred graphene and ultrathin metal films (Pd, Au and Ni) deposited by either thermal evaporation or rf magnetron sputtering. For the evaporated samples, we achieve an ultralow thermal conductivity of 0.06 W m$^{-1}K^{-1}$. We attribute the electronic contribution to the transmission of electrons across atomic pinholes in graphene. With the ultralow thermal conductivity and substantial electronic transport, the new materials could be explored for thermoelectric applications.

The identification of effective approaches to significantly increase the power factor in thermoelectric materials could lead to substantially improved thermoelectric performance. In this context, modulation doping, in which the pathways for transport of charge are spatially separated from the dopant ions, has witnessed a rebirth in interest. Enhanced power factors have recently been reported in multilayer bulk nanoparticle composites, attributed to improved carrier mobilities without degradation of the Seebeck coefficient. While attractive from a device perspective, such materials can be challenging to model and experimentally characterize in order to understand the detailed charge transfer and transport processes, due to a distribution of grain sizes with random relative crystallographic orientations, and ill-defined microstructures. In contrast, precisely layered composites with well-defined layer thicknesses and compositions are ideal systems for the fundamental study of such phenomena. Here we use simple single band and composite models to predict the thermoelectric properties of modulation-doped layered composites. In particular, we have modeled the charge transfer and transport processes in layered composites comprised of doped and undoped layers, including the effects of ionized impurity and deformation potential (acoustic phonon) scattering. The potential for thermoelectric power factor enhancement in such structures will be discussed.
Nowadays, it seems to be a great majority of people that energy needs to be generated, conserved, and recycled in better ways. We need to prevent as much as possible to waste it, since every joule saved means less fossil fuel burnt. Because of that harvesting waste energy are becoming a popular among the scientific community. And, one of the most promising approaches is nano-engineering thermoelectric materials to produce devices. Thermoelectrics are a class of materials able to convert wasted heat energy into electricity. By controlling nano-structured properly, their efficiency increase. And, since the devices have no moving parts, they are extremely reliable. In this talk, different approaches to nanostructure different materials will be shown and how those approaches help to increase the final efficiency of the material and the final device. I will show three recent examples: selenides of Ag and Cu done with our recent development Pulsed Hybrid Reactive Magnetron Sputtering (PHRMS), large area antioide bismuth tellurides, and a three-dimensional interconnected bismuth tellurides nanowires array.

Thermoelectric materials directly convert heat into electricity and vice versa.

A large variety of thermoelectric materials' classes including, intermetallic compounds (e.g. half-Heuslers), silicides and chalcogenides (e.g. Bi\(_2\)Te\(_3\), PbTe and GeTe), have been investigated as candidates for practical applications due to high thermoelectric figure of merit, ZT, values at different temperature ranges.

In the recent years, many of the advances of improving the ZT and thereby enhancing the heat to electricity conversion efficiency, have been focused on generation of nano-features, effectively scattering phonons, for minimization of the lattice thermal conductivity. Yet, such nano-domains are in many cases unstable under the high temperatures operating conditions, tending to grow into the micro-meter scale, while degrading the ZT.

Moreover, the effect of grains- and/or domains boundaries and their high temperature variations on the electronic properties is rarely considered.

In the current presentation, the govern temperature dependent physical metallurgical effects on the ZT, will be described in details, with some innovative approaches for mitigating these adverse effects, by means of thermodynamically driven phase separation and grain boundary Zener pinning effects. In addition, the effect of these and other metallurgical factors (e.g. vacancies and dislocations) on the electronic transport properties will be presented.

A focus on the related activities in the Department of Materials Engineering at Ben-Gurion University of the Negev will be given.

Combined Theory and Data-Driven Approaches Thermoelectrics Materials Discovery Ambabray Jain\(^1\), Alireza Faghaninia\(^1\), Alexander Ganose\(^1\), Vahe Tshityouni\(^1\) and Gerbrad Ceder\(^1,2\)
\(^1\)Lawrence Berkeley National Laboratory, Berkeley, California, United States; \(^2\)University of California, Berkeley, California, United States.

We describe our efforts to discover new thermoelectric materials compositions through a combination of theory and data-driven approaches. In particular, we focus on two efforts. The first is a new model of carrier transport called AMSET that allows one to model the temperature-dependent Seebeck coefficient and mobility from first-principles at reasonable computational cost. This is achieved by adapting classical scattering equations previously developed for 1D parabolic band semiconductors to complex density functional theory band structures. We will explain the theory behind AMSET as well as comparison against experiment and constant relaxation time approaches typically used in the field. Next, we will describe our data-driven approach to suggest new thermoelectric compositions. This effort leverages a corpus of over 3.3 million abstracts of materials science journal articles that we have collected, and for which we have used natural language processing techniques to extract the correlation between a material's composition and its likelihood to be a thermoelectric based on automatically "reading" the prior literature. We demonstrate that this technique can potentially predict new thermoelectric materials years in advance of their first report in the scientific literature and explain the manner in which this machine learning model arrives at predictions. For both methods, we present comparisons to the experimental data, both previously tabulated and conducted with our collaborators for new materials.

Electron-Phonon Coupling and Electronic Transport in N-Type PbTe from First Principles Jiang Cao\(^1\), Jose D. Querales-Flores\(^1\), Aoife R. Murphy\(^2\), Stephen Fahy\(^2\) and Ivana Savic\(^3\)
\(^1\)Tyndall National Institute, Cork, Ireland; \(^2\)University College Cork, Cork, Ireland.

Exploiting the fascinating properties of materials near soft mode phase transitions is an emerging concept in the quest to increase thermoelectric efficiency [1]. Soft phonons may lead to low thermal conductivity, while preserving high electronic conductivity. Here we investigate the unusual electronic transport properties of n-type PbTe, which is a classic thermoelectric material that exists near a soft mode phase transition. Our first principles calculations show that longitudinal optical phonon scattering dominates electronic transport, while acoustic phonon scattering is relatively weak [2,3]. We find that scattering due to soft transverse optical phonons is by far the weakest scattering mechanism, due to the symmetry-forbidden scattering between the conduction band minima and the zone center soft modes [3]. Soft phonons thus play the key role in the high thermoelectric figure of merit of n-type PbTe: they do not degrade its electronic transport properties although they strongly suppress the lattice thermal conductivity [1].

Structural and Electronic Properties of Ferroelectric Domain Walls in GeTe from First Principles Djordje Dangic\(^1\), Eamonn Murray\(^2\), Stephen Fahy\(^2\) and Ivana Savic\(^3\)
\(^1\)Tyndall National Institute, Cork, Ireland; \(^2\)University College Cork, Cork, Ireland; \(^3\)Imperial College London, London, Ireland.

Domain walls in ferroelectric oxides can have significantly different properties than their bulk counterparts [1]. This represents a new avenue for the manipulation of material properties for specific purposes. GeTe is a ferroelectric material that is also one of the best performing thermoelectrics, combining beneficial electronic properties with low lattice thermal conductivity [2] and mechanical stability [3]. In this work, we have performed first principles calculations to understand how domain walls affect structural and electronic properties of GeTe. We have identified five different types of domain walls. We find that strong strain-order parameter coupling is present at all of them, which is beneficial for the thermal conductivity and mechanical stability [2,3]. We will explain the theory behind AMSET as well as comparison against experiment and constant relaxation time approaches typically used in the field. Next, we will describe our data-driven approach to suggest new thermoelectric compositions. This effort leverages a corpus of over 3.3 million abstracts of materials science journal articles that we have collected, and for which we have used natural language processing techniques to extract the correlation between a material's composition and its likelihood to be a thermoelectric based on automatically "reading" the prior literature. We demonstrate that this technique can potentially predict new thermoelectric materials years in advance of their first report in the scientific literature and explain the manner in which this machine learning model arrives at predictions. For both methods, we present comparisons to the experimental data, both previously tabulated and conducted with our collaborators for new materials.

Defective Half-Heusler Thermoelectric Compounds with Intrinsic Vacancies Tiejun Zhu; Zhejiang University, Hangzhou, China.

Typical 18-electron half-Heusler (HH) compounds, ZrNiSn and NbFeSb, have been identified as promising high temperature thermoelectric materials. NbCoSb with nominal 19 valence electrons, which is supposed to be metallic, has recently been reported to also exhibit thermoelectric properties of a heavily doped n-type semiconductor. In this talk we experimentally demonstrate that the nominal 19-electron NbCoSb is actually the composite of 18-electron Nb\(_{3+}\)CoSb (0 ≤ d ≤ 0.05) and impurity phases. Single phase Nb\(_{3+}\)CoSb with intrinsic Nb vacancies, following the 18-electron rule, possesses improved thermoelectric performance, and the slight change in the content of Nb vacancies has a profound effect on the thermoelectric properties. The carrier concentration can be controlled by varying the Nb deficiency, and the optimization of the thermoelectric properties can be realized within the narrow pure phase region. Benefiting from the elimination of impurity phases and the optimization of carrier concentration, thermoelectric performance is remarkably enhanced by ~100%. The similar phenomenon has also been observed in some of other defective 19-electron HH compounds. This work opens a new avenue for searching for nominal 19-electron half-Heusler compounds with intrinsic vacancies as promising thermoelectric materials.

4:00 PM EP13.10.07
Many new thermoelectric materials including half-Heusler alloys, PbTe and SnSe based compounds, skutterudites, clathrates, to a name a few, are known to possess rich and complex bandstructures, with highly anisotropic bands belonging to multiple valleys having manifold degeneracies in both conduction and valence bands. These materials often exhibit very low thermal conductivities, which can be further reduced using nanostructuring techniques to reach down to, or even below the amorphous limit. More recently, however, significant efforts are also being undertaken to take advantage of the rich bandstructure features to achieve power factor improvements as well. These include identifying the best alloying strategies, introducing resonant states in the bands, aligning of the bands, matching of the valleys at the same energy, etc. Large efforts are also placed by the computational materials science community into bandstructure calculations through involved DFT codes and high-throughput material screening using data from a variety of databases.

Less progress, however, is achieved in combining such involved calculations with accurate transport models, which take into account different scattering mechanisms including their energy dependences, the details of intra/inter valley scattering, details of anisotropy in the bandstructure, electronic relaxation details, etc. Lack of these considerations leads to wrong performance estimations, inaccurate comparisons, and sub-optimal design directions. At the moment, most calculations, despite the use of accurate bandstructures, are performed using constant relaxation time approximation due to the very challenging computational complexities of accurate scattering treatment.

Here, we describe the development of an advanced simulator that uses an arbitrary material bandstructure and computes the thermoelectric coefficients beyond the typically assumed constant relaxation time approximation. Our code includes all major scattering mechanisms (e.g., phonons, impurities, alloying) encountered in the materials of interest. The code uses the Fermi’s Golden Rule in the energy dependent relaxation time approximation, computed by numerical considerations of all bandstructure states. Using this, we then report on an investigation of a few typical thermoelectric materials and explore the differences in the performance predictions in cases where the various details of the scattering mechanisms as described above are considered in the calculations, versus if they are omitted using simplified methods. We indeed show that depending on the scattering physics considered, the power factor can vary substantially and materials performance rankings can be altered. More specifically, we show that in the efforts towards improving the power factor of materials through band alignment, different optimized bandstructure conclusions are reached if one uses the constant relaxation time approximation, versus scattering rates that depend on the density of intra-valley states, versus scattering rates that depend on the total density of states. In the case of half-Heusler compounds, for example, we show that the differences in the performance estimation of band aligned structures can vary significantly depending on the scattering mechanism. We show that this variation depends on the effective masses of the aligned bands of the material as well.

Finally, we discuss the numerical issues of these simulations and approximations that could speed up the computation significantly without compromising the accuracy.

Organic/inorganic thermoelectric nanocomposites (TENCs) have seized great attention since they integrate the advantages of inorganic (high electrical conductivity) and organic (low thermal conductivity and mechanical flexibility) parts. Major barriers obstructing the development of this field are the lack of n-type TE materials and the absence of precise control of the morphology directly relevant to TE performance. To resolve these two issues, here we provide a feasible strategy to improve the blend film morphology of n-type TENCs consisting of organic polymer and inorganic metallic nanofiller.

As proof-of-concept, we utilized the magnetic characteristics of cobalt nanowires (Co NWs) to direct the assembly of metallic nanowires in an insulating polyvinylidene fluoride (PVDF) matrix through solution fabrication method. The resulting highly ordered n-type TENCs exhibit significantly increased electrical conductivities (σ) in comparison to randomly packed nanowires. It is interesting to note that the s and Seebeck coefficient (S) of these TENCs are decoupled, which is consistent with the n-type metallic behavior of Co. Both s and S simultaneously increase as a function of the Co NWs content. As a result, the maximum power factor (PF) of 523 μW m−1 K−2 is obtained at 320 K with 45 vol% Co NWs under magnetic alignment, which is among the highest PFs achieved for n-type TENCs. Importantly, these TENCs are highly bendable and thus hold great potential for flexible TE modules. By pairing these n-type TENCs with p-type PEDOT:PSS thin films, we constructed bendable and planar TE generators that produce a maximum output voltage and power of 26.4 mV and 5.2 μW, respectively, when temperature gradient reaches 50 K.

Furthermore, we employed n-type conducting polymer N2200 to replace insulating PVDF in the above TENCs and aimed to understand the favorable contributions of organic semiconductor to the charge carrier transport process. Distinct from Co NWs/PVDF counterparts, Co NWs/N2200 TENCs exhibit the intimately coupled s and S and the highest PF up to 288 μW m−2 K−1 is acquired with 31 vol% Co NWs. Despite extra conductive pathways are anticipated to create in Co NWs/N2200 TENCs relative to PVDF based analogues, the s is undermined by the unsatisfactory porous microstructures in thin films, presumably caused by the rigid molecular chains of N2200 compared to flexible PVDF. To enhance the interconnectivity between Co NWs and N2200, a small amount of PEI-treated n-type single-walled carbon nanotubes (SWCNTs) were added to the optimal binary sample. The s of ternary TENCs increases and then drops with the addition of SWCNTs, yielding an optimal PF as high as 384 μW m−2 K−2 at 380 K at the content of 3 wt% SWCNTs.

**4:45 PM EP13.10.08** Impact of Scattering Mechanism Details on the Thermoelectric Power Factor of Complex Materials *Patrizio Grazioso, Chathurangi Kumarasinghe and Neophyto Neophytou; School of Engineering, University of Warwick, Coventry, United Kingdom.*

In this work, electrical and thermal properties of semi-metallic ZrTe2 and TiSe2 were calculated, and its thermoelectric properties assessed.

Half-Heusler thermoelectric materials have attracted much attention due to their high thermal stability, mechanical strength, power factor (PF) and figure-of-merit (ZT) at high temperatures. In order to translate the material performance into good module performance, electrical and thermal contact resistances must be minimized. Low electrical contact resistance between electrode and thermoelectric material is critical for device performance. Poor contacts can cause Joule heating which can significantly degrade the power output. Ideally, the contact resistivity should be smaller than 1 μΩ cm². In practice, many material systems are far from achieving this resistivity value. In this study, we demonstrate a half-Heusler thermoelectric module with excellent contact resistance and thereby excellent module performance. The contact resistivity was measured using a scanning probe measurement system, and specific resistivity at each interface was calculated. A very low contact resistivity of ~1 μΩ cm² was achieved resulting in power output close to theoretically predicted value. This device fabrication technique provides pathway for high temperature power generation technology in waste heat recovery.
Thermoelectric effects for Heat-to-electricity conversion are fascinating phenomena with many potential technological applications from waste heat energy harvesting, IR camera, e-skin to interactive buildings. We give an overview of those phenomena in electronic or ionic conducting polymers. In the first part, we summarize our finding on the electronic thermoelectric properties of the p-type polymer called poly(3,4-ethylenedioxythiophene) (PEDOT) [1]. PEDOT thermoelectric aerogels are presented with their applications in dual pressure and temperature sensors [2]. We then focus on the recent advances made in the lab regarding n-type conducting polymers [3].

In the second part, we explore the ionic thermoelectric effects in both mixed ionic electronic polymer conductors [4]. This phenomenon is used to create materials orthogonal sensitive to humidity, temperature and pressure.

In a third part, we investigate on ionic polymer transistors. Giant Seebeck effects are found with coefficients that reach 10 mV/K. This effect enables charging a supercapacitor for energy harvesting of intermittent heat sources; but also switching a transistor, thus creating a smart pixel for high temperature sensitivity [5]. The concept of non-ionic aqueous thermoelectric polymers is further explored to obtain both negative and positive ionic Seebeck coefficient and build the first ionic thermopiles.

9:15 AM EP13.11.02 Enhanced Thermoelectric Performance of PEDOT:PSS Nanotubes via AAO Template-Assisted Growth [Hyejeong Lee] 1, Ho Shun Shin 2, Taejin Yoo 1, Seonmin Jin 1, Byoung Hun Lee 1, Jae Yong Song 2, Eun Ji Lee 1 and Ji Young Jo 1; 1Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of); 2Center for Nanomaterials Characterization, Korea Research Institute of Standards and Science, Daejeon, Korea (the Republic of).

As smart devices have become an integral part of our lives, there is a growing demand for the development of self-charging devices that can simultaneously generate and store energy. Among them, thermoelectric generator (TEG) are noiseless and can be miniaturized easily. Conducting polymers are the appropriate choice for wearable thermoelectric devices among TEGs, due to their flexibility, eco-friendliness, lightweight, etc. Poly (3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) has been widely studied owing to its highest electrical conductivity (> 10 Scm -1) with low thermal conductivity (< 1 Wm -1K -1). However, the thermoelectric efficiency of PEDOT:PSS is still low due to the low electrical conductivity and Seebeck coefficient, compared to the inorganic materials. Here we present a strategy to enhance the electrical conductivity and to decrease the thermal conductivity simultaneously, in order to achieve the high thermoelectric efficiency of PEDOT:PSS. We successfully fabricated PEDOT:PSS nanotubes with an average diameter of 200 nm via infiltration in AAO template without any synthesis process. From the transmission electron microscopy (TEM) and Raman spectra, the infiltration method using the capillary phenomenon forms a PEDOT:PSS nanotube with a wall thickness of 10 nm and induces a stretching in the PEDOT:PSS C=C–C=C bond with a linear alignment. We found the increase in electrical conductivity due to stretching of PEDOT:PSS chains as well as the decrease in thermal conductivity through phonon scattering at the inner and outer interfaces of the nanotube.

At first, the PEDOT:PSS solution was dropped on to the AAO template and PEDOT:PSS solution was infiltrated into AAO template for 24 hr at room temperature. Then the sample was baked at 120°C to remove residual solvent followed by Ethylene glycol treatment for 120 min for improving the electrical conductivity of PEDOT:PSS nanotubes. The samples were then rinsed and then baked at 120°C for 10 min. The AAO barrier layer was removed by immersing the template in NaOH followed by vacuum filtering. The PEDOT:PSS nanotubes were then collected from NaOH solution. We believe that the fabrication process of PEDOT:PSS nanotubes using a facile infiltration method not only enhances the thermoelectric efficiency but also helps us in understanding the thermoelectric behavior at lower dimensions.

9:30 AM EP13.11.03 Organic Micro Thermoelectric Generators for Waste Heat Energy Harvesting Matteo Massetti 1, 2, Silvio Bonfadini 1, 2, Luigino Crisante 1, Mario Caironi 1 and Marco Cussignelli 1; 1Istituto Italiano di Tecnologia, Milano, Italy; 2Politecnico di Milano, Milano, Italy.

Micro energy harvesters are becoming more and more relevant as energy resources for distributed low power electronics and sensors networks. In this context, micro thermoelectric generators (µTEG) possess many advantages, as they can be worked in the dark and require limited maintenance. Ideally, such µTEGs should be cost effective and based on abundant materials. Organic conjugated materials have been studied to address such requires, as they can enable lightweight, flexible and cost competitive µTEGs produced through mass scaled printing techniques. Here we report on a new organic, flexible µTEG where doped p-type and n-type organic semiconductors are inkjet printed to form a micro module composed of 128 thermocouples on plastic. In particular, we will present an architecture specifically devised to improve the thermal coupling and simplify the fabrication process. Our successful realization of a printed organic µTEG and the complete thermoelectric characterization allow to envisage future efficient devices delivering µW/cm 2 at low average temperature and low temperature differences.

9:45 AM EP13.11.04 The Role of Polymer Structure on N-Type Organic Thermoelectrics Suhao Wang 1, Hengda Sun 2, Tim Erdmann 2, Daniele Fazzi 2, Magnus Berggren 1, Xavier Crispin 2, Anton Kiriy 2, Tobi J. Marks 2, Antonio Facchetti 1 and Simone Fabiano 1; 1Linköping Univ, Norrkoping, Sweden; 2Technische Universität Dresden, Dresden, Germany; 3Max-Planck-Institut für Kohlenforschung, Mülheim an der Ruhr, Germany; 4Northwestern University, Evanston, Illinois, United States.

Organic thermoelectric based on conjugated polymers are emerging as promising candidate for green energy conversion. Building such devices require both p-type (hole-transporting) and n-type (electron-transporting) materials. Although p-type polymers can efficiently be doped to exceptionally high electrical conductivity (σ) values (>1000 Scm -1) with low thermal conductivity (< 1 Wm -1K -1), the development of n-type polymer lags far behind due to their low conductivity (typically <0.01 S/cm). For example, it has been shown that the naphthalenediimide–bithiophene copolymer P(NDI2OD-T2), a high electron mobility polymer extensively investigated as active layers in OPET/OSC devices, can be doped to a conductivity of only 0.003 S/cm regardless of the dopant and processing conditions.

Recently, we demonstrated that the twisted donor-acceptor structure of P(NDI2OD-T2) can lead to strong charge carrier intrachain localization on the acceptor moiety, thus resulting in low electron conductivity. On the other hand, backbone planarization can be beneficial for charge carrier delocalization, enhancing the charge transport and the extent of the doping process. To this end, we replaced the bithiophene (T2) unit in P(NDI2OD-T2) with the more electron-deficient bithiazole (Tz2) unit, resulting in the analogous P(NDI2OD-Tz2). Hereby, the polymer donor-acceptor character can be reduced and the lower intrachain steric helps planarize the polymer backbone and thus enhancing intermolecular π–π stacking interactions, with consequently a much higher electrical conductivity (up to ~0.1 S/cm) and enhanced thermoelectric response. These results demonstrate how significantly the polymer backbone structure affects the polaron delocalization and the resulting n-doped conductivity, setting molecular-design guidelines for the next generation of conjugated polymers.

10:30 AM EP13.11.05 Improved N-Type Doping and Thermoelectric Properties of a Polymer Semiconductor by Minimizing Donor-Acceptor Character Jian Liu 1, Yongjiang Shi 2, 1; Jingjin Dong 1, Xinrui Qu 1, 2; Ryan Chiechi 1, Giuseppe Portale 2, Mengyao Sc 4, Xugang Guo 2, 3 and Lambert Jan Anton Koster 1; 1Zernike Institute for Advanced Materials, University of Groningen, University of Groningen, Groningen, Netherlands; 2Department of Materials Science and Engineering and The Shenzhen, Southern University of Science and Technology (SUSTech), Shenzhen, China; 3Stratingh Institute for Chemistry, University of Groningen, University of Groningen, Groningen, Netherlands; 4Kee Key Laboratory for Printed Organic Electronics, Southern University of Science and Technology (SUSTech), Shenzhen, China.

Organic semiconductors have attracted increasing attention as low-temperature thermoelectric materials, offering the possibility of fabricating low-cost, large-scale and mechanically flexible thermoelectric modules. The thermal conductivity of organic semiconductors is intrinsically low, leaving the power factor as the most important parameter for optimization. A widely used strategy to optimize power factor is molecular doping, which enables a tuning of the carrier density in organic films. Fine tuning of the electronic properties of donor-acceptor (D-A) copolymers can be readily fulfilled via meticulous selection of the two moieties, which affords substantial electron mobilities >1 cm 2V -1 s -1 in organic thin-film transistors. However, translating those high electron mobilities of D-A copolymers into high electrical conductivities upon n-doping is nontrivial and has rarely been successful to date. The weak n-doping of D-A copolymers limits their use in organic thermoelectrics.
Thin films are fabricated by spin coating technique using a yellow solution of MASnI thin films baked at 100°C shows the best result with Seebeck coefficient about 70 μV/K and electrical conductivity of about 50 S/cm near room temperature. The detailed results and analysis will be shown during the presentation. In future, our plan is to optimize the carrier concentration to enhance the value of ZT.

SESSION EP13.12: Thin Film, Device and Others
Session Chairs: Theodor Kyrtidis and Takao Mori
Friday Afternoon, April 26, 2019
PCC North, 200 Level, Room 225 A

1:30 PM *EP13.12.01 Development of Thermoelectric Thin Films for IoT and Characterization Methods Takao Mori1; 2; CFSP and WPI-MANA, National Institute for Materials Science (NIMS), Tsukuba, Japan; 1University of Tsukuba, Tsukuba, Japan.

There is a vital need to develop technologies to dynamically harvest energy from surroundings to power IoT applications [1]. In regards to utilizing ubiquitous thermal energy like body heat, thermoelectric thin films can be promising [2]. Recently, we have utilized semiconductor fabrication processes to fabricate an organic n-type thermoelectric module outputting over 250 mV with 80°C [3]. The high contact resistance and relatively low thermoelectric performance of the organic materials used, remains a large issue to solve. I will mainly present efforts on developing inorganic thermoelectric thin films, which can be applied to wearable applications via flexible substrates, for example. We have also discovered that utilizing magnetism can be a way to enhance thermoelectric properties, e.g. magnetic semiconductors [4]. There is a possibility to compatibly integrate such thermoelectrics into magnetic devices and sensors to self-power themselves. Development of measurements to accurately evaluate the thermal conductivity of thin films and
interfacial thermal resistance are also vital. We have recently developed a novel TEM in-situ thermal probe, which utilizes nanothermocouples with scanning heat input under STEM, to be able conduct nanoscale heat maps which visualize the heat pathways in nanocomposite materials and in-plane of thin films, for example [5]. Focused picosecond thermoreflectance with advanced analytic methods to enable unambiguous, accurate measurements and evaluation of interfacial thermal resistance will also be presented. CREST, CSFN, WPI-MANA project collaborators are acknowledged.

Solution-Processed PbSe\(_{1-x}\)Te\(_x\) Thin-Films Thermoelectrics Prathamesh B. Vartak, Zhongyong Wang, Yuanyu Ma and Robert Wang; Arizona State University, Tempe, Arizona, United States.

Solution processing of inorganic semiconductor precursors and its subsequent thermal decomposition offers a simple, inexpensive, large area fabrication route to inorganic semiconductor thin films. However, the presence of inherent strong covalent bonds renders these inorganic semiconductors insoluble. Hydrazine as an example is known to form soluble metal chalcogenide precursors but its high toxicity, explosive and carcinogenic nature inhibits its widespread application. Diamine-dithiol solvent mixture was discovered recently to dissolve a variety of metal chalcogenides. This solvent system poses problems of introducing sulfur contamination in metal selenides and tellurides, the presence of free tellurium in metal tellurides, and immediate precipitation of PbTe precursors.

We propose a new approach to prepare metal chalcogenide precursors by mixing elemental metal with diphenyl dichalcogenide in a variety of solvents.2 This approach simultaneously avoids hazardous solvents, eliminates unwanted sulfur and free tellurium impurities, and yields lead selenide and telluride precursors that have been problematic via other soluble precursor syntheses. We characterize the thermal decomposition temperature of the precursors using thermogravimetric analysis and confirm the formation of phase-pure metal chalcogenides using powder X-ray diffraction. We also characterize the chemical structure of a PbSe precursor made in this manner due to its potential thermoelectric applications. We identify the PbSe precursor to be lead(II) phenylselenolate by utilizing a combination of techniques including nuclear magnetic resonance, mass spectrometry, elemental analysis and single crystal X-ray diffraction analysis.

We further prepare PbSe\(_{1-x}\)Te\(_x\) thin films by decomposing a mixture of lead selenide and lead telluride precursors and present their room temperature Seebeck coefficient and electrical conductivity. In addition, we introduce Na dopants by including NaCl into the precursor mixture and systematically study its influence on the thermoelectric properties of PbSe\(_{1-x}\)Te\(_x\) thin films. The film stoichiometry and electronic state of elements were characterized by Rutherford backscattering spectroscopy and X-ray photoelectron spectroscopy. We also use secondary ion mass spectroscopy depth profiling to confirm the presence of Na-dopants in our thin films. The room temperature measurements seem to be promising with undoped PbSe\(_{1-x}\)Te\(_x\) films having Seebeck coefficient of 480 μV K\(^{-1}\) and electrical conductivity of 180 S m\(^{-1}\). Since PbSe\(_{1-x}\)Te\(_x\) is best suited for high-temperature applications, we also present our ongoing efforts to measure the thermoelectric properties of these samples at high temperature.

Flexible Aerosol Jet Printed Thermoelectric Films via Versatile Photonic Sintering Mortorza Saeidi-Javash, Chaochao Dun, Wenzheng Kuang, Nicholas Kempf and Yanliang Zhang, Department of Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, Indiana, United States.

Additive printing is a promising method to fabricate flexible and low-cost thermoelectric devices using high-performance colloidal nanocrystals. However, most of the TE nanoparticles require sintering at elevated temperatures, which poses a major challenge to print and sinter the TE nanoparticles on low-temperature flexible substrates.

In this work, we demonstrate for the first time the aerosol jet printing combined with intense pulsed light (IPL) sintering to transform colloidal TE nanoparticles into high-performance and flexible thermoelectric films. This paves the way for roll-to-roll fabrication of printed TE generators with high power density on a large variety of low-temperature substrates. The conventional thermal sintering process requires long heating time, and is limited to substrates that can survive high temperatures. The IPL sintering is an ultrafast thermal sintering method using a xenon flash lamp to deliver a high-intensity and short-duration (< 2 ms) pulsed light to the printed nanoparticles. By controlling the pulse intensity and duration, the IPL sintering can effectively sinter the printed nanoparticles without overheating or damaging low-temperature substrates.

We printed n-type bismuth telluride based TE films on flexible substrates such as kapton and PET and sintered the films by IPL. The sintering parameters were optimized in order to achieve the highest electrical conductivity and maximum thermoelectric power factor. The electrical conductivity of the flexible films is dramatically improved from non-conductive to 2.7×10\(^4\) S/m, which results in a very high power factor of 726 μW/mK\(^2\) at room temperature. The aerosol jet printing and IPL sintering process is fully roll-to-roll compatible, thus providing a highly-scalable and low-cost manufacturing method to fabricate flexible TE devices for broad energy harvesting and cooling applications.

2:30 PM EP13.12.04
Uni-Leg Thermoelectric Module Comprised by Coated Hybrid-Pervoskite Thin Film Shrikanth Sanj, Tomohide Yabuki and Koji Miyazaki; Mechanical and Control Engineering, Kyushu Institute of Technology, Kitakyushu, Japan.

The conversion efficiency of thermoelectric material is quantified by figure of merit ZT (=\(\sigma S^2/\kappa\)) where \(\sigma\) is electrical conductivity, \(S\) is Seebeck coefficient and \(\kappa\) is thermal conductivity. CsSnI\(_3\) pervoskite can lead to the next-generation energy conversion platforms due to its intrinsic ultra-low thermal conductivity and large Seebeck coefficient.

However, enhancement of electrical conductivity is still required.

In this work, we study the growth parameters and thermoelectric properties of coated CsSnI\(_3\) pervoskite thin film. Our focus is to develop these thin films by cost-effective wet printing process for large area application. Due to shapeability thin films are superior to the corresponding bulk or single crystals. Here, we fabricate CsSnI\(_3\) pervoskite thin film by spin coating process. The base solution is prepared by CsI and SnI\(_2\) precursors. We optimized the effects of mixing time, baking temperature and baking time to evaluate and enhance thermoelectric performance of CsSnI\(_3\) thin films. CsSnI\(_3\) thin films were structurally characterized using several state of the art techniques including XRD and SEM. We measured thermoelectric properties near room temperature and found that growth parameters influence the crystal grain size further the value of figure of merit. CsSnI\(_3\) thin films grown at solvent mixing time about 2 h, heating temperature about 130°C and heating time 5 min show the best thermoelectric performance as Seebeck coefficient 100 μV/K, electrical conductivity 30 S/cm, thermal conductivity 0.4 W/mK, and ZT about 0.1 near room temperature.

Further, we fabricated uni-leg thermoelectric modules on a glass substrate comprised by the best grown CsSnI\(_3\) thin film. Number of legs varies from 3 to 5 in our study. The maximum output power is about 0.8 nW for 5 legs (25 mm x 3 mm x 500 nm) module for temperature difference of about 3°C. Even though output power is low but these results will open a new pathway to thermoelectric modules for flexible electronics. In future, our plan is to optimize the module design and transfer it to flexible and large area substrate.

2:45 PM EP13.12.05
Solid state thermoelectric coolers (TEC) made from nanostructured materials have received attention for Peltier cooling of localized hotspots in microprocessors (1, 2). Research in this area has focused on steady-state operation and cooling. Here, we discuss a concept for pulsed-mode transient heat spreading using planar thin film TEGs. Using detailed computational modelling, we show that it is possible to achieve a local cooling of ~10°C for a high heat flux of 1000 W/cm² by optimizing the TEC material, geometry and operating parameters. We experimentally investigate ultra-thin films of (Bi$_2$Sb$_3$Se$_2$): system of compounds as a viable candidate for such operation. Typical room temperature electrical resistivity of these samples is around 300 μΩ·cm (3). Excellent electrical contacts can be made, as well, with typical values ranging between 10-8 and 10-9 Ω·cm. We report measurements of the thermoelectric properties of few-qnt-perlament Bi$_2$Se$_3$ on sapphire substrate to provide insight into alteration of properties at few-atomic layer scales. This work explores new ideas for TEC operation in handling transient temperature jumps in electronics.

3:30 PM *EP13.12.06

Origin of High Thermoelectric Performance in n- and p-Type SnSe Crystals Li Huang; Department of Physics, Southern University of Science and Technology, Shenzhen, China.

Tin selenide (SnSe) has emerged as a very promising thermoelectric material due to its record high figure of merit ZT for both n- and p-type crystals in intermediate temperature range. In this talk, I will present our recent works regarding its electronic and thermal properties based on first-principles calculations, in combination with the Boltzmann transport theory and experimental measurements. The origins of strongly anisotropic thermal and electrical behaviors in this layered lattice structure will be discussed, which give rise to the highest optimal ZT values along the a (out-of-plane direction) in the n-type SnSe, whereas along b axis in p-type materials. In addition, I will discuss the effects of the intrinsic defects and dopants on its thermoelectric characteristics. Our calculations show reasonable agreements with the experimental observations and provide some guidance for optimizing the thermoelectric performance.

4:00 PM EP13.12.07

Optimization of Thermoelectric Materials and Devices for Self-Powered Wearable Health and Environmental Tracking Systems Abhishek Malhotra$^1$ and Daryoosh Vasheae$^1$; $^1$Electrical and Computer Engineering, North Carolina State University, Raleigh, North Carolina, United States; $^2$Material Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States.

There has recently been an increasing interest in self-powered wearable health and environmental monitoring systems. The Advanced Self-Powered Systems of Integrated Sensors and Technologies (ASSIST) at North Carolina State University, is a prime example of the thrust for these systems. Thermoelectric generators (TEG) can continuously harness the body heat and produce electricity, as such they are the promising candidates for making battery-less wearable systems. Several challenges need to be addressed before TEGs can power such wearables. Particularly, the thermoelectric material properties must be optimized so that the material is most efficient near the body or room temperature. Bi-Sh-Te-Se nanocomposite alloys are known as the state-of-the-art thermoelectric materials for near room temperature applications; however, the existing materials have their peak ZT in the temperature range of 100 °C to 150 °C with smaller values near the body temperature. These nanocomposites often also suffer from lack of reproducibility due to the difficulties in controlling the Te vacancy during the material synthesis. Metalization of these materials for making the TEGs poses other requirements such as durability to survive in the regular usage. Another essential element imposed by the low-temperature differential on the body is related to making thin and long TE legs and low fill factor devices. The integration in textile or wearable bands also dictates certain design restrictions to make reliable devices for body heat harvesting. In this study, we will describe our methods to address some of these issues starting from the material synthesis, device design, and TEG fabrication to integration in wearable testbeds. An extensive investigation was performed on doping optimization and reproducibility of the nanocomposite bismuth telluride based alloys especially n-type materials which are more sensitive to growth process parameters. The effects of Cu doping for synthesizing a reproducible n-type material with high ZT near room temperature was investigated. The peak ZT of 1.2 at room temperature was achieved. Reproducibility of the material was confirmed through tight statistical analysis. For p-type material, Bi-Sh-Te nanocomposites were synthesized with peak ZT of 1.4 near room temperature. Furthermore, physical and chemical processing methods were tested for surface preparation before metallization.

4:15 PM EP13.12.08

Interfacial Patterning as a Framework for Creating High ZT Thermoelectric Materials Shane G. Davies$^1$, Duncan Hardie$^2$, Francis H. Davies$^1$, Ned T. Taylor$^1$, Conor J. Price$^1$ and Steven P. Hepplestone$^1$; $^1$Department of Physics and Astronomy, University of Exeter, Exeter, United Kingdom; $^2$Deregallera Ltd, Caerphilly, United Kingdom.

With ~60% of all generated energy wasted as heat[1], energy harvesting is an important avenue to help provide for our worlds increased power demand in a sustainable way. Thermoelectric (TE) devices offer the unique opportunity to recover this previously wasted energy, and improve performance, via a direct conversion of heat to electricity in a solid state device. The key limitation of TE devices is their poor power conversion efficiency, characterised by the dimensionless figure of merit, ZT. This value depends on both the electron and phonon transport characteristics, which themselves are heavily interdependent. For optimal TE behavior the electronic conductivity should be high whilst the thermal conductivity is kept to a minimum. However, in the majority of cases an increase in electrical conductivity is accompanied by an increase in thermal conductivity due to the Wiedemann-Franz Law[2], which links the thermal conductivity of electrons to the charge carrier density. It is this interdependence which has effectively limited the maximum ZT achievable to its current value of ~3[3]. Therefore, the ideal technique for raising ZT further would break this interdependence and optimize these characteristics independently. With this in mind, we investigate interfacial patterning as a method for controlling the transport properties of phonons. This method utilizes the fundamental difference in electron and phonon wavefunctions to selectively scatter phonons and hence reduce thermal conductivity, whilst having a minimal effect on electronic transport. Using density functional theory, we demonstrate the effectiveness of interfacial patterning on Si/Ge structures. We investigate three differently patterned interfaces, noting how subtle changes in the patterning can have dramatic effects on properties such as the effective mass and the lattice thermal conductivity. This patterning provides a technique to enhance ZT and a framework for producing more viable devices from any heterostructure-based TE materials.

Thermal Transport in Electrodeposited Antimony Telluride Films of Varying Silver Content Laia Ferrer-Arregui$^1$, Zini Yu$^1$, Jiwon Kim$^2$, Nosang Myung$^3$, Jae-Hong Lim$^2$ and Jacho Lee$^1$; $^1$Mechanical and Aerospace Engineering, University of California, Irvine, Irvine, California, United States; $^2$Electrochemistry Research Group, Materials Processing Division, Korea Institute of Materials Science, Changwon-si, Korea (the Republic of); $^3$Department of Chemical and Environmental Engineering and UC-KIMS CIME, University of California-Riverside, Riverside, California, United States.

While electrodeposited antimony telluride thin films with silver demonstrated promising thermoelectric properties, their thermal conductivity and the silver-content-dependence remain unknown. Here we report the thermal conductivity of Ag$_x$(Sb$_{1-x}$Te$_2$) and AgSbTe$_2$ thin films with controlled annealing and temperature conditions and demonstrate the impact of silver content on thermal transport. By annealing the as-deposited samples at 160 °C, the room-temperature thermal conductivity of Ag$_x$(Sb$_{1-x}$Te$_2$) and AgSbTe$_2$ films increases from 0.24 to 1.59 Wm$^{-1}$K$^{-1}$ and from 0.17 to 0.56 Wm$^{-1}$K$^{-1}$, respectively. When the pre-annealing temperature is below 110 °C, the thermal conductivities of the films are lower compared with the Sb$_2$Te$_3$ films (undoped) treated by identical annealing conditions. The thermal conductivity increases are attributed to the crystal growth, which are...
supported by the estimated grain size based on X-ray diffraction analysis. The thermal conductivity reduction of silver-doped films compared with the undoped films is attributed to the inhibited nucleation and crystallization of Sb$_2$Te$_3$ especially for films annealed below 110 °C, supported by the transient thermal conductivity measurement at 94 °C which reveals the crystallization activation energy to be 1.14 eV and 1.16 eV for Ag$_{18}$Sb$_{48}$Te$_{63}$ and AgSbTe$_2$ films, respectively. By increasing the pre-annealing temperature, we observe competing effects between the amorphous and crystalline phases in the silver-doped samples, confirmed by the temperature-dependent thermal conductivity measurement and the semi-empirical models combining different phonon scattering mechanisms. Based on previously reported electrical data, we estimate the room-temperature thermoelectric figure of merit of Ag$_{18}$Sb$_{48}$Te$_{63}$ and AgSbTe$_2$ to be 0.95 ± 0.35 and 0.71 ± 0.07. These results improve our understanding of the role of metal doping in thermal transport, which can guide optimal designs of chalcogenide materials for room-temperature thermoelectric applications.

Thermoelectric Figure-of-Merit of Polycrystalline P-Type Doped SiGe Thin Films Mohammadali Esfamisary, Yingying Zhang, Xiaojia Wang and Uwe Kortshagen; Department of Mechanical Engineering, University of Minnesota, Minneapolis, Minnesota, United States.

Silicon-germanium (SiGe) thin films are low cost and low toxicity candidates for high temperature thermoelectric applications. Thin films of p-type boron doped amorphous SiGe are deposited on quartz substrates via Plasma Enhanced Chemical Vapor Deposition (PECVD). This plasma uses RF powers of 1-10 W with pressures of 220 - 400 mTorr. The substrate is heated to 250°C during the film growth, which improves the quality of the film by providing the atoms with sufficient mobility to find a more stable and lower defect configuration. Boron is used as the dopant with concentrations ranging from 0.5% to 15%. By 15 minutes deposition, thin films with thicknesses of 250 - 400 nm are produced. Post deposition, polycrystalline structure is obtained by thermal annealing of the samples at 650°C for 10 hours. Raman spectroscopy shows three peaks for Ge-Ge, Si-Ge, and Si-Si bonds in both amorphous and polycrystalline films with higher intensities for the latter. This confirms higher crystallinity of the polycrystalline films compared to the initial amorphous samples. The thermoelectric figure-of-merit (ZT) is calculated by the conductivity and thermopower measurements at room temperature. The dark conductivity and Seebeck coefficient are measured in a vacuum chamber and the thermal conductivity is obtained by the ultrafast laser pump-probe technique. The effect of varying doping level, RF plasma power, and Ge concentration on the power factor of thin films is studied. The characterization is performed at two points in the process, pre- and post-annealing. The power factor is highly dependent on the doping concentration in both cases with a peak at the mid-range doping concentration. This is mainly due the balance of the carrier density and carrier mobility in doped samples. Results also show a minimum of three orders of magnitude improvement of the thermoelectric figure-of-merit after annealing in all conditions.

Recent Progress in Organic-Based Aqueous Flow Batteries Michael J. Aziz; Harvard University, Cambridge, Massachusetts, United States.

The ability to store large amounts of electrical energy is of increasing importance with the growing fraction of electricity generation from intermittent renewable sources such as wind and solar. Wide-scale utilization of flow batteries is limited by the cost of redox-active metals such as vanadium or precious metal electrocatalysts. We have developed high performance flow batteries based on the aqueous redox behavior of small organic and organometallic molecules, e.g. [1-8]. These redox active materials can be very inexpensive and exhibit rapid redox kinetics and high solubilities, potentially enabling massive electrical energy storage at greatly reduced cost. We have developed new protocols for measuring capacity fade rates and have discovered that the capacity fade rate is determined by the molecular calendar life, which can depend on state of charge, but is independent of the number of charge-discharge cycles imposed [7]. We will report the performance of the very few chemistries with long enough calendar life for practical application in stationary storage.

http://dx.doi.org/10.1002/aenm.201702056
Until very recently, the choice of electroactive materials in aqueous RFBs has been limited mostly to transition metal redox species, such as all-vanadium RFBs, which however are limited by the high cost of vanadium. Aqueous soluble organic (ASO) redox-active materials have recently shown promise as alternatives to transition metal ions to be employed in RFBs because of structural tunability, cost-effectiveness, availability, and safety features. To date, reported research on ASO species is rather limited and has been focused mostly on quinone, viologen, TEMPO, and ferrocene compounds.

In this presentation, we describe development of a new high energy density organic redox material as a promising ASO anolyte. In our research, we focused on investigating the primary ASO properties (i.e., solubility and redox potential) through a framework of combined nuclear magnetic resonance (NMR), density functional theory (DFT), organic synthesis, and electrochemical studies. Rational introduction of functional moieties in an asymmetrical configuration initiates preferential solvation that significantly enhances the solubility from near-zero to up to 1.8 M in potassium based supporting electrolyte. The electrochemical performance of the new organic redox couple based anolytes was evaluated in a RFB using the well-established ferro/ferricyanide catholyte that leads to a high cell voltage of 1.4 V. Cycled at a high ASO concentration of 1.4 M (96 % of its maximum solubility of 1.45 M in 1 M NaOH ), the flow battery produced an exceptional reversible volumetric capacity of 67.4 Ah L⁻¹ demonstrating for the first time of a ASO redox active material with reversible capacity equivalent to 2.8 M electron concentration.

**Soluble, Stable Organic Redox-Active Materials for Redox Flow Batteries**

**Xiaoliang Wei**
Pacific Northwest National Laboratory, Richland,Washington, United States.

Redox flow batteries (RFBs) are an exciting target for storing renewable energy at a large scale. Currently available commercial RFBs relying on vanadium as the redox material have suffered from high cost to be scale to a grid-level size. Such a challenge could be reduced if redox-active organic molecules could be used instead of vanadium. In addition, the design of redox molecules with various functionalities can tune the molecular properties, which eventually allows for improving the solubility and controlling the redox potentials to optimize their performance. However, there are very few candidates that could serve as organic redox materials and almost all of them act as a single-electron carrier. For increasing the energy density, the effective strategies are (1) increasing voltage gap as the redox materials reversibly respond more negative/positive potentials for negolyte/posolyte, respectively, (2) increasing solubility, and (3) designing redox materials capable of two (or more)-electron storage, which instantly doubles the energy density. Here we present some research results which have been done in our laboratory for the target of increasing energy density. We show a new class of organic material of naphthalene diimide (NDI) that can reversibly store two electrons at neutral pH in aqueous solution. By decorating with glycinate, the solubility of n-type organic semiconducting NDI was improved in aqueous solution. We studied the fundamental two-electron redox behavior from experimental and computational analyses and displayed a prototype RFB containing [K-BNDI] negolyte and 4-OH-TEMPO posolyte with reasonable cyclability, energy efficiency and excellent stability. To improve the stability of redox materials, we also attempted to use redox-active organometalllic molecules such as pseudo-octahedral Co-polypyridyl complexes, and developed rational strategies for enhancing the robustness, namely, the spin-crossover between low and high-spin states and the chelation effect emerging from replacing three bidentate ligands with two tridentate analogues.

**Sulfonate Functionalized Viologens for Energy Storage with Superior Energy Density and Cycling Stability**

**Jian Lu**
Bo Hu, Camden Debruler, Maowei Hu, Wenda Wu and Tianbiao L. Liu; The Department of Chemistry and Biochemistry, Utah State University, Logan, Utah, United States.

To efficiently utilize the intermittent renewable energy source such as wind and solar energy and achieve sustainable society, advanced large-scale energy storage technologies are highly demanded. Among various energy storage devices, aqueous organic redox flow batteries (AORFBs) are one of the most promising battery technologies for large scale storage of intermittent energy because of a number of technological merits including decoupled energy and power, higher current and high power performance, safety features, and synthetic tunability of charge storage molecules. Herein, we developed a serial of low-cost, highly water soluble sulfonate functionalized viologens as anolyte for AORFB.
applications. The negative charged sulfonate pendant side chains and favorable molecular sizes of these viologens enable their compatibility with cation exchange membranes. The newly designed viologens were paired with low-cost I$_2$/Br$_2$/Br and Fe(CN)$_6^{4-}$/Fe(CN)$_6^{3-}$ catholytes in RFBs using cation exchange mechanism. The 1,1'-bis(3-sulfonatopropyl)-4,4'-bipyridinium, (SPr)$_2$V/I RFB delivered 1.0 V battery voltage and reliable battery performance under a pH neutral condition. When the (SPr)$_2$V was paired with a newly designed organometallic catholyte material (NH$_4$)$_2$Fe(CN)$_6$, a 0.9 M pH neutral (SPr)$_2$V/Fe(CN)$_6^{3-}$ system delivered unprecedented storage capacity and cycling stability, specifically, 24.1 Ah/L electrolyte capacity, 62.6% energy efficiency and 100% capacity retention in 1000 cycles (more than 45 days testing duration), which represents the best cycling stability among all reported organic RFBs. To further improve battery voltage and energy density, the (SPr)$_2$V was paired with Br$_2$/Br catholyte. The (SPr)$_2$V/Br RFB delivered a battery voltage of 1.51V, 78% energy efficiency, and up to a 30.4 Wh/L operated energy density in a 1.5 M battery. Other asymmetric sulfonate functionalized viologens, such as (Se)$_2$(SPr)$_2$V and (SPr)$_2$(SBu)$_2$V, with even higher chemical stability and water solubility were also prepared for AORFB applications.

The urgent need for cleaner energy technologies calls for a radical change in the energy mix to favor renewable energy (+138.5 GW added in 2016 [1]) and environmentally responsible energy storage solutions. Within this background, the development of reliable, efficient, low-polluting and low-cost electrochemical storage systems can be considered as particularly important. Among the various possible technologies, Redox Flow Batteries (RFBs) is believed as suitable devices for large-scale energy storage [2]. Basically, both physico-chemical and electrochemical properties of the selected redox-active species are particularly crucial. Thus their solubility, chemical stability and the resulting output voltage (after assembly) define the energy density, the cyclability and the power density of the system, respectively. Interestingly, the use of organic electroactive species enable access to low cost and possibly greener compounds because composed of naturally abundant elements. Moreover, they offer high structural designability through the well-established principles of organic chemistry and notably access to both n- and p-type electrochemical storage mechanisms [3–5]. As part of our ongoing effort in developing novel Aqueous Organic Redox Flow Batteries (ORFBs), we will present our recent results dealing with the synthesis and characterizations of a novel highly soluble organic derivative used as catholyte and based on the stable tetramethylpiperidine N-oxyl moiety [6,7]. The electrochemical properties of the catholyte will be reported as well as additional data obtained in a full battery configuration.

Due to the intermittent nature of sunlight, practical solar energy utilization systems demand both efficient solar energy conversion and inexpensive large scale energy storage. We have developed novel hybrid solar-charged storage devices that integrate organic redox flow batteries (RFBs) and regenerative semiconductor solar cells that share the same pair of redox couples. In these integrated solar flow batteries (SFBs), solar energy is absorbed by semiconductor electrodes and photoexcited carriers are collected at the semiconductor-liquid electrolyte interface and used to convert the redox couples in the RFB to fully charge up the battery. When electricity is needed, the charged up redox couples are discharged to generate the electricity. We have demonstrated that solar energy harvest, conversion, storage, and redelivery can be completed by such a single integrated SFB without any external electrical energy input. After developing high performance III-V solar cells that are carefully matched with various high voltage organic couples and optimizing several generations of SFB device designs, we have achieved integrated SFB device with an overall direct solar-to-output electricity efficiency (SOEE) of 14%. We have further improved the cycling performance of the SFBs by integrating robust organic redox couples. To enable SFBs in practical distributed and standalone solar energy conversion and storage systems in remote locations, we aim to keep a low overall cost for SFB devices while maintaining its high performance, thus lowering the chemical cost of redox active materials could be one of the effective ways to achieve such goal. Therefore, we are particularly interested in new, inexpensive, and robust redox couples with diverse redox potentials.

During the last decades, the demand for environmentally friendly renewable power source has grown rapidly to achieve the sustainable society. To efficiently utilize the widespread but intermittent renewable energy source such as solar and wind energy, low-cost and reliable large-scale energy storage technologies were required. Aqueous organic redox flow batteries (AORFBs) with the merits of decoupled energy and power, higher current and high power performance, safety features, synthetic tunability of charge storage molecules, and potentially low-cost, are ideal solution for the intermittent energy storage and electricity grids balancing. Herein, we designed and synthesized sulfonate functionalized viologen compound [1,1'-bis(3-sulfonatopropyl)-4,4'-bipyridinium], (SPr)$_2$V as a low-cost, highly soluble anode material for pH neutral AORFB application. DFT computational studies suggested charge repulsion and size exclusion enable the compatibility of (SPr)$_2$V with a cation exchange membrane. The superior chemical stability of the (SPr)$_2$V anolyte was confirmed by a 0.5 M half-cell (SPr)$_2$V/Br$_2$ battery test. Paired with the inexpensive I$_2$/catatholyte, the (SPr)$_2$V/I neutral AORFB delivered 1.0 V battery voltage and up to 71% energy efficiency with 99.99% capacity retention per cycle. When combined with (NH$_4$)$_2$Fe(CN)$_6$, a 0.9 M or 24.1 Wh/L symmetric (SPr)$_2$V/(NH$_4$)$_2$Fe(CN)$_6$ delivered ultra-stable cycling performance, nearly no capacity decay for 1000 cycles. To further boost the battery voltage and energy density of the (SPr)$_2$V-based AORFBs, Br$_2$/Br catholyte was chosen to combine with (SPr)$_2$V for AORFB demonstration. The (SPr)$_2$V/Br AORFB delivered 1.51 V battery voltage and 30.4 Wh/L operated energy density due to the high potential of Br$_2$/Br redox couple and high solubility of (SPr)$_2$V anode material. Furthermore, the (SPr)$_2$V/Br AORFB maintained excellent energy and power performance under 1.5 M concentration, respectively, up to 78% energy efficiency and 228 mWh/cm$^2$ power density, which is the highest power density ever reported in neutral AORFBs.

Ref:
Highly soluble redox-active polymers (RAPs) and colloids (RACs) \cite{1} are a new class of materials in the form of fluid dispersions that support a new concept in size-exclusion flow batteries. Because RAPs and RACs rely on intra-particle charge transfer to yield quantitative charge accessibility and high rate, understanding the intrinsic properties of these particles, as opposed to them in the bulk fluids, is of great interest to understand their limitations and to identify design opportunities. In this talk, I will present on the use of RAPs and RACs through a spectrum of powerful electrochemical techniques, ranging from spectroelectrochemical approaches to single-particle analysis.

In a first application, I will describe how nano-resolved scanning electrochemical microscopy (SECM) and its combination with Raman spectroscopy has helped us understand the mechanisms of individual electrochemical entities. These experiments provide us with unprecedented versatility to identify kinetic bottlenecks, such as charge trapping, and to determine the maximum current densities attainable in flow devices. Our data indicate that RACs undergo some conditioning upon electrolysis, and that their charge transport is sensitive to state-of-charge (SoC).

In a second application, I will describe how new redox mediation electrocatalysis using each redox-active pendant in RAPs as an electron transfer agent can be exploited to solve pervasive problems with passivating interfaces in complex chemistries, such as those involved in Li-air batteries. Here, investigations of charge transfer and of transient titration of reaction intermediates allow us to understand electrocatalysis, and the conditions that lead to effective storage or to failure. We expect that our methods will be extendable to other energy storage systems of interest to the community.

Diffusion-Free Grotthuss Topochemistry for High-rate and Long-Life Proton Batteries

Redox flow batteries (RFBs) are some of the most promising energy storage systems because of their scalability and design flexibility; however, their low energy density is a major drawback limiting their widespread application. Most conventional approaches to increase the energy density have involved exploiting high-concentration electrolytes. However, this approach results in many technical issues such as increased viscosity and sluggish kinetics. In this work, we propose a strategy of boosting the energy density by exploiting an active material based on phenazine molecule (5,10-dihydro-5,10-dimethyl phenazine or DMPZ), which is capable of multi-redox reaction at ~0.15 and 0.61 V vs Ag/AgCl. This novel positive electrode material exhibits reversible double-redox activity with fast kinetics and remarkable chemical stability. Coupled with 9-fluorone (FL), the DMPZ/FL flow cell can provide the highest energy density per mole (=85 Wh kg$^{-1}$) ever reported for RFBs. Furthermore, the marked color change of DMPZ at different charged states enables the state of charge to be precisely visualized. This novel strategy on multi-electron redox material can provide a potential pathway toward high-energy-density RFBs.

Erin L. Ratcliff; University of Arizona, Tucson, Arizona, United States.

Intermittent sunlight necessitates the storage of electricity, ideally in controlled chemical reactions analogous to photosynthesis. Many efforts have focused on the oxidation of water at metal oxide semiconductor surfaces, although light-driven electrochemical reactions at photoelectrodes continue to suffer from sluggish half-reactions. One major challenge continues to be the control of multi-electron transfer events with well-defined rate constants. An ideal materials design approach would enable predictable rate constants prior to photo-electrode fabrication.

Electrodes comprised of organic semiconductor films offer the possibility to control redox processes independent of opto-electronic behaviors, making these electrodes a new idea for next-generation photoelectrodes. Examples of proof-of-concept include photo-capacitors and photo-driven water splitting. Yet to date, electron-transfer rates between conductive polymers and redox species remain slower than inorganic materials including metals and oxides, making it difficult to incorporate these inexpensive, printable systems in redox flow systems.

Most recently, we showed that the rate of electron transfer is predictable using a Marcus-Gierischer relationship, whereby the dominant factor controlling the rate of electron-transfer is the overlap in the density of states of the electrode with the density of states of the redox probe. With this new insight, we demonstrated that the microstructure of the polymer electrode becomes a critical component to controlling the symmetry of charge transfer reactions. Control of the microstructure enables moving the charge transfer events into the mass transport limit necessary for energy storage systems.

In this work, we focus on nanoscale manipulation of electron transfer events, relative to mass transfer of the redox probe, to further control electrode performance. Specifically, we investigate the role of heterogeneity of blended polymer electrodes. Both macroscale and nanoscale electrochemical phenomena will be discussed using a combination of spectroelectrochemical and scanning electrochemical microscopy. We demonstrate that the macroscale rate of electron transfer can be further controlled beyond the density of states framework, offering a new paradigm to control multi-electron transfer events not available in inorganic systems.

SESSION ES01.04: Redox Organic Electrode Materials in Metal Ion Batteries I
Session Chairs: Philippe Poizot and Hui Zhan
Wednesday Afternoon, April 24, 2019
PCC North, 100 Level, Room 126 A

1:30 PM *ES01.04.01
Some New Considerations on Aqueous Rechargeable Batteries
Xiulei (David) Ji$^{1,2}$, Jun Lu$^2$ and Alex Greaney$^3$; Department of Chemistry, Oregon State University, Corvallis, Oregon, United States; $^1$Chemical Sciences and Engineering Division, Argonne National Laboratory, Lemont, Illinois, United States; $^2$Materials Science and Engineering Program, University of California, Riverside, Riverside, California, United States.

There is a pressing need for new battery technologies in two key areas: high-energy power batteries for electric vehicles, and large-scale storage batteries to buffer the output from the renewable-but-intermittent solar and wind power generation. For storage batteries, the goal is to minimize the levelized energy cost over the devices’ lifetime. This means that electrode materials containing rare and expensive elements should be avoided. Secondly, the cycle life of storage batteries must be excellent — ideally over 10,000 cycles. Thirdly, these batteries should be quickly rechargeable to store, for example, energy from wind farms. Most importantly, storage batteries should be intrinsically safe, i.e., nonflammable. To meet this list of requirements, batteries with aqueous electrolytes exhibit several distinct advantages. Aqueous electrolytes are cheaper and safer. The simplicity of an aqueous chemistry environment may facilitate long battery longevity, and its high conductivity brings an innate power advantage. In battery chemistry design, one of the most important considerations is the choice of working charge carriers. To date, a major portion of battery technologies rely on metal-ion charge carriers. Surprisingly, non-metal cations, particularly proton-containing cations, i.e., $^1\text{H}^+$, $^2\text{H}^+$ and $^3\text{H}^+$, have received exceedingly little attention. The simplest form of hydrogen cation, a single proton, is nearly “invisible” with a measured radius of ~0.89 fm or ~2.1 fm, using muon or $^3\text{He}$ spectroscopy, respectively. Due to the negligible strain of hosting protons, the rate capability and cycle life of proton batteries have the potential to be far superior to those of existing batteries. In this talk, I will introduce some of our new results, experimental and computational, on the storage of new charge carriers in battery chemistry for grid-storage purposes, particularly related to the Grotthuss mechanism and the ion/electrode interactions. I will compare different charge carriers in terms of their correlations to electrochemical properties, such as capacity fading, polarization, and operation potentials.

Development of Organic Electrode Materials for Anion-Ion Batteries
Thibaut Gutel$^1$, Vincent Cadieu$^2$, Léon Merchat$^3$, Jeremie Salomons$^4$, Lionel Dubois$^4$, Dominique Guyomard$^1$ and Philippe Poizot$^2$; CEA, Grenoble, France; $^1$Université Grenoble Alpes, Grenoble, France; $^2$Institut des Matériaux Jean Rouxel, Nantes, France. Nowadays electrodes of lithium batteries are mainly constituted by inorganic compounds based on transition metals such as cobalt, nickel or manganese. Although their performances are satisfying, these materials present several important drawbacks. Indeed these compounds are expensive because they are prepared due to energy-consuming techniques from rare mineral precursors. Moreover, some metals are toxic and often hard to recycle. Eventually their reactivity leads to safety issues in abusive conditions. Organic electroactive compounds such as nitroxide based polymers or carbonate salts offer a cost-effective and environmental friendly alternative to conventional electrode materials for electrochemical storage. Interestingly these products can be prepared from low cost precursors using classical organic and polymer chemistry techniques. Moreover these compounds are easy to recycle or reuse at their end of life. Eventually organic electrode materials can followed n-doped but also p-doped redox mechanisms which enable to
imagine new battery configurations (cation-ion, dual-ion or anion-ion). But until now, their use is still challenging due to low cycle life usually related to their high solubility in organic solvents of electrolytes. Following the pioneer work of Yao et al. with its concept of molecular-ion based “rocking chair” battery, this work is focused on the development of optimized full organic battery using anion as a shuttle during charge/discharge in order to study their electrochemical performances for in particular high power applications.

First various polymers based on viologen redox unit were studied as negative electrode materials and the introduction of crosslinker but also the influence of the nature of counter-anion have been investigated. A particular strategy was identified in order to stabilize the specific capacity of polyviologen (PV) along cycling. In parallel, an original and insoluble structure based on lithium diaminoterephthalate (Li2DAnT) has been developed and even if some moderate electrochemical performances have been obtained, this development depends strongly for the first time the interest of terephthalate backbone to suppress the dissolution of p-doped organic materials. Finally the formulation of organic electrodes using PV, Li2DAnT but also using polynitrooxides (PTMA+) based composites were optimized in particular for screen printing process and several full organic batteries have been assembled and tested in anion-ion configuration. These results pave the way for the development of metal-free battery with high electrochemical performances.

2:15 PM ES01.04.03
Forming Stable Cathode-Solid Electrolyte Interface—Benefits of Organic Electrode Materials in All-Solid-State Batteries Fang Hao1, Xiaoweil Chi1, Yanliang Liang1, Rong Xu2, Hua Guo3, Kjeji Zhao4, Jun Lou4 and Yan Yao1; 1University of Houston, Houston, Texas, United States; 2Purdue University, West Lafayette, Indiana, United States; 3Rice University, Houston, Texas, United States.

Forming stable cathode-solid electrolyte interface is one of the greatest challenges in sulfide-based all-solid-state sodium batteries (ASSSBs). So far these ASSSBs suffer from low specific energy and poor cycling performances due to the interfacial incompatibility between cathode materials and sulfide electrolytes. Resistive layer forms at the interface due to the electrolyte decomposition at high potentials. Most previous cathodes are also too rigid to accommodate the volume change upon cycling, resulting in the inter-particulate contact loss. Herein we show an organic cathode material, pyrene-4,5,9,10-tetrone (PTO), that can form an (electro)chemically and mechanically compatible interface with Na2PS4. PTO has a moderate redox potential (2.2 V vs. Na+/Na) that aligns with the electrochemical stability window of Na2PS4. PTO also has a low Young’s modulus (4.2 × 0.2 GPa) that is similar to that of Na2PS4 (10.7 × 0.6 GPa), hence ensuring intimate PTO-Na2PS4 contact during cycling. The PTO-based ASSSB exhibits high specific energy of 587 Wh kg-1 at material-level and 89% capacity retention over 500 cycles. This work reveals an effective cathode design strategy towards compatibility with solid electrolytes and thus high-performance ASSSBs.

2:30 PM ES01.04.05
Redox Polymers with Heteroaromatic as Electrode-Active Materials for Batteries Birgit Esser1; 2; Institute for Organic Chemistry, University of Freiburg, Freiburg, Germany; 2Freiburg Materials Research Center, University of Freiburg, Freiburg, Germany.

In face of the climate change there is a strong and growing demand for the storage of renewable energies. Organic electrode materials have attracted great interest, as they can be prepared from renewable, sustainable or limited-resources, they are easy to recycle as well as potentially safer and cheaper to produce, leading to a low carbon footprint. A promising class of organic electrode materials are redox polymers — polymers containing groups that can be reversibly reduced or oxidized. In this talk organic redox polymers will be presented containing heteroaromatics as redox-active functionalities. The design, synthesis and electrochemical properties of these polymers will be discussed as well as their application as electrode-active materials in batteries. Mechanistic studies will be presented that show how the mobility of the redox polymer within the composite electrode as well as interactions between redox-active groups influence the specific capacity of the electrode as well as its cyclability.

4:00 PM ES01.04.05
Structure, Function and Electrochemistry of Novel Hybrid Organic/Inorganic MOFs Energy Storage Materials Kevin V. Nielson, Yujing Bi, Liping Zhang and Tianbiao L. Liu; Utah State University, Logan, Utah, United States.

The structure tunability and built-in porosity of metal organic frameworks (MOFs) materials makes them promising electrode materials to host metal ions. Herein, Novel MOFs materials consisting of redox active ligands and earth abundant transition metals were rationally designed and synthesized for ion intercalation energy storage applications. Structural characterization by X-ray diffraction, IR absorption, and elemental analysis confirmed target structures were assembled successfully. Electrochemical studies including cyclic voltammetry, electrochemical impedance spectroscopy, and full cell battery tests were conducted to verify these organic/inorganic materials have improved electrochemical reversibility, conductivity, and stability over purely organic or inorganic materials. For example, a Ni redox MOFs delivered outstanding battery performance for 1000 cycles with capacity retention up to 82%. Further studies on ionic conductivity, valence state analysis, gas adsorption, and charge storage mechanism were conducted to better understand the electrochemistry, structure/function relationship of these novel MOFs materials.

4:15 PM ES01.04.06
High Capacity and Long Cycle-Life Quinone-Type Active Materials for Use in Rechargeable Batteries Maseun Yao, Hisanori Ando, Tetsu Kiyobayashi and Nobuhiko Takeichi; AIST (National Institute of Advanced Industrial Science and Technology), Ibeda, Japan.

Using a redox active organic material as an electrode material of rechargeable lithium batteries can reduce the amount of minor metal-based materials from the current system. Among many organic candidates, we have focused on a series of low-molecular-weight quinone derivatives since they show high capacities based on their multi-electron transfer type redox reaction. However, many of them often show poor cycle-stabilities; therefore, improving the cycle-stability is an important concern. One of the reasons for the capacity fade is believed to be the dissolution of redox-active low-molecular-weight molecules into the electrolyte solution.

To suppress the solubility of the quinone-based molecules, we synthesized some oligomers in which the quinone sites are connected by some covalent bond or fused, and proved that these oligomers have longer cycle-lives than the monomers. For example, anthraquinone (AQ), a quinone containing the anthracene skeleton, shows a high initial discharge capacity of about 200 mAh/g with the average potential of 2.3 V vs. Li+/Li; however, its capacity notably decreases upon cycling. On the other hand, a fused larger polycyclic quinone having the pentacene skeleton (pentacenetetrone), which has lower solubility, exhibits a longer cycle-life than AQ. In addition, the solubility of the AQ derivatives can be lowered by oligomerization. We synthesized an AQ dimer and trimer, in which the AQ units are connected by the acetylene unit, and found that they are insoluble in ordinary solvents and show a longer cycle-performance. In particular, the trimer retained an almost constant capacity during the one hundred cycles. A similar result was also observed for the naphthazarin (5,8-dihydroxy-1,4-naphthoquinone) derivatives which undergo a four-electron transfer redox reaction. While the lithium salt of the naphthazarin itself (monomer) showed a high capacity of about 400 mAh/g with the average potential of 2.7 V vs. Li+/Li during the first cycle, its cycle stability was also poor. On the other hand, a dimer fused by the dithiin ring showed an improved battery performance; a high initial capacity of 416 mAh/g with a relatively stable cycle-performance was obtained.

We consider that the above-mentioned oligomers have a stronger attractive intermolecular force than the monomers which should contribute to a less solubility than the monomers. To obtain a theoretical insight into the intermolecular interactions, a quantum chemistry calculation was performed. Our calculation gave x-stacked structures for a series of the AQ oligomers, the charged naphthazarin and its fused dimer. The estimated binding energy for the monomers are about 20 kJ/mol, which are typical values for such stacked small molecules. As for the oligomers, a few times higher values (70-100 kJ/mol) were obtained. In general, intermolecular forces represented by the Van der Waals forces are considered to be very weak; however, the obtained stacking force values are much higher than the binding energy of the hydrogen bonding (10-40 kJ/mol) which is a relatively strong intermolecular force and comparable to the level of the covalent bonding (100-300 kJ/mol). This calculation indicates that oligomerization will be very effective to enhance
the intermolecular attractive interaction which should contribute to suppressing the dissolution. In summary, the oligomerization and/or ring-fusion of a redox active molecule showing multi-electron transfer reaction will be a guide for designing a new organic active material that can satisfy both the long cycle-life and high energy density requirements.

Molecular Design Strategies to Achieve Multi-Electron Redox Reactions of N-Containing Heterocyclic Molecules for High Voltage and Energy Electrode Materials
Ji Eon Kwong, Dong Joo Min, Kyu Nam Lee and Soo Young Park; Seoul National University, Seoul, Korea (the Republic of).

Organic redox-active molecules composed of only earth-abundant elements such as C, H, N, O, and S are very promising for the next-generation secondary batteries with low cost and sustainability. A lot of organic cathode materials have been reported, so far; however, their redox potentials are still mostly below 3.0 V vs. Li/Li⁺ which is considerably inferior to the conventional ones. Recently, a few organic molecules showing redox potential above 3.5 V vs. Li/Li⁺ are reported including triphenylamine (TPA), carbazole (Cbz), and phenothiazine (PTZ), whose charge/discharge mechanisms rely on oxidation reactions of N-containing heterocyclic redox centers. Although they show excellent cycle stability and high rate performance, most of them can undergo only a one-electron oxidation reaction, which limits their practical capacity below 100 mAh/g. Here, we report molecular design strategies to achieve a large specific capacity of the N-containing heterocyclic organic molecules by inducing multi-electron redox reactions. First, a series of novel organic molecules bearing phenoxazine (PXZ) as a new p-type redox center is reported. In the molecules, multiple PXZ units are covalently connected together by a phenyl ring core as a minimal linker. Through the combination of experimental and theoretical studies, it is revealed that the three-dimensional molecular geometry and the negligible re-organization during the redox reactions allow them to undergo reversible multi-electron redox reactions with minimal redox peak splitting. In the coin cells, they can deliver large specific capacity of more than 120 mAh/g with a discharge plate at 3.7 V vs. Li/Li⁺. It is noteworthy that they show excellent cycle stability over 500 cycles and good rate capability.

Second, we present a series of fixed pyrroles recently developed in my group as a new cathode active materials. They exhibit multi-electron oxidation reactions at above 3.5 V vs. Li/Li⁺ to provide large specific capacity. Their electrochemical properties and electrode performances are discussed in this presentation.

Viologen Redox Flow Batteries for Scalable and Sustainable Energy Storage
Bo Hu and Tianbiao L. Liu; Chemistry and Biochemistry, Utah State University, Logan, Utah, United States.

Redox flow batteries (RFBs) are a viable technology to store renewable energy in the form of electricity that can be supplied to electricity grids. However, widespread implementation of traditional aqueous inorganic redox flow batteries (AIRFBs), such as vanadium and Zn-Br, RFBs, is limited due to a number of challenges related to materials, including low abundance and high costs of redox-active metals, expensive separators, and corrosive and hazardous electrolytes. To address these challenges, our group has demonstrated a series of pH neutral aqueous organic redox flow batteries (AORFBs) based on tunable and sustainable viologen anolytes (e.g. methyl viologen (MV), 1,1′-bis[(3-trimethylammonio)propyl]-4,4′-bipyridinium ([NPr]2MV), and 1,1′-bis[3-sulfonatopropyl]-4,4′-bipyridinium ([SPr]2MV) with a variety of organic and inorganic catholytes. Viologen compounds display excellent chemical and electrochemical stability, desirable redox potential, and high solubility in water. The MV/FcNCI (FcNCI abbreviated for ferrocenyl(methyl)trimethylammonium chloride) AORFB was reported by us with outstanding cycling stability and power density, representing as a benchmark organic flow battery. By means of molecular engineering, we have not only tuned the molecular structures of viologen molecules and also achieved even better stability compared to the benchmark molecule, methyl viologen. These efforts have led to several outstanding pH neutral AORFBs: (1) the ([NPr]2V)/FcNCI anolyte, achieving a cell voltage of 1.72 V and a power density of 130 mW/cm²; (2) The 1.38 V ([NPr]2V)/TEAPORFB represents the most stable total organic RFB (99.93% capacity retention per cycle for overall 500 cycles), and (3) the ([SPr]2V/(NH4)2Fe(CN)6 AORFB represents the most stable AORFB (nearly 100% capacity retention after 1000 cycles) with a demonstrated high capacity (24.1 Ah/L). The presented high performance viologen AORFBs underline the great promise of scalable redox-active molecules for green energy storage. Particularly, this poster presentation emphasizes that fundamental understandings of redox-active electrolytes at molecular level are crucial to develop new generations of redox flow batteries for large scale and dispatchable renewable energy storage.

ES01.05.02
Supercapacitors from Solution-Processed Composites
Nelson E. Coates, John Wang and Jeffrey Urban; Lawrence Berkeley National Lab, Berkeley, California, United States; California State University - Maritime Academy, Vallejo, California, United States.

To accelerate the deployment of non-fossil fuel based transportation and grid-scale energy generation technologies, both high-power, and high-energy storage devices are needed. Supercapacitors are an emerging technology that can meet both of these storage needs by combining the high energy densities traditionally associated with batteries, with the high power densities traditionally associated with capacitors. Here, we describe recent progress fabricating capacitors from solution-processed composite materials, which is promising way to achieve high-performance supercapacitor architectures from a wide variety of electrode materials.

In their most simple form, capacitors can be thought of as geometric devices consisting of two conductors separated by an insulator. These two conductors can hold opposite charges, and thus store energy by creating an electric field in the volume of space between the two conductors. Because capacitors can store energy merely by moving charges in conductors as opposed to relying on slower electrochemical reactions to create mobile charges, they naturally have the ability to source higher power than batteries. But because simple capacitors do not store any energy in chemical reactions, they suffer from lower energy storage capacities than batteries. The amount of energy that is able to be stored in capacitors is much smaller than their curvature or area. Existing research into increasing the areas of capacitor electrodes, and decreasing the separation distance between them has been limited by the number of available electrode materials that can form structures with a continuous network of interpenetrating electrode phases, while still preventing charge transfer or electrochemical reactions between the electrodes.

A promising way to engineer a material geometry combining conducting phases with an enormous interfacial area separated by a very thin insulating layer is by using solution-cast materials. Solution-processing permits the mixing of a wide range of morphologically and chemically distinct electronic materials, which can either undergo non-equilibrium phase separation or spinodal decomposition into composites that have an enormous interfacial area to volume ratio and extremely small separation between the two phases. Our
preliminary results demonstrate that solution-processed composites have great potential for achieving high-performance capacitor architectures with a wide variety of electrode materials.

ES01.05.03

Organosilyl Nitrile and Organosilyl Nitrile/Carbonate Blend Electrolytes for Lithium-Ion Battery Applications Leslie J. Lyons1, Scott Beecher2, Evan Cunningham1, Tom Derrah1, Steven Sharp1, Shengyi Su1, Seiyong Yoon1, Junmin Zhu1, Monica Usrey2, Adrian Peña-Hueso3, Tobias Johnson4 and Robert West5; 1Department of Chemistry, Grinnell College, Grinnell, Iowa, United States; 2Silatronix, Inc., Madison, Wisconsin, United States.

Novel organosilicon nitrile (OSN) solvents have low flammability, broad electrochemical windows and excellent thermal stability, which make them promising materials for lithium-ion battery (LIB) electrolytes.1 This presentation will explore the ion transport of a variety of electrolytes composed of the organosilyl nitrile (OSN) solvents which vary in the degree of carbonation ions. The nonaqueous electrolyte media are also essential to offer wide electrochemical windows which have been studied for the role of posolys in nonaqueous medium while only a few nitrile electrolytes have been designed in this system.2 Herein, we present a new category of fused heterocyclic rings that can be employed as the negolyte. Our attempts to introduce various substituents to the core cyclic ring altered the electrochemical and chemical reversibility.

Redox flow batteries (RFBs) are one of the promising energy storages with a grid scale owing to their decoupled energy and power density, which lead to scalability and flexibility in design. To aim at higher energy density more than that of the current technology of vanadium RFBs, the redox-active molecules should have higher solubility and larger voltage gap than vanadium. The nonaqueous electrolyte media are also essential to offer wide electrochemical windows for RFBs. Many redox-active organic materials have been studied for the role of posolys in nonaqueous medium while only a few nitrile electrolytes have been designed in this system.2 Herein, we present a new category of fused heterocyclic rings that can be employed as the negolyte. Our attempts to introduce various substituents to the core cyclic ring altered the electrochemical and chemical reversibility.

The degree of molecular planarity and Lewis acidity/basicty of redox-active heterocyclic molecules critically determine the reversibility in cyclic voltammetry profile. The decorations of functionality also shift the redox potential and the number of electrons transferred. In addition, the asymmetric structure of heterocyclic rings may increase the solubility in the nonaqueous media. Through the fundamental studies on the design of heterocyclic rings and the corresponding electrochemical/chemical analyses, we demonstrated the optimum negolyte that can potentially provide high energy density and cyclic stability in nonaqueous RFBs. This study gives the guideline to develop new redox-active organic molecules for the application of RFBs.

Mellitic Trimides Showing Three One-Electron Redox Reactions for Large Capacity Organic Electrode Materials Dong Joo Min, Ji Eon Kwon and Soo Young Park; Seoul National University, Seoul, Alabama, United States.

Since the development of the transition metal oxide-based electrodes has been reaching its theoretical limits, organic electrode materials have attracted much attention as alternatives due to light weight, abundance, low cost, sustainability, and chemical diversity. Among others, cyclic imides, which consist of two acyl groups bound to a nitrogen atom, are one of the most promising redox centers for organic electrode materials due to their stable and reversible one-electron reduction. Although a lot of organic electrode materials bearing two cyclic aromatic imides such as perylene diimides, naphthalene diimides, and pyromellitic diimides showed superior cycle and rate performance, they can deliver rather low specific capacities. In fact, regarding their reversible two-electron reduction, the theoretical capacities of the diimide cores possessing no substituents at the two N-positions are up to 137, 201, 248 mAh/g for perylene, naphthalene, and pyromellitic diimide, respectively. Practically, small substituents are necessarily required to utilize them for electrode materials, which typically limits their practical capacity far below 200 mAh/g.

Here, we present a series of mellitic trimides which bear three cyclic imide groups fused to one phenyl ring with C3-symmetry. Theoretically, the non-substituted mellitic trimide core is able to accept three electrons to deliver a specific capacity up to 282 mAh/g. As a model compound, ethyl-substituted mellitic trimide (ETI, theoretical specific capacity = 218 mAh/g) shows well distinguished and reversible three-onelectron redox reactions at -0.97, -1.62, and -2.36 V vs. Ag/Ag+, respectively, in the cyclic voltammetry experiments. In the galvanostatic charge/discharge test, ETI electrode delivers a specific capacity of 225 mAh/g, one of the highest capacity among the imides electrodes, with three distinct plateaus at 2.82, 2.30, and 2.09 V vs. Li/Li+, respectively, in the coin cell.

Organic Semiconductor (Photo)electrodes in Redox-Based Electrochemical Flow Cells Zhiting Chen, Jonathan Harris, Bharati Neelamraju, Melanie Rudolph and Erin L. Ratcliff; The University of Arizona, Tucson, Arizona, United States.

Controlling interfacial electron-transfer rates is fundamental to maximizing device efficiencies in electrochemical technologies including redox-flow batteries, chemical sensors, bioelectronics, and photo-electrochemical devices. In many of these technologies, control of multi-electron transfer events with well-defined rates constants is required, but is often limited by natural choices. Electrodes comprised of organic semiconductor films offer the possibility to control redox properties independently of opto-electronic behaviors, making these electrodes idea for next-generation photoelectrodes. Yet to date, electron-transfer rates between conductive polymers and redox species remain slower than inorganic materials including metals and oxides. Most recently, we showed that the rate of electron transfer is predictable using a Marcus-Gerischer relationship, whereby the dominant factor controlling the rate of electron-transfer is the overlap in the density of states of the electrode with the density of states of the redox probe. With this new insight, we demonstrated that the microstructure of the polymer electrode becomes a critical component to controlling the symmetry of charge transfer reactions. In this work, we focus on nanoscale manipulation of electron transfer events, relative to mass transfer of the redox probe, to further control electrode performance. Specifically, we investigate the role of heterogeneity of conductive polymer electrodes, using a model system comprised of varying sized ultra-microelectrodes formed from blends of poly(3-hexylthiophene) (P3HT) and poly(methyl methacrylate) (PMMA). We demonstrate that the mcraque rate of electron transfer can be further controlled beyond the density of states framework, offering a new paradigm to control multi-electron transfer events.

An Analysis of Lithium Sulfur Interactions via GITT Measurements Daisy Patino, Bo Dong, Ruoxu Shang, Taner Zerrin and Cengiz S. Ozkan; University of California, Riverside, Riverside, California, United States.

The galvanostatic intermittent titration technique (GITT) is an electroanalytical tool commonly used in lithium ion technologies which uses transient and steady state measurements to obtain kinetic and thermodynamic properties of electrodes materials. The GITT procedure involves applying short current pulses followed by relaxation periods. In conventional lithium ion cells, when we apply current pulses, we induce concentration changes within the host electrodes. In lithium sulfur batteries however, the concentration change occurs in the electrolyte due to the reduction process of sulfur to electrolyte-soluble polysulfides. Hence, it is a complex procedure to quantify values such as, chemical diffusivity coefficient of lithium ions and the resistivity through the electrolyte in lithium sulfur cells, as opposed to conventional solid state lithium ion cells. Accordingly, research efforts to utilize GITT for lithium sulfur cells, omit the polysulfide shuttle mechanism to obtain a semi-solid state model. Herein, we explore a complete lithium sulfur model that enables more accurate qualitative depictions for mass transport rates, chemical reaction rates, and sulfur utilization.

Improved Radical Stability of Violanolytes in Aqueous Organic Redox Flow Batteries Maowei Hu, Bo Hu and Tianbiao L. Liu; Chemistry and Biochemistry, Utah State University, Logan, Utah, United States.

Redox flow batteries (RFBs) are a viable technology to store renewable energy in the form of electricity that can be supplied to electricity grids. Methyl viologens are a highly attractive anode material due to it high solubility in water, low cost, fast electrochemical kinetics, and excellent chemical stability under pH neutral conditions. Our group reported a 1.2 V methyl viologen (MV)/4-hydroxyl-TEMPO (4-HO-TEMPO) neutral aqueous organic redox flow battery (AORFB) and a high theoretical energy density FeNCU/MV AORFB. In this presentation, we introduce a highly stable 1.38 V viologen/TEMPO AORFB using 1,1'-bis[3-(trimethylammonio)-propyl]-4,4'-bipyridinium tetrachloride known to date. Compared to the (NPr)2-TEMPO as a catholyte. The (NPr)2-V/NMe4-TEMPO AORFB displayed outstanding cycling stability, 97.48% total capacity retention or 99.995% capacity retention per cycle for 500 cycles at 60mA/cm2 and a high power density of 128.2 mW/cm2 under pH neutral conditions, representing the most stable total AORFBs known to date. Compared to the (NPr)2-V/NMe4-TEMPO AORFB (97.48% total capacity or 99.995% capacity retention per cycle), the long-term cycling stability of the MV/NMe4- TEMPO AORFB (91.21% total capacity, which is equivalent to 99.982% capacity retention per cycle) is apparently inferior to that of the (NPr)2-V/NMe4-TEMPO. We believe that the more stable charged state, [(NPr)2V]+, than [MV]+ contribute to the observed improved cycling stability of the (NPr)2-V/NMe4-TEMPO AORFB. To confirm this hypothesis, we used UV-vis absorption spectroscopy test the radical stability of [(NPr)2V]+ and [MV]+ (0.1 mM in 2 M NaCl). Over 48 hour continuous measurements, the absorption of [MV]+ showed a slow decay. For [(NPr)2V]+, almost no absorption decrease was observed. This studies confirmed that the outstanding cycling stability of the (NPr)2-V/NMe4- TEMPO AORFB is attributed to the exceptional radical stability of [(NPr)2V]+. The present study not only stresses the importance of the molecular engineering strategy to improve active materials’ stability but also advances the state of the art AORFBs for sustainable and green energy storage of renewable energy. Thursday Morning, April 25, 2019
PCC North, 100 Level, Room 126 A

8:00 AM ES01.06.01
PTMA@CTAB Core-Sphere Nanospheres Hybrids with Reduced Graphene Oxide as High-Performance Free-Standing Cathodes For Lithium-Ion Batteries He Jia and Jean-Francois Gothy; Institute of Condensed Matter and Nanosciences, Division of Bio and Soft Matter, Université catholique de Louvain, Louvain-la-Neuve, Belgium.

High-performance lithium-ion batteries based on organic active materials currently constitute one of the most investigated energy sources due to their inherent advantages such as renewability, lightness, fast charge and discharge, and more environmentally friendly features. Among different active organic materials investigated so far, poly(2,2,6,6-tetramethylpiperidinyloxy-4-yl methacrylate) (PTMA), a polymer bearing persistent nitroxide radicals as repeating units, has become one of the most promising candidate as cathode polymeric material for lithium-ion batteries, which exhibits fast reversible redox reactions and allows high energy storage, high potentials and a long cycling...
life. However, PTMA is easily dissolved into organic electrolytes and displays limited electrical conductivity, greatly hindering the performances of lithium ion batteries based on this polymer. Moreover a high mass loading of PTMA leads to the aggregation of active materials which cannot be fully utilized and hence in a decrease of the lithium performance of the battery.

Here, we report a facile and novel method for the fabrication of high performance free-standing cathodes using PTMA/CTAB nanospheres as active units and rGO@MWCNT as conductive framework. The introduction of PTMA nanostructures and their uniform distribution in the composite system shortens the ionic pathways in the active material and allows almost 100% active substance utilization. At the same time, the GGO coating on each of PTMA nanosphere not only effectively increases its stability in the electrolyte (0.03% capacity loss per cycle), but also avoids the aggregation of PTMA and leads to a high effective mass loading of active material. Most importantly, the composite electrode shows as high as 105 mAh/g specific capacity based on the mass of the whole electrode in the voltage range from 2V to 4V, which is almost the highest reported value for PTMA cathode materials. The presented work successfully improves conductivity and stability of PTMA as cathode which can be also extended to various organic materials to obtain high performance free-standing electrodes.

Solution-Processable Electroactive Polymers as Active Materials for Macroscale Energy-Storage Devices with High-Rate Capability
Jeffrey W. Long1, Megan B. Sassin2, Ashley N. Hoffnester1, Anna Österholm1, Chin Lo3 and John Reynolds2
1 Naval Research Laboratory, Washington, District of Columbia, United States; 2 Georgia Institute of Technology, Atlanta, Georgia, United States.

Electroactive polymers exhibit desirable properties for electrochemical storage, but their broader implementation is limited by the conventional methods by which they are prepared. Electropolymerization routes produce high-quality films, yet with thickness typically <1 μm. Solution-phase synthesis yields larger quantities of material, but in precipitate form that can be difficult to process into high-performance electrodes. The Reynolds group at Georgia Tech has recently introduced a family of solution-processable electroactive polymers, where solubility characteristics are controlled by derivatizing ProDOT and EDOT with particular side chains [1,2]. The ability to dissolve/disperse such polymers at high concentrations (e.g., in polar organic solvents) facilitates their incorporation into macroskopically thick carbon nanotube/nanofiber papers that serve as a base electrode architecture for macroscale devices. By distributing the polymer as a thin coating on a 3D carbon-based current collector, the fast-switching characteristics inherent to these ProDOT and EDOT polymers is maintained, while the capacity per geometric footprint is amplified by factors of ten or greater compared to analogous planar thin films. The chemical properties of these polymers can be further tuned for reactivity in either aqueous or nonaqueous electrolytes, which expands the range of electrochemical device configurations that will benefit from these charge-storing materials. We perform electrochemical tests on polymer-modified carbon paper electrodes in three-electrode half-cells and two-terminal devices, assessing such critical performance metrics as rate-dependent capacitance/capacity, self-discharge, and cycle life.

Pushing Further the Superlativity of Dilithium Benzenedipropiolate—Towards Extreme Capacities for Organic Electrode Materials

Daniel Brandelli, Antonia Kotronia, Marc Deschanps, and Stéven Renaud

1, Institut des Matériaux Jean Rouxel (IMN) - Université de Nantes, Nantes, France; 2Department of Chemistry - Ångström Laboratory, Uppsala University, Uppsala, Sweden; 3Blue Solutions, Quimper, France.

Organic electrode materials (OEMs) for lithium-ion batteries (LIBs) constitute a very promising alternative to standard electrodes materials that are prepared from finite and non-renewable minerals resources, since they instead are being potentially environmentally friendly, cheap, and abundant if derived from biomass via eco-friendly processes. However, their commercial use is currently held back, primarily due to their poor energy density. High specific capacity OEMs are therefore of uttermost interest. During the last 5 years, OEMs with the ability of an unexpected reversible reduction of carbon-carbon double bonds have sporadically been reported [1]. As a consequence of this redox process – coined ‘superlativity’ – specific energies several times higher than commercial standards (graphite) and Li/C ratios of 1/1 have been reported.

In a previous work on the ‘superlativity’ of dilithium benzenedipropiolate [2], we reported that this material can reversibly reduce its unsaturated carbon-carbon bonds in addition to the expected reduction of its carbonyls, leading to a Li/C ratio of 1/1 and specific capacity as high as 1363 mAh g⁻¹; the highest ever reported for a lithium carbonylate. However, the stability of this redox behavior was poor and obvious capacity fading was observed after a few cycles. We here show that better capacity and stability can be achieved with appropriate electrode formulation and optimization of parameters such as calendaring or temperature/electrolyte match (liquid or industrial quality polymer electrolytes).

Nickel-Salen Type Polymer as Conducting Agent and Binder for Carbon-Free Cathodes in Lithium-Ion Batteries

Jung-Hyun Kim, O'Meara Cody, Irina Chepurnaya, Mikhail Karushev, Sayth Dhamasaena, Hanna Cho, Benjamin Yurkovich, and Sam Koigan; 1Mechanical and Aerospace Engineering, Center for Automotive Research, The Ohio State University, Columbus, Ohio, United States; 2Powermers Inc, Westerville, Ohio, United States.

Polymeric salen-type metal complexes, often denoted as poly[M(Schiff)₂] (M = transition metals), is one of promising electronically conducting polymers. Among the poly[M(Schiff)₂] family, poly[Ni(CH₃-Salen)₃] has been most intensively investigated due to its promising electrochemical properties for energy storage devices such as supercapacitor and lithium-ion (Li-ion) battery. The poly[Ni(CH₃-Salen)] have been proven to have similar performance to other conducting polymers in terms of conductivity, while their commercial use is currently held back, primarily due to their poor energy density. High specific capacity OEMs are therefore of uttermost interest. During the last 5 years, OEMs with the ability of an unexpected reversible reduction of carbon-carbon double bonds have sporadically been reported [1]. As a consequence of this redox process – coined ‘superlativity’ – specific energies several times higher than commercial standards (graphite) and Li/C ratios of 1/1 have been reported.

PVdF Based Binder for Gelled Electrodes Used in Hybrid Polymer Lithium Battery

Helene Renaud, Olivier Prat, Djamel Mourzagh, Jeremie Salomon, Gaelle Besnard, Julio Abusleme, Daniel Glossener, and Marc-David Branda; 1 Commissariat à l’énergie atomique et aux énergies alternatives, Grenoble, France; 2Solvay Speciality Polymers, Bollate, Italy; 3Advanced Innovation Office, Solvay SA, Brussel, Belgium; 4Solvay R&I, Aubervilliers, France.

One of the most ambitious challenges for the planet for the next few future years is to reverse the worldwide CO2-related global warming and decrease the pollution of large modern cities by the burning of fossil fuels. Accordingly, the full or partial replacement of inner combustion engines by electric motors and the use of alternative green energy sources, such as solar or wind or geothermal for powering the stationary applications appear as necessary to reach these objectives, in conditions that energy storage systems could ensure a clean regulation the energy production. Henceforth, batteries and more especially rechargeable lithium batteries really represent a viable energy storage technology for supplying low-emission plug-in hybrid electric vehicles (HEVs), even for emission-free pure electric vehicles (EVs) or for the integration of renewable intermittent energy sources. Indeed, lithium based batteries exhibit high specific energy (high voltage charged with high specific capacity), long cyclelife, high efficiency, high charge/discharge rate capability and low self-discharge. In addition, it is a versatile technology easily adaptable to the application by playing with the electrode materials and electrolyte composition.

However, most commercial batteries widely use liquid electrolyte composed of organic solvents containing salt and impregnating a separator. This implies to define inevitably
Diversity-Oriented Approaches to Tailoring Ion-Selective Polymer Membranes for Aqueous and Non-Aqueous Electrochemical Devices

Moreover, assembled with hybrid polymer membrane without any addition of complementary electrolyte, the gelled electrodes work successfully at various discharge rates, even at high rates and exhibit a very stable behavior with very long cyclife.

Diversity-Oriented Approaches to Tailoring Ion-Selective Polymer Membranes for Aqueous and Non-Aqueous Electrochemical Devices

Brett Helms, Lawrence Berkeley National Lab, Berkeley, California, United States.

Low-Cost and ion-selective membranes are required to meet the growing demands for peak performance by next-generation batteries for EVs, aviation, and the grid. To that end, I will showcase a highly disruptive membrane platform based on polymers of intrinsic microporosity, whose pores are on the length scale of solvated ions and small molecules that are sometimes used as the battery’s active materials (e.g., as in flow batteries). The design space for these polymer membranes is advanced using a variety of computational tools, including computational materials genomics. The foundational knowledge built using these tools provides a roadmap for the diversity-oriented synthetic development of polymer membranes with specific pore architectures and chemistry, specifically tailored for the battery’s chemistry. I will also outline foundations on which to build adaptive membranes, where judiciously placed molecular switches allow for the membrane’s transport properties to be modulated in-situ in response to excursions that are otherwise detrimental to the battery’s cycle-life. There remains much to be learned about the origins of their adaptive and dynamic properties, and how these feed back across multiple length and timescales in the electrochemical cell.

Electrostatically Tuned Microdomain Morphology and Phase-Dependent Ion Transport Anisotropy in Single-Ion Conducting Block Copolyelectrolytes

Chenxi Zhai1, Huanhuan Zhou1, Teng Gao1, Lingling Zhao1 and Shangchao Lin1,2; 1Mechanical Engineering, Florida State University, Tallahassee, Florida, United States; 2Materials Science and Engineering, Florida State University, Tallahassee, Florida, United States; 3Energy & Environment, Southeast University, Nanjing, China.

Block copolyelectrolytes are solid-state single-ion conductors which phase separate into ubiquitous microdomains to enable both high ion transference number and structural integrity. Ion transport in these charged block copolymers highly depends on the nanoscale microdomain morphology; however, the influence of electrostatic interactions on morphology and ion diffusion pathways in block copolyelectrolytes remains an obscure feature. In this paper, we systematically predict the phase diagram and morphology of diblock copolyelectrolytes using a modified dissipative particle dynamics simulation framework, considering both explicit electrostatic interactions and ion diffusion dynamics. Various experimentally controllable conditions are considered here, including block volume fraction, Flory–Huggins parameter, block charge fraction or ion concentration, and dielectric constant. Boundaries for microphase transitions are identified based on the computed structure factors, mimicking small-angle X-ray scattering patterns. Furthermore, we develop a novel “diffusivity tensor” approach to predict the degree of anisotropy in ion diffusivity along the principal microdomain orientations, which leads to high-throughput mapping of phase-dependent ion transport properties. Inclusion of ions leads to a significant leftward and upward shift of the phase diagram due to ion-induced excluded volume, increased entropy of mixing, and reduced interfacial tension between dissimilar blocks. Interestingly, we discover that the inverse topology gyroid and cylindrical phases are ideal candidates for solid-state electrolytes in metal-ion batteries. These inverse phases exhibit an optimal combination of high ion conductivity, well-percolated diffusion pathways, and mechanical robustness. Finally, we find that higher dielectric constants can lead to higher ion diffusivity by reducing electrostatic cohesion between the charged block and counterions to facilitate ion diffusion across block microdomain interfaces. This work significantly expands the design space for emerging block copolyelectrolytes and motivates future efforts to explore inverse phases to avoid engineering hurdles of aligning microdomains or removing grain boundaries.

Crossover Mechanisms in Polymer Membranes for Redox Flow Batteries

Leeo J. Small, Harry D. Pratt, Cy Fujimoto and Travis M. Anderson; Sandia National Laboratories, Albuquerque, New Mexico, United States.

Redox flow batteries (RFBs) offer a scalable solution to grid scale energy storage. The polymer membrane in the RFB that separates the anolyte and catholyte is often underappreciated, preventing mixing of anolyte and catholyte while enabling counter-ion transport. During typical RFB operation, many membranes allow not only inert counter-ions, but also redox-active species to be transported through them. This unwanted transport of redox-active species, called crossover, effectively robs the battery of capacity and decreases performance. Understanding the fundamental mechanisms by which redox-active species are transported through the membrane is essential to designing next generation membrane materials. Here we discuss our recent progress evaluating the performance of several commercial and custom-made membranes using model aqueous and non-aqueous RFB chemistries. We demonstrate how fundamental membrane materials properties can be related to overall RFB performance. Trade-offs in membrane design (e.g. high conductivity vs. high diffusion) are shown to influence crossover mechanisms and overall RFB performance, offering insight to improving the performance of RFBs for grid scale energy storage.

Multifunctional Hydrogels for Energy Storage

Guihua Yu; The University of Texas at Austin, Austin, Texas, United States.

It is the reason why CEA-Liten and Solvay has engaged a large R&D program to propose a new safer and durable lithium battery system constituted of a hybrid polymer membrane and two gelled electrodes. The gelled character of the electrodes, i.e. the retention of the electrolyte in the electrode microstructure is favored by the use of a Solvay proprietary poly(vinylidene fluoride) based polymer as binder, capable to trap a lithium ion conducting organic solution. Specifically designed it ensures high adhesion, it allows obtaining adhesive microporous electrodes to metallic (Al or Cu based) current collector with porosity fully filled by carbonate based electrolyte. The method for preparing such gelled electrodes was developed in acetonitrile media, according to a three-step procedure similar to classical electrodes of Li-ion cell. Thus, after dispersion of the powder compounds in acetonitrile in presence of the electrolyte, the electrode ink is coated, dried and densified by calendaring in air under appropriate conditions. Prepared with ethylene carbonate / Propylene Carbonate (EC:PC 1:1) solution containing bis(trifluoromethanesulfonyl)imide lithium salt, LiTFSI (1M) or lithium hexafluorophosphate, LiPF6 (1M) at the labscale but also in continuous mode, the gelled graphite (Cgr) based or LiNi0.5Mn0.3Co0.2O2 (NMC) based electrodes exhibit regular surface, homogenous thickness with low roughness and good adhesion. In addition, its properties of flexibility and cohesion allow its implementation in wound roll of several meters.

Moreover, assembled with hybrid polymer membrane without any addition of complementary electrolyte, the gelled electrodes work successfully at various discharge rates, even at high rates and exhibit a very stable behavior with very long cyclife.
Hydrogels have become an appealing material platform for energy storage technologies. Developing hydrogels with enhanced physicochemical properties, such as mechanical strength, flexibility, dimensional stability, and fast charge transport, offers new opportunities for significantly improving the performance of energy storage devices. In this talk, I will discuss recent innovations in rational design and synthesis of hydrogels with diverse features, including stimuli-responsive, self-healing, and highly stretchable for next-generation electrochemical devices. I will then focus on how hydrogels have been integrated into energy storage systems, highlighting exciting examples that demonstrate the versatility of hydrogel materials in terms of tailorable architectures, conductive nanostructures, 3D frameworks and multi-functionalities.

Liquefied Gas Electrolytes for Low-Temperature Li-Metal Batteries
Yangyang Chen Yang1, Davies Dai2, Yiwei Yin1, Chengeng Fang1, Jungwoo Lee1,2, Xuefeng Wang2, Cyrus Rustgi1,3 and Y. Shirley Meng1,2,3; 1Materials Science and Engineering Program, University of California, San Diego, La Jolla, California, United States; 2Department of Nano Engineering, University of California, San Diego, La Jolla, California, United States; 3South 8 Technologies, San Diego, California, United States.

The key to enabling high-energy-density lithium (Li) metal batteries is the development of electrolyte for resolving Li metal challenges, in particular, the dendritic growth and low coulombic efficiency. The low-temperature operation is a large challenge for lithium-ion batteries, resulting from the sluggish diffusion, including the reduced electrolyte conductivity by electrolyte freezing, largely increased SEI resistances and the limited Li-ion diffusivity in the electrodes. However, there has been little change of electrolyte chemistry since their commercialization. These liquid electrolytes often limit the energy density and low-temperature operation of these devices, which hinder many potential applications. Our work uses electrolytes based on solvent systems which are typically gaseous under standard conditions and show excellent performance in electrochemical energy storage devices. Systems using fluoromethane-based liquefied gas electrolytes demonstrate remarkable rate capability (up to 10 mA cm⁻²) and excellent dendrite-free long-term (>500 cycles) cycling of Li metal anodes with a high coulombic efficiency of up to 99.9%. Both the rate and cycling performance are well maintained at a low temperature down to -60 °C. The superior performance is ascribed to the formation of a compacted Li metal deposition microstructure and a conductive, stable solid electrolyte interphase (SEI). This study opens up a promising avenue toward the applications of high-energy-density Li metal batteries.

4:15 PM ES01.07.06
Poly (aryl ether sulfone) Network Copolymer Membranes for Direct Methanol Fuel Cell (DMFC) Applications
Ende Can and Esra Yilmaz; Chemical Engineering, Yeditepe University, Istanbul, Turkey.

Fuel cells, which are electrochemical devices that convert the chemical energy into electrical energy have been considered as an alternative to existing power systems with high energy density, stable mode of operation and low pollution to environment. Fuel cells are most commonly classified by the type of electrolyte used in the cell. Proton exchange membrane fuel cells (PEMFCs), also classified as polymer electrolyte fuel cells (PEFCs) are low temperature fuel cells which represent a promising potential for portable devices, automobiles and power sources. The anode reactant is gaseous hydrogen in PEMFCs. Direct methanol fuel cell (DMFC) is a subgroup of PEMFCs and differs from it by the anode reactant which is liquid water and methanol. For DMFCs, a fuel reformer is not necessary as the platinum-ruthenium catalyst used in the DMFC anode can remove the hydrogen from liquid methanol. Use of methanol as a fuel has various advantages as it has a relatively high energy density, it is inexpensive, and in addition it can be easily stored and transported. On the other hand, DMFCs can be utilized in applications with limited power requirements, like mobile electronic devices or chargers and portable power packs for materials handling vehicles. The key component of a DMFC is the polymer electrolyte membrane (PEM) that acts as a mechanical separator between anode and cathode and demonstrates important functionalities like proton transport and methanol barrier. In this study, membranes of cross-linked sulfonated poly(aryl ether sulfone) derivatives were prepared and characterized for use in Direct Methanol Fuel Cell (DMFCs). For this purpose, partially sulfonated poly(aryl ether sulfone) (PESS) was synthesized and modified through an addition reaction of glycicyl methacrylate to the hydroxyl ends of the PESS polymer. The synthesized pre-polymer (PESSGMA) was then cross-linked via homo-polymerization and the oxidative polymerization with styrene and changing amounts of vinyl phosphonic acid (VPA). Crosslinking of the PESS polymer significantly decreased the swelling in water, ion exchange capacity, and the proton conductivity as well as the methanol permeability. The incorporation of VPA in the PESSGMA network on the other hand, increased the proton conductivity and the oxidative polymerization while keeping the outstanding resistance to methanol cross over which was significantly higher than that of the commercial Nafion membrane. Membranes of PESSGMA network copolymers with VPA showed Tg values in the range of 94 °C - 114 °C, water uptake values below 32% at 80 °C, proton conductivity values in the range of 16-32 mS cm⁻¹ and methanol permeability values in the range of 6.5x10⁻⁹ - 1.92x10⁻⁹ cm² s⁻¹ at 60°C [1]. In addition results of Fenton’s test showed that these membranes possessed excellent oxidative stability in a strongly oxidizing environment. Hence, the PESSGMA-VPA and PESSGMA-STY-VPA copolymer membranes developed in this study exhibit a high potential for use in DMFC applications. Moreover, these membranes can alternatively be useful in organic redox flow batteries as the proton-conducting polymer electrolyte membrane that keeps the reductive couples apart. The proton conductive PESSGMA-VPA network copolymer membranes should resist the cross-over of polar organic molecules like methanol and therefore have the capability to find applications in organic redox flow batteries.

4:30 PM ES01.07.07
Highly Conductive Polybenzimidazole Based Membranes Applied to All Vanadium Redox Flow Batteries
Lihui Wang1, Andrew Pingitore1, Wei Xie1, Yang Zhiew1, Mike L. Perry2 and Brian Benicewicz1; 1Univ of South Carolina, Columbia, South Carolina, United States; 2United Technologies Research Center, East Hartford, Connecticut, United States.

A series of polybenzimidazole (PBI) membranes were synthesized using sol-gel process and modified for all vanadium redox flow batteries (VRFB). These membranes demonstrated not only a high in-situ and ex-situ stability in concentrated sulfuric acid and in oxidative vanadium (V) solutions but also exhibited high conductivities and low performance degradation during in-cell testing for the ‘conventionally imbibed’ meta-polybenzimidazole (m-PBI) membranes cast from N,N’-dimethylacetamide (DMAc) solutions. The PBI membrane doped with 2.6 M H₂SO₄ shows a proton conductivity of 390 mS/cm at room temperature and VO²⁻ permeability as 2.30E-08 cm²/s. Different strategies were anticipated to block the porous structure of PBI membranes and further decrease vanadium ion permeability while maintaining the high proton conductivity. A VRFB operated with the modified PBI membrane shows over 98% coulombic efficiency under a large range of applied cell cycling current densities from 100 to 450 mA/cm².

SESSION ES01.08: Membranes and Electrolytes for Rechargeable Batteries II
Session Chair: Wu Xu

Stable High-Voltage Lithium Metal Batteries Enabled by Organic Ether Electrolytes
Wu Xu1, Xiaodi Ren1, Shuhong Jiao1,2 and Ji-Guang Zhang1,2; 1Energy and Environment Directorate, Pacific Northwest National Laboratory, Richland, Washington, United States; 2Department of Materials Science and Engineering, University of Science and Technology of China, Hefei, China.

The state-of-the-art lithium (Li)-ion batteries are approaching their energy density limit and cannot meet the fast increasing demand for higher energy density requirements. Due to the ultrahigh theoretical specific capacity (3,860 mAh g⁻¹) and the extremely low standard electrochemical redox potential (-3.040 V) of Li metal, it has long been regarded as an ideal anode material. The research and development of rechargeable Li metal batteries has therefore been revived in recent years. However, the big challenges related to Li metal anode, such as the safety issues due to the formation of metallic Li dendrites during repeated charge/discharge cycles and the short cycle life because of low Li Coulombic efficiency (CE), have not been completely solved and there is still a long way to go for the commercialization of rechargeable Li metal batteries. Many approaches have been reported to address the above challenges to Li metal anode and Li metal batteries, and many achievements have been reported recently. Among the reported strategies, the electrolyte design is one of the most effective and facile approaches to improve Li CE and cycling stability. Organic ether solvents have been found to be more stable with Li metal
Electrodeposition in Viscoelastic Polymer Aqueous Electrolyte

Electrodeposition plays an important role in electrochemical storage technologies based on batteries. It should be carefully managed to facilitate safe and stable operations in a broad range of conditions. In liquid electrolyte, deposition is subject to a variety of hydrodynamic and morphological instabilities, leading to a strong convective process near the interfaces. In many situations, the instabilities are problematic as the produced complex flows cause dendrite formation at planar interfaces, which is linked to the failure of microcircuits and overlimiting conductance.

This study focuses on the effects of aqueous viscoelastic electrolyte and the buoyancy force on the electrodeposition instabilities. By introducing a small amount of the polymers, the viscosity of the electrolyte largely increases without compromising ionic mobility. As a result, the voltage window of limiting current increases in the viscoelastic aqueous electrolyte. In the gravitationally unstable configuration, the variation of salt density leads to a Rayleigh-Bernard flow that increases the current. In this case, the influence of individual factors of the buoyancy effect is studied in the viscoelastic electrolyte system. And the qualitative and quantitative comparison with theoretical and simulation studies are performed to help clarify the mechanisms.

Organic Electrolytes in Promoting the Performance of Lithium-Ion and Sulfur-Based Batteries—X-Ray Spectroscopy Studies

Organic electrolyte is the key part in battery, but for various types of battery the requirements are different. An intercalation battery may prefer the formation of protective but ionic conducting solid-electrolyte interphase that is usually decomposed from the organic electrolytes, while the sulfur-based batteries need the electrolytes to suppress the formation of polysulfides. How to develop suitable electrolytes still remain technically challenging. In my group, we take the in situ operando view to check the performance of electrolytes and electrodes using X-ray absorption spectroscopy at both hard and soft X-ray regions. These element-specific methods enable us to examine the light elements in electrolytes and heavy elements in electrodes for comprehensive understanding. I will illustrate examples in lithium-ion batteries and lithium/magnesium-sulfur batteries to demonstrate how electrolyte can promote/inhibit the reactions.

Next generation electrochemical energy storage systems based on divalent metal cations occupy a new frontier of research and development efforts related to materials chemistry and design. High energy density batteries based on Mg or Ca metal anodes are yet to be realized due to problems associated with the stability and ion transport properties of organic electrolytes and insertion cathodes. In this presentation we will discuss results related to controlling Mg$^{2+}$ electrolyte properties via tuning of the organic solvent structure. While the role of competitive solvent and anion interactions in defining the properties of univalent organic electrolyte systems has received considerable investigation, such knowledge is still emergent in the divalent electrolyte field. This presentation will serve as a discussion of our recent findings on how the elemental solvent or co-solvent (e.g. glymes, cyclic ethers) structure defines stable Mg$^{2+}$ anion solvation populations, which in turn determine critical electrolyte performance attributes including ionic conductivity and Mg metal plating efficiency. Specifically, we will present electrochemical characterization of several inorganic and organic Mg-salts including MgCl$_2$, MgF$_2$H$_2$, Mg(CB$_2$H$_2$)$_2$, and Mg(BF$_4$)$_2$ across a systematic variation of etheral solvents along with characterization of the resulting solvation environments through solution spectroscopies including Raman, NMR, and X-ray absorption spectroscopy (XAS). These experimental results are further augmented with the aid of density functional theory and molecular dynamics simulations, providing insight into how the solution and interfacial chemistry regulates the behavior of Mg$^{2+}$ electrolyte systems.

Specifically, we will present electrochemical characterization of several inorganic and organic Mg-salts including MgCl$_2$, MgF$_2$H$_2$, Mg(CB$_2$H$_2$)$_2$, and Mg(BF$_4$)$_2$ across a systematic variation of etheral solvents along with characterization of the resulting solvation environments through solution spectroscopies including Raman, NMR, and X-ray absorption spectroscopy (XAS). These experimental results are further augmented with the aid of density functional theory and molecular dynamics simulations, providing insight into how the solution and interfacial chemistry regulates the behavior of Mg$^{2+}$ electrolyte systems.

Lithium-ion batteries (LiBs) have been predominant in electric vehicles and electronic devices applications because of their unparalleled combination of energy density and reasonable cost. Stabilizing the cathode/electrolyte interface at high voltage is necessary to achieve higher capacities while still maintaining capacity retention. However, the traditional organic carbonate-based electrolytes are not stable at these high voltages, new strategies must be adopted to stabilize this interface. One such strategy is through the use of inorganic electrolytes and insertion cathodes. In this presentation we will discuss results related to controlling Mg$^{2+}$ electrolyte properties via tuning of the organic solvent structure. While the role of competitive solvent and anion interactions in defining the properties of univalent organic electrolyte systems has received considerable investigation, such knowledge is still emergent in the divalent electrolyte field. This presentation will serve as a discussion of our recent findings on how the elemental solvent or co-solvent (e.g. glymes, cyclic ethers) structure defines stable Mg$^{2+}$ anion solvation populations, which in turn determine critical electrolyte performance attributes including ionic conductivity and Mg metal plating efficiency. These experimental results are further augmented with the aid of density functional theory and molecular dynamics simulations, providing insight into how the solution and interfacial chemistry regulates the behavior of Mg$^{2+}$ electrolyte systems.

Enabling High Voltage NMC/Gr Cell Performance with a Polyfluorinated Electrolyte Blend

Enabling High Voltage NMC/Gr Cell Performance with a Polyfluorinated Electrolyte Blend

Enabling high-energy, high-voltage lithium-ion batteries requires the detection, measurement and mitigation of degradation processes that decrease both energy- and power-density during prolonged cycling. This presentation will discuss different diagnostic methods of high-voltage reactivity with LiNi$_{0.3}$Mn$_{0.3}$Co$_{0.4}$O$_2$ (NMC532) cathodes, as well as the use of a high-voltage electrolyte (polyfluorinated electrolyte blend of difluoroethylene carbonate and hexafluoro-2-dimethylcyclopentene, referred to as FE-3) to increase stability and cycling performance. FE-3 leads to less oxygen loss from the surface of the NMC532 structure, less surface degradation, and a lower parasitic oxidation current, compared to the traditional organic carbonate electrolyte. On the graphite anode, FE-3 shows superior passivation behavior, and graphite electrodes preformed with FE-3 show excellent capacity retention and lower impedance rise and transition metal dissolution when cycled at high voltage with the traditional organic carbonate electrolyte and an NMC532 cathode. This work shows that soluble reduction products from an incompletely passivated graphite anode are major contributors to cell impedance rise at high voltage.
A Facile Approach to Generate Highly Active and Durable Heterogeneous Electrocatalyst for the Oxygen-Evolving Reaction from Ni-Loaded, Metal-Organic Framework-Graphene Composite—In Situ Electrospinning to Fabricate High Throughput Electrocatalyst Process Mohamed Hassan1, Ahmed Soliman2, Woroud Elmehelmy1, Arwa Abugable1, Stavros Karakalos1, Mady Elibari2, Abdou Hassani1 and Mohamed H. Alkordi3, 1Center for Materials Science, Zewail City of Science and Technology, Giza, Egypt; 2Department of Chemistry and Materials Science, Aalto University, Aalto, Finland; 3College of Engineering and Computing, University of South Carolina, Columbia, South Carolina, United States; Condensed Matter Physics Department, Jozef Stefan Institute, Ljubljana, Slovenia.

We report on a novel approach through which metal-organic framework constructed on graphene platelets is converted, in situ, into highly active and durable water splitting electrocatalyst. This approach to construct highly active and durable Ni(OH)2 nanoparticle/graphene hybrid electrocatalyst utilized the Ni-loaded, graphene-supported metal-organic framework (UIO-66-NH2-Ni/G) as a sacrificial pre-catalyst to generate the true catalyst, in situ, under the electrolysis conditions. The resulting nanocatalyst was shown to enclose Ni(OH)2 nanoparticles imbedded within hydrous zirconia and deposited on top of G platelets, demonstrating a high electrocatalytic activity towards oxygen-evolution reaction (ηO2 = 0.38 V vs. RHE) and highly durable catalyst. This strategy can potentially be extended to several other systems as a less energy-consuming alternative to the commonly utilized pyrolysis pathway to generate electrocatalysts from MOFs.

Single-Ion Conducting Polymer Coatings for Mitigation of the Polysulfide Shuttle Effect in Metal-Sulfur Rechargeable Batteries Hunter Ford, Peng He and Jennifer Schaefer; University of Notre Dame, Notre Dame, Indiana, United States.

The development of new rechargeable battery systems employing novel chemistries is imperative to meet the increasing energy storage demands of emerging technologies. Metal-sulfur batteries are a promising set of chemistries for moving beyond lithium-ion, owing to the widespread abundance of sulfur and the high theoretical energy density of many metal-sulfur couples. However, it is well known that metal-sulfur systems suffer poor performance as a result of the polysulfide shuttle effect. Building on previous work demonstrating the delicate balance of ion transport in a functional interlayer1, i.e. allowing cation transport while minimizing polysulfide transport, thin single-ion conducting polymer coatings are investigated for their ability to mitigate the polysulfide shuttle effect in lithium- and magnesium-sulfur cells. Relative to a bulk polymer layer, a thin coating contributes significantly less to the total cation conduction resistance observed in the cell. The decreased resistance stemming from a thin layer design enables exploration of a polymer composition space that favors polysulfide restriction at the expense of cationic conduction, such as the use of highly crosslinked ionomer networks in which the primary mechanism of cation conduction is solid state. Differences in solid state Li+ and Mg2+ conduction present the need for polymer compositions tailored specifically to the cation identity. Relationships between cell performance and a given ionomer chemical composition, structure, and transport mechanisms are determined with a combination of ex situ characterization techniques and full cell cycling.

Organic Derived Nanomaterials for Emerging Energy Storage Jiangang Mai; State Key Laboratory of Advanced Technology for Materials Synthesis and Processing, Wuhuan University of Technology, Wuhuan, China.

Nanomaterials can offer large surface area, facile strain relaxation upon cycling and efficient electron transport pathway to achieve high electrochemical performance. Organic compounds have achieved immense priority over inorganic materials for their manageable structures, suitable operating voltage and abundance as well as renewability. We have synthesized graphene oxide-wrapped organic dipotassium terephthalate (K2TP)(GO) hollow microcruds using an abundant and renewable organic resource. During the potassitation process, the crystalline phase of K2TP gradually transformed into amorphous K2TP. They demonstrate enhanced potassium storage performance compared to bulk K2TP, which mainly ascribed to the fast K+ ion transfer kinetics, high electronic conductivity and short diffusion distance. In addition, we have also developed a facile and high-yield strategy for the oriented formation of CNTs from metal-organic frameworks (MOFs). The appropriate graphitic N doping and the confined metal nanoparticles in CNTs both increase the densities of states near the Fermi level and reduce the work function, hence efficiently enhancing its oxygen reduction activity. Moreover, we also obtained thio-cyanato-functionalized SiO2 (SCN-SiO2) micropheres through the hydrolysis and condensation of organic silicon source (3-thiocyanatopropyltrimethoxysilane). A vinyl-functionalized SiO2(CH2=CH-SiO2) layer and a thiol-functionalized SiO2 (SH-SiO2) layer was also coated onto the surface of SCN-SiO2 in sequence. The rationally designed yolk@shell structured SiO2/C composite anode materials manifest high specific capacity, excellent rate capability and superior cycling stability in lithium storage. Our work presented here can inspire new thought in constructing novel organic compound structures and accelerate the development of energy storage applications.

2:30 PM ES01.09.02
Progressively Releasing Potassium Ions via Electrospun Nafion-Based Separator for Lithium Metal Batteries Mengfei Hu and Donghui Long; East China University of Science and Technology, Shanghai, China.

High-energy-density lithium metal batteries have aroused widespread interest due to the high theoretical capacity. However, uncontrolled dendrite formation and infinite volume expansion hinder the practical application of lithium metal anode. Herein, we develop a new strategy to make adsorption induction and ionic intervention well-combined to modulate the Li deposition behavior. A K+-doped Nafion nanofiber separator, having abundant lithophilic groups and porous framework is electrospun. It can provide high affinity with electrolyte and large electrolyte uptake. It also provides uniform pathway for lithium ions transportation, and a parclose for the stress of volumetric change during lithium plating/stripping. Moreover, it can release K+ as an inhibitor to prevent aggregation of Li ions by forming an electrostatic shielding on the surface of electrode. As a result, the functional separator can guide uniform lithium deposition, leading to high Coulombic efficiency (98.5%) and low overpotential (~15 mV) in symmetric cells with long lifespan. This work shed the dawn of the research on the multi-functional electrospun separators for dendrite-free lithium metal batteries.

2:45 PM ES01.09.03
Heterocyclic N-Rich Salts for Li Metal Battery Mxung-Jin Lee, Victor Roev, Min Sik Park, Hongsoo Choi and Dongmin Im; Samsung Advanced Institute of Technology, Suwon, Korea (the Republic of).

In order to realize a perfect solid polymer electrolyte (SPE) concept for lithium batteries, there is a need for lithium new salts. The new salts must be cheap and stable and able to provide a large number of charge carriers to meet the demands on ionic conductivity. In polymer electrolytes, the salt concentration is usually high, thus an important factor affecting the ion conductivity is the equilibrium between “free” anions, ion pairs, and higher aggregates, which tend to form in concentrated electrolytes. Weakly cation coordinating anions, such as the triflate, perchlorate or the “imide”/TFSI anions are therefore good candidates for SPE lithium salts. The chemistry of new salts employed in SPEs, today, is in many cases based on the electro reduction power of fluoride atoms. Lithium salts with organic anions, heterocyclic aromatic anions are considered as candidates of choice for this application because they are expected to combine good ionic conductivity and wide electrochemical stability. Especially, those organic salts have electrochemical stability toward Li metal anode and have a good efficiency. A high value of the lithium ion transference number is also desirable. Much less is published on the corresponding triazolate anion; P2I stacking and association of the flat aromatic molecules are probably responsible for the depressed mobility of the anion, thus accounting for the enhancement in the cation transference number.

3:00 PM ES01.09.04

Covalent Organic Nanosheets(CONs) as an Effective Storage Materials as Sodium-Ion Battery Electrodes Min-Sung Kim, Won-Jae Lee and Jin Kuen Park; 1Hankuk University of Foreign Studies, Yongin, Korea (the Republic of); 2Kyungpook National University, Daegu, Korea (the Republic of).

Here, we demonstrated the structure-related energy storage performance of covalent organic nanosheets (CONs) synthesized by Stille cross-coupling under conventional reflux and solvothermal conditions, displaying that the specific surface area and self-assembled morphology of the nanosheets can be effective regulated by a deliberate choice of the synthetic method and monomer combination. The Sodium-ion storage capacity in the mentioned above CONs could be increased by elevating their conductivity of charge carriers via enforcement of a network polymer backbone planarity or by enhancing their specific surface area while maintaining polymer structure constitution. Comparing the anodes manufactured by combining each synthesized CONs, the electrodes based on CON-16 showed the highest cycling performance and rate capability, maintaining a reversible discharge capacity of up to 250mAh/g after 30 cycles at a current density of 100 ma/g.

3:15 PM ES01.09.05
Impact of Thin Coating Layers on Metal Dissolution for Battery Applications Yufang He, Yaqi Zhu, Xinhua Liang and Jonghyun Park; Missouri University of Science and Technology, Rolla, Missouri, United States.

Dissolution of active material is one of the primary reasons for capacity fade in lithium-ion batteries, particularly at elevated temperatures. Ultra-thin coated cathode particles via Atomic Layer Deposition (ALD) exhibit superior battery performance over bare particles. However, we have observed a coating layer can decrease or accelerate the metal dissolution depending on the coating materials. For instance, an ultra-thin CeO2 coating intensifies Mn dissolution of lithium manganese oxide cathode material during cycling of battery, whereas ultra-thin AI2O3 coating tends to inhibit Mn dissolution. A detailed study of Density Functional Theory (DFT) has been carried out to illustrate the experimental observations. First, the manganese vacancy formation energy is calculated, along with the bonding strengths of Mn-O of uncoated, Al2O3 coated, and CeO2 coated particles via Crystal Orbital Overlap Populations (COOP) calculations. Further, the projected density of state calculation of Mn is used to confirm the electronic occupancy of Mn atom for each case. Surprisingly, the atomic analysis is consistent with the experimental observations. This finding can provide new insights into ALD coatings and their impact on metal dissolution in cathode materials.

SYMPOSIUM ES02

Next-Generation Intercalation Batteries
April 23 - April 25, 2019

Symposium Organizers
Brent Melot, University of Southern California

SESSION ES02.01: Oxygen Redox Chemistry I
Session Chairs: Y. Shirley Meng and Louis Piper
Tuesday Morning, April 23, 2019
PCC North, 100 Level, Room 126 C

10:30 AM ES02.01.01
Structural Origin of Oxygen Redox Reversibility in Li-Rich Layered Oxide Cathodes for Li-Ion Batteries Chong Yin, 1, 2 Bao Qiu, 1 Jiaming Bai, 1 Zhaoping Liu 2 and Feng Wang; 1 Brookhaven National Laboratory, New York, New York, United States; 2 Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China.

Lithium-rich (LR) layered oxides are among the most promising high-energy cathode candidates for next-generation Li-ion batteries LIBs, with excess capacity enabled by oxygen redox (OR). Recent studies show that their actual OR reversibility is largely determined by the local structural ordering, especially stacking faults. However, due to the challenge in quantitative determination of stacking faults, there has been intense debate on how stacking faults affect the OR in LR layered oxides. In this work, we made quantitative analysis of the dependence of stacking faults on the Li contents in Li1+xNi0.13Co0.13Mn0.54O2 through synchrotron X-ray and neutron diffraction measurements coupled with structure refinements using FAULTS program. Results from the refinements using a composite 2-phase model (C2-m and R-3m phases) match well with experimental data, and so allowing us to make quantitative investigation on the correlation between the stacking faults and OR reversibility. Finding from this study, along with its implication to rational design of LR layered oxide cathodes will be discussed.

10:45 AM ES02.01.02
First-Principles Modeling Of Peroxo-/Superoxo-Like O-O Dimers for High Capacity Cathode Materials of Lithium-Ion Batteries Zhenlian Chen1, 2, Xiao C. Zeng2 and Jun Li1; 1NIMTE, Chinese Academy of Sciences, Ningbo, China; 2Department of Chemistry, University of Nebraska–Lincoln, Lincoln, Nebraska, United States.

High capacity cathode material is key to meet high expectation on lithium ion battery for electrical transportation and smart grids. Cumulatively cationic and anionic redox has been identified as a promise mechanism for next generation cathode materials. The peroxy-/superoxo- like O-O bonding is believed to play important role in anionic redox. 1 However, fundamental understanding of the mechanisms such as the origin and reversibility of peroxy-/superoxo- like O-O dimer is still lacking. So far, theoretical modeling are limited and fail to show peroxy-/superoxo- like O-O dimers in delithiated phases 3, 4, which has been detected during electrochemical performances 5, 6. This talk will show the evolution of peroxy-/superoxo- like O-O dimers during the delithiation process with first-principles modeling. Several morphologies of transition metal peroxy/superoxo complex are found in the partially delithiated phase of Li1+xMnO2 (3/4≤x≤5/4) and oxygen release is predicted to happen when x≥3/2. There are two categories of O-O dimers, one links the MnO6 in same Mn layer or adjacent Mn layers. In the other category, one or two O-O dimer(s) belong(s) to one MnO6 octahedron. The bond length of O-O dimer ranges from 1.25 Å to 1.45 Å, close to the O-O bonds in peroxides and superoxides. Crystal orbital Hamilton population (COHP) analysis shows strong anti-bonding character near to Fermi level and partial charge density indicates π-like anti-bonding charge hole compensate the charge deficiency in delithiated phases during 3/4≤x≤5/4. Surprisingly, peroxy-like
dimers are also found in the second lithium delithiation of polyanionic cathode Li$_2$CoSiO$_4$, challenging the long understanding that only two-electrons conventional cationic redox is recognized in orthogonal silicate cathode family. This study may open a new venture to understand the anionic redox, helpful to rational design of new generation cathode to achieve high energy-density.

11:00 AM ES02.01.03
Reversible Anionic-Cationic Redox in High-Capacity Polyanionic Tetrahedral Silicate Cathode Materials
Xiaohui Zhang, Bojoen Schwarz*, Zhenlian Chen, Cai Shen, Liyuan Huai, Deyu Wang, Zhiheng Zhang, Wenqiang Du, Haitao Zhang, Helmut Ehrenberg* and Jun Li*,
1 Chinese Academy of Sciences, Ningbo, China; 2 Karlsruhe Institute für Technologie, Karlsruhe, Germany.

High capacity cathode materials are a key to the success of high performance lithium ion battery to emerging technologies for electrical transportation and smart grids. Accumulating cationic and anionic redox in transition metal peroxo/superoxo complex has been identified as the key mechanism to achieve superior reversible capacity in multi-lithium compounds. However its associated lattice oxygen releases are a fundamental threat to battery safety and long term performance stability. Here we present a prototype study of Co-Mn lithium silicate composites, in which Co-peroxo/superoxo redox is observed in tetrahedral structured polyanionic materials for high reversible capacity over 230 mAh/g accompanied by zero gas release. Two lithium reactivity and its structure evolution are carefully studied by in operando synchrotron X-ray absorption spectroscopy and powder diffraction. First-principles molecular dynamics are employed to provide the first of its kinds understanding of Co-peroxo/superoxo interaction in the domain of two lithium reactivity. Because of the importance of polyanionic composition in the high safety category of lithium cathode, this study may open a new venture to design rationally a new generation cathode that will achieve high energy-density and high safety simultaneously.

11:15 AM ES02.01.04
Li-Rich Layered Sulfides—An Indirect Way to Better Understand Anionic Redox in Oxides
Saijoy Saha, Gwenaëlle Rousse and Jean-Marie Tarascon,
1 Sorbonne Universités - UPMC Université Paris 06, Paris, France; 2 University Pierre and Marie Curie, Paris, France; 3 Reuseau sur le Stockage Electrochimique de l’Energie (RS2E), Amiens, France.

To comply with the ever-growing demand of energy to power portable electronics and electric vehicles, increasing the energy density of lithium-ion batteries (LIB) has become a major bottleneck. Li-ion battery cathode materials have relied solely on cationic redox reactions, until the recently discovered anionic redox chemistry exchanges, from the approach to design new cathode materials with high energy density, for example, Li$_2$Ni$_{0.2}$Mn$_{0.8}$O$_2$ and Li$_2$Ni$_{0.13}$Mn$_{0.87}$CoO$_{1.9}$ (Li-rich NMC), etc. However, due to certain drawbacks, Li-rich oxides are not far away from commercialization. While intense research is currently devoted to understand this issue, we take a different strategy to contribute to the current understanding of anionic redox, by moving to Li-rich layered sulfides.

While the pure Li$_{1.33}$Ti$_{0.55}$S$_2$ was reported to be electrochemically inactive, we have designed new phases of nominal composition Li$_{1.33}$.05.5Ti$_{0.77}$Fe$_{0.23}$S$_2$ with $y = 0.1 – 0.5$, that are electrochemically active and exhibit an electrochemical activity comparable to Li-rich layered oxides. The voltage profile begins upon charge with a sloped oxidation, associated to the cationic Fe$^{3+}$ oxidation followed by a plateau due to the contribution of the anionic 2$\text{S}^2$$.y$ composition. Maximum reversible discharge capacity up to 245 mAh/g could be obtained for the $y = 0.3$ (Li$_{1.11}$Ti$_{0.78}$Fe$_{0.22}$S$_2$) composition. Via detail study on Li$_{1.11}$Ti$_{0.78}$Fe$_{0.22}$S$_2$, we show a very small voltage hysteresis compared to Li-rich NMC. Concerning the issue of kinetics, oxygen redox is found to be severely affected by sluggish kinetics. However in Li$_{1.11}$Ti$_{0.78}$Fe$_{0.22}$S$_2$, we found that the charge-transfer resistance is very small and remains nearly constant throughout the cycle as opposed to oxides where the resistance builds up drastically with deeper oxidation of oxygen. Despite these positive effects, voltage fading still persists in Li-rich sulfides, though the voltage fade is very less and tends to stabilize after few cycles. The voltage fade is merely ~40 mV. In short we demonstrate that increasing the covalency of metal-ligand bonds by moving to Li-rich sulfides can show paths to mitigate practical bottlenecks of anionic redox.

SESSION ES02.02: Na-Ion Intercalation
Session Chairs: Bryan McCloskey and Benjamin Morgan
Tuesday Afternoon, April 23, 2019
PCC North, 100 Level, Room 126 C

1:30 PM *ES02.03.01
Increasing the Energy Densities of Na-Ion Batteries—Fundamental and Practical Aspects
Saritha Maryappan, Qing Wang and Jean-Marie Tarascon,
1 CNRS3459, Reuseau sur le Stockage Electrochimique de l’Energie (RS2E), Amiens, France; 2 Sorbonne Université - UPMC Université Paris 06, Paris, France.

Batteries, as one of the most versatile energy storage device, are key enablers for the decarbonisation of both the transport and power sector. Li-ion batteries being light weight and capable of providing high energy density have conquered the transport sector, therefore, there is a sorely need for low cost batteries for grid applications linked to the use of renewable energies. In this regard, Na-ion battery technology that utilizes more sustainable materials is rapidly developing as a possible alternative to the Li-ion for massive energy storage applications. Several prototype Na-ion batteries using various chemistry have already been demonstrated; the most feasible being the two types of technologies based either on sodium layered oxides Na$_2$MO$_x$ (x ≤ 1, M= transition metal ion(s)) or polyanionic compound such as Na$_2$V$_2$(PO$_4$)$_3$.5F as positive electrode and carbon as negative electrode. Nevertheless, both technologies suffer with poor specific energy in comparison to their lithium counterparts, the major limitation being the poor achievable capacity and/or the redox voltage of the positive electrode. The polyanionic phases suffer high molecular weight and hence poor capacity, while the sodium layered oxides cannot achieve their theoretical capacity due to their structural instability. In order to increase the specific energy of the sodium ion cells, at first, it is essential to understand the origin of such limitations. Hence, we have studied the poly anionic Na$_2$V$_2$(PO$_4$)$_3$.5F and several sodium layered oxides systems and bench marked their performances in practical Na-ion full cells. The results will be discussed by considering the fundamental aspects such as structure-stability-electrochemical performance relationships of the electrode material, moisture stability, interfacial reactivity and thermal stability of the charged electrode, hence safety of the Na-ion cells. Finally, a new material design approach will be discussed with the hope that they will help the battery community to develop high capacity electrode materials that can overpass the limitations of the present generation sodium ion batteries.

2:00 PM ES02.03.02 Solution Phase Na3V2PO4F7 Nanoparticles Synthesis for High Power and High Energy Density Sodium-Ion Battery [Hyungseok Kim1,2, Jesse S. Ko1 and Bruce S. Dunn1;1Univ of California-Los Angeles, Beaverton, Oregon, United States; 2Center for Energy Storage Research, KIST, Seoul, Korea (the Republic of)].

Room temperature Na-ion batteries are highly considered as an alternative technology to Li-ion batteries and are projected to be manufactured at a much lower cost. The development of high power high energy density Na-ion batteries is contingent upon carefully choosing high performance positive and negative electrodes. Among the candidate phosphate materials, sodium vanadium fluorophosphate (Na3V2PO4F7) has gained considerable interest with its high redox potential of the material (operating voltage ~3.8 V vs. Na/Na+) and high theoretical capacity (130 mAh g⁻¹). To date, the primary synthesis approach for obtaining Na3V2PO4F7 is high temperature solid state reaction, however, to drive down the cost of SIBs, it would be beneficial to use a low cost and low energy consumption synthesis approach. In this study, we aim to implement a two-step solution phase synthesis (Pechini and hydrothermal) to consume less energy and minimize our impact on the environment to prepare Na3V2PO4F7 nanoparticle which is demonstrated as a high-rate high cycle life positive electrode material. At various charging rates, Na3V2PO4F7 achieved a high capacity of 130 mAh g⁻¹ (1C/10) and up to 80 mAh g⁻¹ (20C). The high rate capability of this material is owed to its nanometric size and its small volume expansion of 3% upon continuous charge-discharge cycles. For these reasons, the cycling behavior showed superior stability where after 100 cycles, 93% of the initial capacity was maintained. Na3V2PO4F7 was then paired with an Sn-reduced graphene oxide negative electrode and in its full cell format achieved a capacity of 115 mAh g⁻¹ (1C) and 68 mAh g⁻¹ (20C). This full cell devices represents a feasible Na-ion battery devices capable of performing on par with commercial Li-ion battery devices (LiCoO2/graphite).

2:15 PM ES02.03.03 Reversible Asymmetric Structure Evolution in NaTMO2 Xin Li; Harvard University, Cambridge, Massachusetts, United States.

Layered sodium transition metal oxide system of NaTMO2 (TM=3d transition metal ions and their mixture) forms a unique materials platform to study the transition metal, oxygen and sodium interactions. Specifically, Fe and Mn, which are not stable in LiTMO3:45 PM [2] Yang & Devereaux, J Power Sources 389, 188 (2018) taken for granted [3].

Oxygen activities, and suggest that oxygen release and lattice oxygen redox are independent processes involved in intercalation batteries, a relationship that has been indiscreetly contributions and its reversibility/cyclability upon electrochemical cycling. The contrasts between different systems provide important clarifications to understand the mysterious beyond X-ray absorption, mRIXS is capable to not only detect the lattice oxygen redox states in battery electrodes [2], but also precisely quantify the lattice oxygen redox activity of Mn and Mn2O3:45 PM [2] Yang & Devereaux, J Power Sources 389, 188 (2018) taken for granted [3].

2:30 PM ES02.03.04 Structural Phase Transitions and Intercalant Ordering in Layered Na- and K-Ion Cathode Materials Jonas Kaufman1, Michael Toriyama2 and Anton Van Der Ven1; 1University of California, Santa Barbara, Santa Barbara, California, United States; 2University of Illinois at Urbana-Champaign, Urbana-Champaign, Illinois, United States.

Na- and K-ion batteries offer cheaper, safer alternatives to their Li-ion counterparts. However, additional structural phase transitions upon cycling can lead to faster mechanical degradation in their electrode materials. This is largely because Na+-K+ ions, unlike Li+ ions, are stabilized not only in octahedral coordination but also in prismatic coordination. The latter allows for more complex intercalant orderings due to the availability of a second triangular sublattice. The ordering of Na/K within a given structure greatly influences the voltage profile and ion transport, but can be difficult to resolve experimentally. We have performed first-principles statistical mechanics studies of the layered Na6Co2O7 and K6Co2O7 cathode materials, which exhibit several stable host structures with Na/K in either octahedral or prismatic coordination, related by gliding of CoO2 sheets. Phase stability between these structures and stable Na/K orderings within each structure are presented and compared to experiments. We have identified several “Devil’s staircases” of infinite hierarchical orderings that Na6CoO7 displays over its composition range. K6CoO2 stabilizes similar orderings for intermediate K concentration and a new family of structures with mixed octahedral and prismatic coordination in the same layer at higher concentrations. This mixed phase brings about significant distortions of the CoO2 layers and may facilitate stacking sequence changes at the end of discharge. Potential mechanisms for ion migration in these materials are discussed, as well as implications for Na/K ordering in other layered transition-metal oxides.

2:45 PM BREAK

SESSION ES02.03: Advanced Characterization
Session Chairs: Brent Melot and Louis Piper
Tuesday Afternoon, April 23, 2019
PCC North, 100 Level, Room 126 C

3:15 PM *ES02.02.01 mRIXS of Novel Transition-Metal and Oxygen Redox States in Intercalation Batteries Wanli Yang; Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Modern developments of ultra-high efficiency imaging of Resonant Inelastic X-ray Scattering (mRIXS) has opened up this fundamental-physics technique for energy material researches with much improved throughput and superior chemical sensitivity beyond conventional spectroscopy. This has become a timely and critical solution to clarify the unusual redox states involved in high energy density materials, including both the cationic and anionic redox reactions in intercalation-type battery electrodes. This presentation will not discuss the complex physics involved in the RIXS process (Tutorial on RIXS planned in this MRS meeting); instead, mRIXS will be introduced from the chemistry point of view to the material science community with examples on both transition-metal and oxygen states. We show that mRIXS could distinguish spectroscopic signatures of a novel MnI+ state in batteries from conventional Mn states, based on the extra dimension of information that is completely missing in x-ray absorption spectroscopy [1]. We then elaborate the problems and challenges of probing oxygen redox reactions in battery electrodes, and demonstrate that, based on the same technical improvement beyond X-ray absorption, mRIXS is capable to not only detect the lattice oxygen redox states in battery electrodes [2], but also precisely quantify the lattice oxygen redox contributions and its reversibility/cyclability upon electrochemical cycling. The contrasts between different systems provide important clarifications to understand the mysterious oxygen activities, and suggest that oxygen release and lattice oxygen redox are independent processes involved in intercalation batteries, a relationship that has been indiscreetly taken for granted [3].

3:45 PM ES02.02.02 How to Obtain Bulk Sensitive Soft X-Ray Spectra Operando From Lithium-Ion Batteries Arthur Braun; Empa, Dübendorf, Switzerland.
Much efforts are undertaken in lithium ion battery research for the identification of processes taking place at the surfaces of electrode materials and components. However, for an intercalation battery also the bulk properties are relevant because the bulk is the host of the lithium ions, notwithstanding that it is the surface where the lithium enters and exits the positive and negative electrodes.

The functionality of the battery electrodes is at large reflected by their electronic structure as it amounts from the crystallographic arrangement of the ions in the electrode materials. In the last 30 years it has become popular to investigate the electronic structure of battery materials and components with x-ray methods, including their *operando* and in *situ* assessment, and including synchrotron radiation centers as the necessary x-ray sources.

It has turned out that the soft x-rays are particularly suited for the elucidation of the electronic structure of the electrodes, particularly the oxide based positive electrodes. It is an unfortunate weakness of the soft x-rays that they have a relatively low penetration depth and thus relatively low information depth. Practically, the attenuation of soft x-rays is around 1 micrometer, whereas the particulates of spinel based cathodes in lithium secondary batteries range in the order of 25 micrometers. Bulk specificity and soft x-rays rule thus each other out. It is thus virtually impossible to get a soft x-ray spectrum at the 3d metal 2p absorption threshold or an oxygen 1s spectrum from the bulk of such industry grade battery material, neither *ex situ* nor in *situ*: unless you use a spectroscopic trick which has matured to real life applicability since only recently.

I will therefore demonstrate how the battery in *situ* cell can be charged and discharged and during this process hard x-rays with 11 keV energy can penetrate the entire cell, and the X-ray Raman contribution from the fluorescence signal can be extracted for example for the Mn 2p features.

It was therefore possible to record a large number of Mn2p soft x-ray multiplets which showed characteristic changes in their relative spectral weight of L2 and L3 peaks while lithium ions are being inserted in the electrode and extracted from the electrode.

Very interestingly it was possible to tickle out the spin states of the Mn ions which shows that there is an intermediate Mn3+ phase which undergoes a high spin and a low spin transition, which hitherto was not known in the condensed state, solid chemistry and battery technology community. The design of the in *situ* cell and the spectroscopic principle of the X-ray Raman method, available only since few years for the battery expert, are explained as well.

**Investigation of the Interactions Between Electrodos in Li10Ti2O17 – Based Batteries with Complementary Surface Analysis Techniques (XPS, SAM, ToF-SIMS)** Nicolas Gauthier1, 2, Cécile Courrèges1, Julien Demeaux1, Lionel Goubault2, Cécile Tessier2 and Hervé Martinez1, 1IPREM (UMR5254), Pau, France; 2Recherche, SAFT, Bordeaux, France.

LiTi2O3(2) (LTO)-based negative electrode for lithium-ion batteries is of interest for electrical vehicles due to its safety, low cost and cycling stability [1]. In this study, the effect of the positive electrode on the electrochemical performances of LTO electrodes, in relation with the Solid Electrolyte Interface (SEI) properties, has been investigated [2]. Full cells LTO/LiNi0.5Co0.2Mn0.3O2 (NMC) and LTO/LiMn2O4 (LMO) were cycled at 40°C over 100 cycles and the electrodes were analyzed by XPS, Scanning Auger Microscopy (SAM) and Time of Flight Secondary Ion Mass Spectrometry (ToF-SIMS) after one and 100 cycles. Moreover, LTO/LTO symmetrical cells were also analyzed in order to be free of the positive electrode impact. For each system, LTO electrodes are homogeneously covered by surface layers since the first cycle which induces an irreversible capacity loss. This latter is more important for LTO/LMO compared to LTO/NMC and LTO/LTO. Both SEI layers are composed of organic (polyethylene oxides, oxalates) and inorganic species (LiF, phosphates and fluorophosphates) but in different proportions and with different 2D and 3D spatial distributions: fluorne species are detected deeper in the electrode than organic species and in higher quantities for LTO/LMO for instance [3]. Moreover, the SEI is thicker on the LTO electrode when cycled versus LMO compared to NMC and contains small amounts of manganese, homogeneously spread over the surface and deeply inserted in the SEI, which entails an increase of the system impedance. In conclusion, a thick SEI associated with the presence of metallic species could alter the passivating role of the SEI and explain the less efficient electrochemical performance of LTO/LMO cells.

Analysis after cycling at higher voltage are currently in progress to study the evolution of interfacial layers composition and thickness and to better understand the interactions between the two electrode materials.

**Tracing Reactivity Through Outgassing in Ni-Rich and Li-Rich Li-Ion Cathode Materials** Bryan D. McCloskey1, 2; 1Chemical Engineering, University of California, Berkeley, Berkeley, California, United States; 2ESDR, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Outgassing of active materials in Li-ion batteries provides a route to quantitatively study degradation processes that occur during cycling. In particular, we are primarily interested in quantifying the individual and coupled decomposition/transformations of the cathode – a lithiated transition metal oxide (TMO) – and the electrolyte – mostly commonly carbonate blends (ethylene carbonate, diethyl carbonate, etc) with lithium hexafluorophosphate (LiPF6) as the salt. Previous observations of high-voltage instabilities include TMO surface reconstruction, transition metal dissolution, electrolyte decomposition, and formation of surface species. However, this picture is still incomplete, with the dependence on electrolyte and TMO composition not yet fully understood. We will present results in which isotopic labeling of 18O in Ni-rich and Li/Mn-rich NMCs is combined with quantitative gas evolution analysis to show that residual solid lithium carbonate (Li2CO3) on the surface of TMOs has a direct impact on electrolyte and electrode degradation. In particular, oxygen release from the TMO lattice is related to the amount of Li2CO3 present in the cathodes. Our results suggest that the role of impurities on interfacial reactivity in batteries is critically important and should be a key parameter considered in similar future studies.
Towards New Thiophosphate and Sulfide Based Solid Electrolytes—Challenges and Perspectives

Bettina V. Lotsch, 1, 2, 3 Nanochemistry, Max Planck Institute for Solid State Research, Stuttgart, Germany; 2 Chemistry, University of Munich (LMU), Munich, Germany.

Fast lithium solid electrolytes are critical components of all-solid-state batteries (SSB) which promise safer operation and higher power and energy densities compared to commercial Li ion batteries. The highly polarizable anionic sulfide sub-lattice of thiophosphates, prominently represented by the tetragonal Li10GeP2S12 (LGPS) family of compounds, provides a rather flat energy 3D landscape with low activation energy paths for lithium ion movement, rendering thiophosphates and, more generally, sulfides, the currently most promising class of materials for the discovery of ultrafast ionic conductivities in solids [1,2,3]. However, LGPS-type thiophosphates are known to readily decompose under ambient conditions, often leading to electronically conductive or insulating products with sluggish Li ion dynamics. In addition, there is an undisputed need to replace the precious Germanium by more earth-abundant elements whilst maintaining high Lithium conductivities of > 1 mS/cm. We will discuss several strategies to tackle these challenges. First, our recent efforts in exploring the solid solution system Li11+2xSi12-xP12-xS12 will be described, which lead to the discovery of new solid electrolytes in the LSiPS family displaying conductivities of > 1 mS/cm [2,4]. While fast in absolute terms, we will show that these materials are in fact glassy ceramics, carrying amorphous side-phases which reduce the apparent Lithium conductivities. Further, the solid solution system Li-Sn-S will be discussed as a source of new sulfide-based superionic Lithium conductors with layered structures. Li11(S1-xSnxS)2 exhibits a lithium ion diffusivity of 6 x 10-15 m2/s at room temperature as determined by pulsed field gradient (PFG) NMR [5,6]. We will show that Li[x]≤(Li11S12SnS2) hydrates in air while maintaining high Li diffusivities and, hence, exhibits greatly improved environmental stability as compared to most sulfide-based solid electrolytes. We will furthermore discuss the exfoliation—restacking of lithium tin sulfide nanosheets into conformal thin films and their strongly hydration-dependent in-plane conductivity, which bodes well for the use of these environmentally robust sulfide solid electrolytes not only in SSBs, but also as solution-processable humidity sensors.

References:
In secondary batteries, the anode/electrolyte interphase plays a key role in the electrochemical performances. As the liquid organic electrolyte undergoes degradation in the electrochemical potential window of a cycling battery, a Solid Electrolyte Interphase (SEI) is formed upon cycling. This interphase layer leads to a double-edged problematic: the formation of the SEI lowers the coulombic efficiency and causes irreversible volume capacity loss, but it also passivates the electrode from the electrolyte and prevents further aging processes. Knowing this, any modification of the SEI should be performed with parsimony as it could break the balance between the positive and negative aspect of the SEI. By synthesizing a chemisorbed thin fluorinated layer upon anode material, we managed to improve the passivating power of the SEI leading to enhanced electrochemical performances. We also demonstrated that very low quantities of fluorine on the active electrode material surface leads to several beneficial effects. We aimed to prospect the influence of the surface fluorination on different aspect of a Li-ion battery, from the active material to the electrolyte interface, thanks to a multi-scale probing approach. The chemical nature of the surface layer was describe by the mean of the XPS, as well as the fluorine distribution on the surface with both AES and SAM. The fluorine has been quantified around 10 at. % of the extreme surface of the Li$_2$Ti$_3$O$_7$ (LTO) material, without diffusion in particles bulks. The bulk and surface-properties of fluorinated LTO (LTO-F) were also investigated by coupling XRD, Raman Spectroscopy and NMR $^1$H, showing no modifications of the crystallographic structure. The influence of the surface fluorination on the electrochemical performance was investigate by galvanostatic cycling and by coupling XPS and SAM on cycled electrodes. We had a specific attention to the impact of the fluorination on the SEI thickness and stability in charge and discharge. Indeed, LTO-F exhibit a new reactivity toward the electrolyte, leading to a thinner and stabilized SEI. Finally, the gas generation of the LTO-F electrodes has been investigate by Gas Chromatography – Mass Spectrometry (GC-MS), as gassing is known to be a roadblock to the commercialization of LTO$^{2-3}$. We demonstrate that the CO$_2$ outgassing is reduced by the surface fluorination.

11:15 AM ES02.05.03

Synthetic Design of Surface Stabilized High-Ni Layered Cathodes for Lithium-Ion Batteries Mingjian Zhang$^{1,2}$, Chong Yin$^1$, Peng Pan$^2$, Jiaming Bai$^1$ and Feng Wang$^{1}$, Brookhaven National Laboratory, Upton, New York, United States; $^3$Peking University, Shenzhen Graduate School, Shenzhen, China.

There has been considerable interest in developing low-cost, high-energy electrodes for batteries. However, synthesizing materials with the desired phases and properties has proven difficult due to the complexity of the reactions involved in chemical synthesis. Additional challenge comes from the fact that synthesis is often undertaken under non-equilibrium conditions and, hence, the process is hard to be predicted by theoretical computations. In situ, real-time probing of synthesis reactions allows for identification of intermediates and determination of thermodynamic/kinetic parameters governing kinetic reaction pathways, thereby enabling synthetic design of materials with desired structure and properties. In this presentation, we will report our recent results from technique development and application to in situ probing and synthetic control of local structural ordering and stoichiometry during synthesis of high-Ni layered LiNi$_{1-x}$(MnCo)$_x$O$_2$. Findings from this study, along with its implication to designing surface-stabilized high-Ni layered oxide cathodes, will be discussed.

ACKNOWLEDGMENT

Iron-Based Fluoro(hydroxy)phosphate A$_{2}$FePO$_4$V ($\text{A} = \text{Na}, \text{Li}; \text{V} = \text{F}, \text{OH}$) as Cathode Materials for Aqueous Batteries—Two Case Studies Lalit Sharma$^1$, Shigeto Okada$^2$ and Prabeer Barpanda$^3$, $^1$Materials Research Centre, Indian Institute of Science, Bangalore, Bangalore, India; $^2$Institute for Materials Chemistry and Engineering (IMCE), Kyushu University, Fukuoka, Fukuoka, Japan.

Safety and cost of existing organic electrolytes force us to revisit possible application of aqueous electrolytes. It not only reduces the toxicity but along with fast rate kinetics, it also provides a two-fold increase in the ionic conductivity. However, not all electrode materials are compatible with aqueous electrolytes. Moreover, the limited working potential range to avoid water splitting makes it important to look for efficient and stable electrode materials in aqueous media. In this work, we are presenting two such case studies using earth-abundant Fe-based compounds. First, Na$_2$FePO$_4$F is demonstrated as a cathode material for aqueous sodium-ion batteries where the half-cell delivered a discharge capacity of 85 mAh g$^{-1}$ at 1 mA cm$^{-2}$ current density. Excellent rate kinetics were observed. A full cell was also assembled with Na$_x$FePO$_4$F anode. The Na$_2$FePO$_4$F / Na$_x$Ti$_3$O$_7$ full cell delivered a reversible capacity of 85 mAh g$^{-1}$ working as a 0.8 V battery. The second work is based on LiFePO$_4$OH cathode for aqueous lithium-ion batteries. In half-cell configuration, it delivered a discharge capacity of 140 mAh g$^{-1}$ with very good rate kinetics. Interestingly, it was found to be working in the anodic range for aqueous batteries. The structural characterization along with electrochemical studies will be presented for both case studies.

Evidences of Structural Metastability and Reversibility for Voltage Decay in High-Capacity Li-Rich Layered Cathode Oxides Y. Shirley Meng; University of California, San Diego, La Jolla, California, United States.

The practicality issue of the lithium rich layered oxide materials originate from irreversible structure transformation and voltage decay upon cycling—processes in which defect electrochemistry plays a vital role. Understanding the correlation between defect generation and voltage decay is essential for implementing rational design strategies to improve voltage stability and long term cycling. In this talk I will demonstrate the unique metastable structure of cycled Li-rich layered oxide resulting from defect formation. Modification can be applied to drive the cycled material back to a stable state and subsequently lead to the voltage recovery. This study of structure metastability and reversibility opens up new opportunities for resolving the voltage decay issue in high-capacity layered oxides, more importantly the insights might help the researchers to improve other aspects of the anion redox active materials.

2:00 PM ES02.06.02

The discovery of oxygen redox in Li-rich NMC cathode materials has revived the hopes for high-energy density batteries. [1-2] These materials are derived from the parent compound, Li$_2$MnO$_4$ [3-4], which was initially considered electrochemically inactive due to its Mn$^{4+}$ oxidation state in octahedral coordination. However, reversible capacities were demonstrated for Li$_2$MnO$_4$ in a span of 4.3-4.7 V vs. Li/Li$^+$, and the material稳定性 at high voltages however the exact charge compensation mechanism remains unclear [5]. Recent fundamental studies of oxygen redox have largely focused on 4d and 5d-based model systems, [1] which are prone to less gas evolution. However, elucidating the origin of the excess reversible capacities in LR-rich NMC electrodes requires a fundamental understanding of the nature of oxygen participation within Li$_2$MnO$_4$.

We report the chemical and structural evolution of Li$_2$MnO$_4$ upon cycling using a suite of characterization techniques to evaluate the extent of oxygen release in activating the Mn redox. In addition, oxygen-release is also found to be responsible for gradual structural disordering that occurs upon cycling. These results are discussed in the context of Li-rich NMC electrodes; especially the role of oxygen at the cathode-electrolyte interface [2, 6].

In the pursuit of high energy density Li-ion battery cathodes, Li-rich systems have demonstrated high reversible capacities that are considered accessible through oxygen redox. Investigation into the oxygen redox mechanism and identification of attractive oxygen redox candidates has driven increased utilization of x-ray spectroscopy techniques that directly probe the oxygen environment. In particular, resonant inelastic x-ray scattering (RIXS) at the O K-edge has emerged as a prime technique to provide sensitivity to the oxygen chemical environment. Sharp RIXS features have been observed in a range of transition metal (TM)3d systems, including Li-rich NMC [1], Na2,[Mg0.23Mn0.77]O; [2] and Li1+xMn0.88O2; [3] that are considered signatures of oxidized oxygen. Yet, even for the model Li-rich NMC systems, uncertainty in the interpretation of these RIXS features remains as well as questions on the local environment and long-term stability of oxidized oxygen states.

Here, we focus on the stability of Li[Li0.15Na0.15Mn0.53Co0.13]O2; a model LR-NMC system, at high degrees of delithiation under the x-ray exposure conditions needed to conduct RIXS measurements. Combining xAS and RIXS, our studies demonstrate the sensitivity of surface transition metal and bulk oxygen states to aggressive x-ray beam exposure in LR-NMC systems. In addition to the surface photoreduction of transition metals, we find a strong loss of inherent oxidized oxygen states with x-ray exposure. Our studies demonstrate the utilization of RIXS for the identification of oxidized oxygen states, while providing new insight into the nature of oxidized oxygen environments.

References:
Further, polymer electrolytes composed of ABA-triblock copolymers and [Li(glyme)][TFSA] SILs are proposed to simultaneously achieve high ionic conductivity, thermal stability, and a wide potential window. Different block copolymers, consisting of a SIL-incompatible A segment (polystyrene, PSi) and SIL-compatible B segments (poly(methyl methacrylate) (PMMA) and poly(ethylene oxide) (PEO)) are utilized. The SILs can be solidified with the copolymers through physical crosslinking by the self-assembly of the PST segment. The thermal and electrochemical properties of the polymer electrolytes are significantly affected by the stability of the [Li(glyme)]+ complex in the block copolymer B segments, and the preservation of the SILs contributes to their thermal stabilities and oxidation stabilities greater than 4 V vs. Li/Li+. The [Li(glyme)]+ complex cation is unstable in the PEO matrix, whereas the complex structure of [Li(glyme)]1- is stable in the PMMA-based polymer electrolyte. By using the PMMA-based polymer electrolytes, 4-V class Li batteries with a LiC02O2 cathode and a Li metal anode can be stably operated; in contrast, this is not possible using the PEO-based electrolyte.

Suppression of Interlayer Atom Migration in Layered Transition-Metal Oxides
Julija Vinckeviceite, Maxwell D. Radin and Anton Van Der Ven; Materials, University of California, Santa Barbara, Santa Barbara, California, United States.

Layered transition-metal oxides continue to be an exciting area of new cathode materials. For instance, Li-excess materials appear to produce larger capacities but currently suffer from poor cyclability. Furthermore, additions of Al, Mg, and other elements into current cathodes are used to cycle batteries at higher voltages to extract more energy from the same cathode materials. In both cases, new compositions are introduced in the transition-metal layer, replacing some of the Co, Ni, or Mn. As these increasingly complex systems are (dis)charged to the extremes of their capabilities, many (not yet well understood) processes can result in battery degradation. Importantly, the layered cathode materials tend to break down when most of the active cation has been deintercalated at the end of charge, resulting in poor capacity retention and voltage fade. As Li atoms deintercalate from the layered transition-metal oxide, vacancies become available for interlayer atom migration, and atoms that leave the transition-metal layer may become stuck in the Li layer resulting in irreversible structural changes. Therefore, it is important to understand how the presence of Li, Mg, or Al in the transition-metal layer could affect (potentially irreversible) interlayer atom migration.

Using first-principles methods, we have discovered that the composition of the transition-metal host plays a very important role in facilitating interlayer atom migration. The pathway for migration includes a dumbbell with a Li ion. We analyze the energetics and electronic structure of dumbbell formation to explain why certain systems may experience more interlayer migration than others. Furthermore, we propose design principles for mitigating interlayer migration, with specific implications for NCA, Mg-doped, and Li-excess cathodes but also general insight that can be applied towards a wide range of new cathode materials. This new understanding can help in designing high energy batteries without compromising on material stability.

4:15 PM ES02.07.03

Layered lithium transition metal oxides cathodes (LiNi1-x-yMnxCo2O4) have become the cathode of choice for state-of-the-art lithium-ion batteries, which now dominate the portable energy storage market and even become the leading choice for grid storage. However, these NMC materials still achieve less than 25% of their theoretical energy density, so there is much space for improvement. Increasing the nickel content both increases the energy density and decreases the materials cost. The high nickel 622 composition is in commercial use today. The 811 composition has even higher capacity and tolerates higher materials loading and higher rates better than 622, so will become the material of choice if its increased instability can be controlled. One option to increase the capacity is to increase the charging voltage, but that leads to even higher instability. An alternative option is to reduce the 1st cycle loss, which approaches 15% of the initial capacity. We will discuss our approaches to reducing this loss, more than half of which can be recovered by reducing the discharge rate, that is the capacity is kinetically limited and by materials modification should be recovered. Part of the remainder is lost to CEI formation. This work was supported by the Assistant Secretary for Energy Efficiency and Renewable Energy, Office of Vehicle Technologies of the U.S. Department of Energy, through the Advanced Battery Materials Research Program (Battery500 Consortium).

Improved Manufacturing Method for Layered Nickel-Rich NMC Cathode Materials
Thomas A. Kodenkandath1, Steve Will1, Chistrel Benemlans1, Shiriram Santhanagopalan2, Xuemin Li2 and Matthew Keyser2; 1Hazen Research, Golden, Colorado, United States; 2National Renewable Energy Laboratory, Golden, Colorado, United States.

Hazen Research, Inc., in collaboration with the National Renewable Energy Laboratory (NREL), has demonstrated a new method, in laboratory-scale experiments, of producing nickel-rich NMC cathodes. These NMC cathodes of the type Li(Ni1-x-yMnxCo2O4) (Ni >0.6) were produced using single-source inorganic-organic precursors and a process involving vertical spray pyrolysis and fluidized-bed reactions in a semicontinuous mode. The method produced amorphous phases during spray pyrolysis, which after undergoing a fluidized-bed reaction, resulted in spherical, free-flowing and nondusting soft agglomerates of well-crystallized layered nickel-rich NMC particles. The cathodes showed electrochemical performance with an initial capacity of ~200 mAh/g, a voltage stability in the range of 3.0–4.5 V, an energy density of ~800 Wh/kg, a coulombic efficiency of ~90%, and a capacity retention of approximately 70% over 100 cycles. The presentation will discuss the process, characterization, and electrochemical properties of the NMC-622 cathode powders.

Towards Battery Chemistries Beyond Lithium-Ion Batteries—Ultrafast Sodium/Potassium-Ion Intercalation into Hierarchically Porous Thin Carbon Shells
Asif Mahmood1,2, Hassina Tabassum2 and Li Shuai1; 1Southern University of Science and Technology, Beijing, China; 2Peking University, Beijing, China.

The lithium ion batteries (LIBs) have been playing a vital role in last couple of decades to light the portable electronics due to high energy storage capability and longer cyclic life. However, the long term applications of LIBs at larger scale for automotive and other related applications face severe challenges due to lower Li abundance and higher cost. Very recently, secondary ion batteries using other metallic ions (Na+/K+) for charge storage have shown promising results in replacing traditional LIBs, owing to higher natural abundance and much lower cost. A number of electrode materials have been investigated as anode material for LIBs including carbon, ferrocyanides, phosphates, metallic nanostructures as well as metal/carbon hybrids etc. However, search for efficient electrode materials for SIBs/KIBs remains elusive.

Carbon, being the most abundant and currently commercialized anode material in LIBs, present ideal candidate for commercial SIBs/KIBs. However, the crystalline carbon structures exhibit poor insertion capability of large Na+/K+ ions (Na storage capability of 35 mAh/g in comparison to Li storage capability of 372 mAh/g) which must be addressed in order to derive highly active carbon based Na/K batteries. Although hard carbon has shown good Na+ insertion capability, however, long range order limits their full exploitation. In essence, it is imperative to present new chemistries of carbon based electrode materials which can replicate their lithium ion storage capability in sodium ion and potassium ion batteries. We have recently found that carbon materials with short order gives better insertion of large metal ions owing to relaxed interlayer spaces (~0.375 nm) in comparison to long range order where interlayer spacing is necessarily ~0.34 nm. A metal-organic framework (MOF) based methodology was used to derive hierarchically porous S and N co-doped thin carbon (S,N@C) with shell-like (average shell size ~20-30 nm, shell wall ~8-10 nm) morphology for enhanced Na+/K+ storage. Taking benefit from hollow shell-like structure and thin shell wall, the S,N@C exhibited excellent Na+/K+ storage capability without structural degradation with faster mass transport at higher discharge rates resulting in limited compromise over charge storage at high charge/discharge rate. Owing to these advantages, the S,N@C delivered high reversible capacity of 448 mAh/g at 100 mAh/g and maintain discharge capacity up to 337 mAh/g at discharge rate of 1000 mAh/g. Owing to shortened diffusion pathways, the S,N@C delivered an unprecedented value of 204 mAh/g and 169 mAh/g at discharge rate of 16000 mA/g and 32000 mA/g respectively, with excellent reversible capacity for much longer cyclic life (~4500 cycles). In addition to excellent Na+ storage capability, the S,N@C exhibited high K+ storage capability with reversible storage capability of 252.8 mAh/g at current density of 1 A/g after 80
cycles. The post-electrochemical tests revealed excellent structural stability without any visible agglomeration for rationally designed materials. The post-electrochemical RAMAN analysis revealed a slight red shift after cycling with Na+/K+ ions indicating slight expansion of carbon lattice upon reversible cycling signifying the possibility of relaxation in thin carbon lattice. The methodology clearly shows possibility of using carbon as electrode in sodium/potassium ion batteries.

Ultrafast Sodium/Potassium ion intercalation into hierarchically porous thin carbon shells, Adv. Mater., 2018, 10.1002/adma.201805430

ES02.08.02 Theoretical Lithium Perchlorate Transport Properties Calculation to Lithium-Air Battery Applications Juliane Fiates, Leandro Zanotto, Guido C. Araujo, Luís F. Franco and Gustavo Doubek; University of Campinas, Campinas, Brazil.

The world’s growing production of carbon dioxide and the desire to use more sustainable energy sources are motivating the minimization of fossil fuels employment. In this context, the development of technologies in advanced energy storage devices appears as a possibility to turn feasible the transition of engine vehicles from internal combustion to full electric motion. The lithium-ion battery which is the technology used in portable electronics has already achieved its theoretical limit (around 200 Wh/kg) [1]. Therefore, the development of novel high energy density batteries is essential to overcome limitation of the actual system. In recent years the lithium-oxygen/air battery has received great attention because of its high theoretical energy density (11686 Wh/kg), which is comparable to oil combustibles [2]. A typical lithium-oxygen battery consists of a metallic lithium anode, a porous diffusion cathode, which is commonly made of carbon composite and a catalyst, and an aprotic electrolyte which acts as a media to lithium ions transport. A full understanding of electrolyte battery element is important to find a proper composition to achieve reversibility and good capacities on charge and discharge processes. So, we are proposing in this paper the evaluation of lithium perchlorate/dimethyl sulfoxide electrolyte by molecular dynamic simulation and the calculation of transport properties such as conductivity, diffusivity and viscosity to a homogenous media. The methodology is based on building the electrolyte molecular structure and on simulating the system to evaluate transport properties. Molecular Dynamics simulation was performed with LAMMPS (Large-scale Atomic/Molecular Massively Parallel Simulator). PACKMOL [3] package was used to generate the ionic-electrolyte configuration. The interaction potential parameters (both intermolecular and intramolecular) were set according to the chosen force field [4, 5]. Crossed intermolecular parameters were calculated by Lorentz-Berthelot combining rules. The electrostatic interaction was computed using the Particle-Mesh scheme. For Lennard-Jones interactions, a long-range correction beyond the cutoff was applied. A step for equilibration in the canonical ensemble was carried out followed by a production stage in isothermal-isobaric ensemble. The properties were analyzed at different temperatures: 273 K, 298 K, and 313 K. The post-processing step consists on calculating transport coefficients. These coefficients will be calculated by Green-Kubo relations. The dimethyl sulfoxide density and diffusivity calculated by simulation were compared with experimental data and good agreement was observed. The electrolyte system analyses show that this approach can be used as electrolyte scanning method to evaluate feasible compounds to lithium-air batteries applications.

ES02.08.03 New Generation of Flexible Li-Ion Batteries Based on a Sheet of Carbon Nanotubes Hamda M. Alshibli1, 2, 3, Daniel Choi1, Sultan Al Dalmiani2, Prena Chatveerdi1, Amsingh Bhambh Kanagaraj1 and Maryam Al Nahyan1; Khalifa University of Science, Technology and Research, Abu Dhabi, United Arab Emirates; United Arab Emirates space Agency, Abu Dhabi, United Arab Emirates; Khalifa University of Science, Technology and Research, Abu Dhabi, United Arab Emirates.

Recently, the demand for thinner, lightweight design, longer life span, space effective and flexible batteries is increasing. Out of the above advantages, especially flexibility attracts scientists’ attention due to a wide range of applications and enabling variety of shapes. This study is focusing on integrating all parts of Li-ion batteries into one flexible and light sheet. We use a sheet of multi-walled carbon nanotubes, so called ‘Bucky paper’ as a matrix for cathode and anode materials while we use polymer as a solid electrolyte. Two different approaches are being implemented to assemble the batteries: First, we prepare the battery in the form of sandwich and then press the major components of the battery such as cathode, anode and solid electrolytes. We can control the load and the heating temperature of the effect. This could enhance the quality of interface among three layers. Second, low viscous polymer electrolyte is coated on anode and cathode bucky paper and press them with different loads and temperature. One challenging is to form stable interfaces between the two layers - anode/polymer electrolyte/cathode sandwich. This can be overcome by soaking the sandwich structure in the liquid electrolyte in glove box and let them to dry and using adhesive conductive binders between the sandwich to improve the interface. Integration of three major battery components (cathode, anode, solid electrolyte) is in progress.

ES02.08.04 A Universal Approach to Produce Nanostructured Binary Transition Metal Selenides as High Performance Sodium Ion Battery Anodes Zeeshan Ali1, 2, 3, and Yanglong Hou1, 2, 3; 1Department of Materials Science and Engineering, College of Engineering, Peking University, Beijing, China; 2Beijing Key Laboratory for Magnetoelectric Materials and Devices (BKLMMD), Beijing, China; 3Beijing Innovation Centre for Engineering Science and Advanced Technology (BIC-ESAT), Beijing, China.

Binary transition metal chalcogenides have recently drawn boosted attraction as anodes for sodium ion batteries (SIBs) owing to their greatly enhanced electrochemical performances. Superior intrinsic conductivity and richer redox reactions, as compared to monometal chalcogenides, are the main origins of improved performances of these binary transition metal chalcogenides. In pursuit of employing various binary transition metal selenides (B-TMSs) for energy storage, a simplistic and universal synthesis approach is highly desirable. Here, we present a facile and comprehensive strategy to produce various combinations of nanostructured B-TMSs by the use of either nitrates or sulfates of corresponding metals in a high yield room temperature solution reaction. Furthermore, the structure evolution mechanism of nano rods from precursor nanosheets was investigated through the study of products obtained after various reaction durations. As proof of concept, high surface area and hierarchical nanosheets of Fe2NiSe2, Fe2CoSe2 and NiCoSe2 (termed as FNSe, FCSe and NCSe respectively) were manufactured and employed as anodes for sodium ion batteries. These as prepared anodes of B-TMSs exhibited adequately high energy capacities (e.g. 755, 660 and 397 mA h g−1 after 100 cycles at 1 A g−1 for FNSe, FCSe and NCSe, respectively) and excellent rate capabilities (e.g. 776 mA h g−1 at 0.5 A g−1 and 432 mA h g−1 at 20 A g−1 for FNSe, 655 mA h g−1 at 0.5 A g−1 and 466 mA h g−1 at 20 A g−1 for FCSe and then 660 mA h g−1 at 0.5 A g−1 and 366 mA h g−1 at 20 A g−1 for NCSe). In addition to this, FNSe and FCSe also presented extraordinary stable life of 2500 cycles (with reversible capacities of 554.2 and 554.6 mA h g−1 at 4 A g−1, respectively). In situ X-ray X-ray diffraction analysis combined with ex situ X-ray and selected area diffraction analysis revealed that the electrodes of FNSe, reversibly transform into the discharge product (Na2Se) through multistep reaction with sodium ions. When employed in sodium full batteries with lab-made Na0.5V2(P04)3/C cathode, as prepared B-TMSs anodes presented reasonably high reversible specific capacities (228.5, 216.5 and 100.2 mA h g−1 at 0.1 A g−1 after 100 cycles for FNSe, FCSe and NCSe, respectively). Overall, the presented strategy will pave the way for the development of numerous binary transition metal chalcogenides which are the potential materials for energy storage and conversion systems.
A Cost Effective Route to Synthesize LiFePO₄ in a Quasi-Open Environment Assisted by Starch as an Oxidation Protective Component

Fei Gu, Kichang Jung, and Alfredo A. Martinez-Morales

Materials Science and Engineering, University of California, Riverside, Riverside, California, United States; Chemical Engineering, University of California, Riverside, Riverside, California, United States.

The development of Li-ion cathode materials is moving forward to a new era. Lithium iron phosphate (LiFePO₄, LFP) is widely used by the battery industry and it has the potential to continue playing an important role in the future. Mainly driving by a stable operating voltage (3.5 V vs. Li/Li⁺) and a high theoretical capacity (170 mAh/g). Additionally, LFP has excellent cycling performance, high safety, environmental friendliness, and low raw material cost. To further increase the competitiveness of LFP by decreasing production cost, an approach to synthesize LFP with coated carbon (LFP/C), via lithiation in a quasi-open air environment is investigated in this work. In contrast to the generic solid state synthesis for LFP, our approach is more time efficient with the lithiation process completing under 30 minutes. Furthermore, our approach is a cost-effective process since the reaction is conducted under atmospheric pressure in a quasi-open environment. Starch is used as a carbon source during synthesis, providing a reducing environment to protect the synthesized LFP from oxidation, while forming a carbon coating on the surface of LFP. The carbon coating enhances the electrochemical performance of the assembled Li-ion batteries by improving electric conductivity of the LFP cathode. The combination of LFP synthesis process and LFP carbon coating process in one step further improve the efficiency of our quasi-open synthesis approach.

Starch is selected as carbon source because it has a high carbon content that produces LFP/C with a high efficient coating, at a low fabrication cost. This work investigates the effect of the amount of starch added, reaction temperature, and reaction time for LFP synthesis. Several techniques are used to characterize the properties of synthesized LFP/C. The crystal structure and chemical composition of the synthesized material are characterized by X-ray Diffraction (XRD) and Energy Dispersive Spectroscopy (EDS). The grain size of resulting materials is determined by Scanning Electron Microscopy (SEM). The degree of carbonization is characterized by Raman spectroscopy and Fourier transform infrared spectroscopy (FTIR). The electrochemical performance of synthesized cathode is investigated by Cyclic Voltammetry (CV) and the performance of assembled batteries is tested via an Arbin Tester. The mechanism of starch assisted LFP synthesis and the decomposition process of starch are investigated. These reaction processes are studied by Differential Scanning Calorimetry and Differential Thermal Analysis (DSC and TGA, respectively).

Electrochemical Intercalation of 2D Graphene with FeCl₃

Kai L. Kuntz, Carolyn Chen and Scott Warren; University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

Intercalation—the insertion of guest species into the interlayer space of a layered host material—is a platform to drastically alter properties. By inserting either an electron donor or acceptor species into a material, the fermi energy of the host shifts, resulting in different electronic and optical properties. While layered materials have been intercalated since 1841, their two-dimensional (2D) counterparts have only recently been intercalated with the first demonstration in 2009. As the host dimensions are reduced, the energetic penalty for intercalation, and therefore the rate and mechanism, are altered. Furthermore, since 2D materials are known to exhibit different electronic and optical properties than bulk, intercalation offers a unique platform to further alter and tune the properties of thin material.

Iron trichloride (FeCl₃) intercalates both bulk and few-layer graphite, resulting in a hole-doped graphite host, with the stage determining the extent of doping. In a stage I intercalation compound, each host layer is adjacent to an interlayer carbon, while in lower stages, the stage number dictates the number of host layers between intercalant layers. Ultimately, the carrier concentration and resulting properties of the compound are dependent on the stage of intercalation.

FeCl₃ has been previously intercalated in bulk and few-layer graphite thermally, and in bulk graphite electrochemically in water (Carbon N. Y. 3(5), 285-290 (1997)) or propylene carbonate (Carbon N. Y. 36, 383-390 (1998)). Thermal methods produced stage I FeCl₃-graphite, while electrochemical methods yielded stage II in the bulk material. We hypothesize that reducing the dimensions of the graphite host will reduce energetic barriers and allow for stage I compounds to be produced electrochemically. Furthermore, we hypothesize that FeCl₃ might be able to be deintercalated from few-layer graphite, enabling this compound to be studied for reversible optoelectronic applications.

Here, we electrochemically intercalate bulk and few-layer graphite with 10M FeCl₃ in propylene carbonate under inert environments (< 1 ppm O₂, < 0.1 ppm H₂O). We monitor the intercalation through in-situ techniques, including cyclic voltammetry, optical microscopy, and Raman-spectroscopy, as well as ex-situ techniques, including X-ray photoemission spectroscopy (XPS). Characterization of the resulting compound via XPS indicate the presence of FeCl₃ in the interlayer space. Raman spectroscopy further supports the electrochemical intercalation of bulk and few-layer material, resulting in a hole-doped host. Interestingly, we find that the thin material results in mixed stage I and stage II compounds, verifying our initial hypothesis that reduced dimensions enable access to higher stages and carrier concentrations, which was unattainable in bulk material by electrochemical methods. Furthermore, we investigate the reversibility of this intercalation through calculations and experiments. Calculations using density functional theory indicate that this intercalation should be reversible. We use in-situ characterization techniques to investigate this experimentally.

In this work, we employ in-situ and ex-situ techniques to demonstrate the first electrochemical intercalation of few-layer graphite with FeCl₃, allowing the role of dimensions in the intercalation to be investigated. Furthermore, this work is the first to demonstrate stage I FeCl₃-graphite through electrochemical techniques. Finally, we address the reversibility of this system and its promise for reversible optoelectronic technologies, including optical switches and batteries.

Three-Dimensional Hierarchical LiNi₀.5Mn₁.₅O₄ Desert-Waves—Topography-Inspired Conductive Network for Lithium-Ion Batteries with High-Rate Capability

Tao Mei and Xianbao Wang; Hubei University, Wuhan, China.

Inspired by the topography of desert, three-dimensional (3D) hierarchical LiNi₀.5Mn₁.₅O₄ desert-waves (LNMO-DW) composed of primary two-dimensional (2D) nanodiscs is ingeniously synthesized via a template-free route. Its formation can be attributed to the synergic effect of hydrate hydrate (HH) and ethylene glycol (EG) during the hydrothermal process. The as-obtained 3D hierarchical LNMO-DW triggers fast electrode kinetics and abundant electroactive zones by enabling multi-directional efficient transmissions for both lithium ions and electrons. The rate capability and cycling stability of LNMO-DW are improved to a superior level compared with the control groups and other reported works, which proves that 3D hierarchical desert-waves-like structure is one of the optimal structures for LNMO. Its specific capacity reaches 130 mAh/g at 10 C after 200 cycles, together with capacity retention of 91%. Noticeably, even when cycling at the high rates of 15 and 20 C after 200 cycles, the discharge capacities are still up to 117 and 108 mAh/g, respectively. The corresponding structural formation mechanisms and electrochemical principles have also been unravelled.

Tunnel Intergrowth Structures in Manganese Dioxide and Their Influence on Ion Storage

Yifei Yuan, Bryan Bylbes, Cong Liu, Jun Lu, Khalil Amin, Ekaterina Pomerantseva and Reza Shahbazian-Yassar; 1University of Illinois at Chicago, Chicago, Illinois, United States; 2Drexel University, Philadelphia, Pennsylvania, United States; 3Argonne National Laboratory, Argonne, Illinois, United States.

Controlled synthesis of homogeneous tunnel-structured materials has been a grand challenge due to the lack of understanding on heterogeneities associated with tunnel structuring and abnormalities. The presence of tunnel structure heterogeneity disables the quantification and optimization of the performance of various tunnel-structured functional materials in their targeted applications such as catalysis, water purification, energy storage, and sensing. Manganese dioxide (MnO₂) is a highly polymorphic material with several well-known tunnel-structured phases such as β-MnO₂, α-MnO₃, and T-MnO₃ featuring 1×1 tunnels, 2×2 tunnels, and 3×3 tunnels, respectively. For over a century, the tunnel-dependent properties of MnO₂ in areas such as catalysis and ion transport have been gradually realized, and numerous studies have been devoted to the synthesis of homogeneous tunnel phases. Until recently, the structural details of the tunnel phases have not been revealed clearly, especially down to the atomic level.

Here, we demonstrate for the first time the correlation between homogeneity of the tunnels and their dimensions. Utilizing state-of-the-art aberration-corrected scanning transmission electron microscopy that is sensitive to local structure information, we found that while β-MnO₂ possesses a homogeneous 1×1 tunnel phase, the tunnel homogeneity decreases when tunnel dimension increasing from 2×2 tunnel-structured α-MnO₃ to 3×3 tunnel-structured T-MnO₃. For α-MnO₃, a complicated 2×3 and 2×4 tunnel intergrowth as
well as tunnel shift (~7 Å) and rotation (~90°) with smaller 1×2 tunnels accommodating the structure mismatch are disclosed. For T-MnO$_2$, a larger density of defective tunnel intergrowths is observed. The existence of large tunnels (~10 Å) such as 3×4, 3×5, 3×6, 4×4, 4×6, 5×3, 5×4, and 5×5 tunnels is discovered in this work for the first time. Such tunnels are found to be stable within the 3×3 tunnel-dominated T-MnO$_2$ matrix. The complicated tunnel intergrowths discovered in this work are shown to affect the ion storage behavior in the tunnel-structured materials as revealed by in situ TEM of a single MnO$_2$ nanowire exhibiting such tunnel heterogeneity. The findings of this work call for renewed attention to the synthesis of homogeneous tunnel-specific MnO$_2$ phases for applications where tunnel homogeneity is desired.

**ES02.08.09 Sodium Ion Conduction in Germanium Phosphide and Germanium Arsenide**
Migdad Razzaq$^{1}$, Shunda Chen$^{1}$, Sahyasaachi Sen$^{1}$, Kirill Kovnin$^{2}$ and Davide Donadio$^{3,4}$; $^{1}$University of California, Davis, Davis, California, United States; $^{2}$Iowa State University, Ames, Iowa, United States.

For decades, the state-of-the-art has been lithium-ion batteries (LIB). But, with the growing need for energy storage and applications, new battery materials have to be studied. This would allow to replace lithium with more abundant and safer elements like sodium.

Here we use first-principles calculations to study the intercalation of sodium in two germanium-based layered materials: germanium phosphide (GeP) and germanium arsenide (GeAs), which are promising candidates for applications in sodium-ion batteries. Both GeP and GeAs have a Gallium Telluride-like layered monoclinic crystal structure. The interlayer van der Waals (vdW) gap provides promising sites for metal ion intercalation and diffusion. Our calculations, performed in the framework of density functional theory with an accurate non-local vdW functional, show a rich phenomenology. Sodium adsorption becomes exothermic beyond a threshold concentration and causes significant rearrangements of the crystal structure, accompanied by semiconductor/metal/semiconductor transitions. Nodged elastic band calculations, in addition to molecular dynamics, are used to study the diffusion path of the sodium ions.

**ES02.08.10 An Innovative Metal-Sulfide Cathode Active Material for Aluminum-Ion Batteries**
Yuxiang Hu; Chemical Engineering, The University of Queensland, Brisbane, Queensland, Australia.

Rechargeable aluminum-ion batteries (AIBs) are attractive next generation energy storage devices due to its low cost, high specific capacities, and good safety.$^{[1]}$ However, the lack of suitable electrode materials with high capacity and enhanced rate performance makes it difficult for real applications. Herein, we report the preparation of three dimensional (3D) reduced graphene oxide (RGO)-supported SnS$_2$ nanosheets hybrid and its enhanced electrochemical performance as a novel electrode for AIBs. A to-date one of the highest capacities of 392 mAh g$^{-1}$ at 100 mAh g$^{-1}$ and good cycling stability is achieved in the resultant new material. The 3D reduced graphene oxide-based network and nano-size active material endow the composite high electronic conductivity and fast kinetic diffusion, which contributes to the high cycling performance (112 mAh g$^{-1}$ at 1000 mAh g$^{-1}$). Furthermore, our detailed characterization also verifies the intercalation and de-intercalation of the aluminum anions into the layered SnS$_2$ nanosheets during the charge-discharge process.$^{[2]}$

**ES02.08.11 Nitrogen-Filling into Oxygen Vacancy Enable the Enhanced Fast Lithium-Ion Storage**
Yanglansen Cui$^{1}$, Nicholas Bedford$^{1,2}$, Rose Arnal$^{1}$ and Da-Wei Wang$^{1}$; $^{1}$School of Chemical Engineering, The University of New South Wales, Sydney, New South Wales, Australia; $^{2}$X-ray Sciences Division, Argonne National Laboratory, Argonne, Illinois, United States.

Although the transitional metal oxide (TMO) has been intensively investigated as the promising candidate for lithium-ion storage due to their high theoretical specific capacity, the poor conductivity and sluggish of solid ion diffusion rate still hinder their rate capability. Herein, the nitrogen doped amorphous tungsten oxide (N-WO$_3$) is fabricated and further used as electrode material for lithium-ion storage. Besides, the atomic structure of the obtained N-WO$_3$ is investigated by X-ray absorption spectrum (XAS) including XANES and EXAFS-FIT, suggesting that the tungsten center in N-WO$_3$ is not only coordinated with oxygen atom but also the nitrogen atom. Impressively, the as-prepared N-WO$_3$ exhibits an ultrastatic storage capability of 315 mAh g$^{-1}$ even at a high current density of 10 A g$^{-1}$ with only 5% decay of capacity after 4000 cycles which is superior to that of most reported WO$_3$-based electrodes. The coordinated N in N-WO$_3$ facilitate both the charge transfer and solid-state lithium ion diffusion rate, leading to the rate capability enhanced. The methodology proposed in this work will point out a way to design TMO-based electrode materials on large-scale.

**ES02.08.12 Tin Phosphide Based Materials with Low Irreversible Capacity as Anode for Sodium-Ion Batteries and Capacitors**
Francois Beguin and Agnieszka Chojnacka; Poznan University of Technology, Poznan, Poland.

Nowadays, owing to the low cost and abundance of sodium resources, Na-ion batteries (NiBs) and Na-ion capacitors (NiCs) attract a lot of research attention. However, the optimization of the Na-ion technology requires urgently the development of stable anode materials with high reversible capacity, low irreversible capacity and appropriate potential window. Tin based materials form rich alloys with sodium, yielding much higher theoretical capacity (from 847 mAh g$^{-1}$ for Sn to 1132 mAh g$^{-1}$ for SnP$_3$) than carbon-based materials. Despite the very large reversible capacity ($C_{\text{irr}}$) displayed by SnP$_3$, its relatively high $C_{\text{irr}}/C_{\text{cap}}$ ratio ($C_{\text{irr}}$ irreversible capacity) makes it inappropriate for practical application. In this context, we disclose a simple and inexpensive method to obtain SnP$_3$-based electrode materials showing low irreversible capacity and excellent cycle life, allowing them to be employed as negative electrode for electrochemical energy storage systems.

SnP$_3$ was formed by facile high-energy ball milling in Ar atmosphere, and it was then mixed with hard carbon (HC) in the mass ratio 1:1 by ball milling. The electrochemical properties of SnP$_3$ and HC/SnP$_3$ electrodes were determined by cyclic voltammetry (CV) and galvanostatic charge with potential limitation (GCPL) using Na as counter/reference electrode and 1 mol L$^{-1}$ Na$_2$CO$_3$ in a 1:1 mixture of ethylene carbonate (EC) and propylene carbonate. The HC/SnP$_3$ and HC/SnP$_3$-based electrodes display a very low irreversible capacity, ca 60 mAh g$^{-1}$ and 83 mAh g$^{-1}$, respectively. In addition, the HC/SnP$_3$-based electrode exhibits low ohmic drop of 13 mV, as compared to 30 mV for SnP$_3$. Electrochemical dilatometry during sodium insertion (potential range from 2 V to 0.1 V vs Na/Na$^+$) in SnP$_3$ and HC/SnP$_3$-based electrodes with same mass of SnP$_3$ demonstrated volume change of 70% and 50%, respectively, revealing that hard carbon acts as a buffer for SnP$_3$. The viability of presodiated SnP$_3$ and HC/SnP$_3$-based anodes in a full electrochemical cell has been demonstrated in Na-ion capacitors (NiCs) with activated carbon (AC) positive electrode, and using 1 mol L$^{-1}$ Na$_2$CO$_3$ in a EC/PC electrolyte. Both NiCs systems demonstrated an energy density ca. 45 Wh kg$^{-1}$ at a current density of 0.5 A g$^{-1}$ in the cell potential range 2.2 V - 3.8 V. After 4500 cycles at 0.5 A g$^{-1}$, an excellent capacitance retention of 97% was observed for the NiC with HC/SnP$_3$ electrode, demonstrating that these materials are promising anodes for a new generation of NiCs and NiBs.

**ES02.08.13 Effect of Porosities and Surface Morphologies in Si Anode for Lithium Ion Batteries using Magnesiothermic Reduction**
Jiamei Liu$^{1}$; Changling Li$^{1}$, Bo Dong$^{1}$, Yiran Yan$^{2}$, Ruoxu Shang$^{3}$, Cengui S. Ozkan$^{1,3}$ and Mihrimah Ozkan$^{1,3}$; $^{1}$Electrical Engineering, University of California, Riverside, Riverside, California, United States; $^{2}$Material Science and Engineering, University of California, Riverside, Riverside, California, United States; $^{3}$Mechanical Engineering, University of California, Riverside, Riverside, California, United States.

Si, with its high theoretical capacity (3572 mAh g$^{-1}$), high energy density and low self-discharge rate, is considered as the most promising anode material for next generation lithium ion batteries (LIBs). Recently, we published a ultra-fast Mg-thermal-reduction method for the production of scalable coral-like Si powders with a high surface area and...
three-dimensionally (3D) interconnected structures. In this work, we obtained Si materials with different porosities and surface morphologies via controlling over magnetostructural reduction. The porosities, surface morphologies, and phase purities of the synthesized nano-Si powders were analyzed by BET analysis, SEM, TEM, XRD, and Raman spectroscopy. Furthermore, electrical characteristics of different Si electrodes were examined by electrochemical impedance spectroscopy (EIS), cyclic voltammetry, and galvanostatic charge-discharge test. The Si electrodes exhibited long cycling stabilities, good rate capabilities, and high reversible capacities. We proved that the cycling performance and stabilities of these Si anodes significantly depend on the conditions of magnetostructural reduction.

ES02.08.14
Sodium Intercalation in TiO2 Electrodes During Dis-Charging of Sodium-Ion Batteries Monitored by Operando XANES Measurements
Andreas Siebert1, Xinwei Dou2, Roberto Félix1, Evelyn Handick1, Raul G. Dzie1, Regan Wilks1, Daniel Buchholz2, Giorgia Greco3, Stefano Passerini1 and Marcus Bar1,4,5, Helmholtz-Zentrum Berlin, Berlin, Germany; 2Helmholtz Institut Ulm, Ulm, Germany; 3Forschungszentrum Jülich GmbH, Erlangen, Germany; 4Energy Materials In-Situ Laboratory Berlin (EMIL), Berlin, Germany.

Lithium ion batteries (LIBs) are currently one of the preferred technologies to store electrical energy. However, the worldwide availability of Li is limited, and it is questionable whether the rising energy storage demands can be fulfilled by LIBs in the future [1]. Sodium ion battery (SIB) technology could provide an alternative, as Na is readily available, cheap, and environmentally friendly. SIBs additionally allow AI to be used as a new collector instead of Cu, which is heavier and more expensive. Recently, the excellent performance of a SIB anode based on TiO2 nanoparticles has been demonstrated [2,3]. In contrast to the well-optimized electrochemical behavior of state-of-the-art anodes, however, there is still a lack of understanding of the mechanisms involved in the performance of these nanoparticle anodes. In particular, it is challenging to unravel the structural and electronic changes of the anatase TiO2 nanoparticles and the loss of crystallinity of the anodic nanomaterial upon Na uptake. For instance, it has been shown that initial sodiation leads to an irreversible capacity loss of nearly 40% [3].

X-ray absorption near edge spectroscopy (XANES) of the Ti K-edge is ideal for studying the electronic and geometrical structure around the probed Ti atom and its nearest neighbors and, hence, can reveal effects of sodium intercalation. However, ex situ experiments performed on disassembled electrodes can raise questions about the relevance of the results due to the expected changes of the electrode material due to air exposure, sample transport, and preparation. To gain direct, relevant insights into the intercalation process of Na into the TiO2 nanoparticle anode material, we designed an operando XANES experiment using a modified coin cell equipped with an X-ray transparent Kapton® window and a 6 μm-thick Al foil current collector. This setup allowed the measurement of the Ti K-edge (at the HZB BESSY II synchrotron source in the HiKe endstation [4] at the KMC-1 beamline) of the TiO2 electrode while cycling the coin cell battery, i.e. desodating the electrode.

The Ti K absorption edge reveals the average Ti oxidation state of the TiO2 anode material, which changes during the sodiation from the expected +4 (Ti4+) oxidation state in the original anatase structure to values below +3. The operando results of the Ti K-edge show, that the oxidation state increases during the desodiation but does not reach Ti4+ again due to the presence of irreversibly intercalated sodium. The study is also focused on the evolution of the pre-edge structure of the Ti K-edge during the descharging. In the initial sodiation cycle, the pre-peak changes from the characteristic four-peak feature related to anatase [5] to a structure dominated by a single peak, hinting at a change in the number of nearest neighbors around the probed Ti atoms (from six to five or even four neighbors) [6]. The single peak intensity increases during the first desodiation, suggesting that the anode material does not completely recover the original anatase structure after the first full descharging cycle. The subsequent cycling shows the same spectroscopic trend on the pre-edge feature, revealing a stable intercalation process after the irreversible structural rearrangement of the TiO2 during the first sodiation process.

ES02.08.15
Intermetallic Clathrates as Insertion Anodes for Li-Ion Batteries
Andrew M. Dopilka1, Ran Zhao1, Jon M. Weller1, Svilen Bovev2, Xihong Peng2 and Candace K. Chan1; 1Material Science and Engineering, School of Engineering of Matter, Transport, and Energy, Arizona State University, Tempe, Arizona, United States; 2Department of Chemistry and Biochemistry, University of Delaware, Newark, Delaware, United States; 3College of Integrative Sciences and Arts, Arizona State University, Mesa, Arizona, United States; 4School of Molecular Sciences, Arizona State University Tempe, Arizona, United States.

Stable intercalation anodes for Li-ion batteries are generally comprised of two groups: graphite and Ti/Nb oxides. Graphite electrodes are reversible but can’t be operated at high current rates because of particle fracture and dendrite formation as a result of volume expansion and a low reaction potential (0.1 V). Li2TiO3 is a popular insertion anode that demonstrates good stability (zero strain) and fast charging but its high reaction voltage (1.55 V) lowers the energy density of the full cell. A crystal framework that allows low strain Li-insertion at a lower potential (i.e. 0.5 -1.0 V) could allow for fast charging with less propensity for dendrite formation while also increasing the energy density of the cell. Intermetallic compounds tend to have reaction voltages with Li between 0.2 V – 1.0 V, which makes them interesting candidates for insertion anodes. However, Li alloying accompanied by a large volume expansion is common in these materials (e.g. Si, Ge, Sn) so host frameworks that allow bulk Li insertion into the structure before a Li alloying reaction are needed. Intermetallic clathrates are crystal structures that are comprised of a group IV framework of cages which host alkali guest atoms in the center of the cages (e.g. Ba46Si44, K4Ge44). This structure type has led to many interesting materials properties such as thermoelectricity, superconductivity, hydrogen storage, and tunable optical properties. Recently, our group has been studying the electrochemical reactions of clathrates with Li to understand how the defects of clathrates affect the electrochemical properties and if reversible Li insertion into the crystal structure is possible.

Our recent results investigating the Ba46Al44Si44 and Ba46Al44Ge44 Type I clathrate systems will be summarized1,2. Interestingly, the Si clathrates do not undergo amorphization reactions typical of intermetallic compounds, indicating that the structure is stable in the potential range for anodes. The Ge clathrates, however, do undergo amorphization reactions to form Li-rich amorphous phases. From density functional theory calculations, X-ray diffraction, and electrochemical impedance spectroscopy, Li insertion into the cage structure seems unlikely. We find that the Ba inside the cage frustrates Li mobility and that bulk diffusion in the cage structure would require guest atom vacancies.

Next, the synthesis and electrochemical characterization of empty type II Si clathrates (Si84) would be reported. Previous work has proven with nuclear magnetic resonance (NMR) that Li can be inserted into the empty clathrate cages of Si84. This manifests as a potential plateau at (300 mV) prior to the amorphization of the Si lattice. This is distinctly different from diamond structured Si which only shows the typical two-phase amorphization reaction plateau. Initial results suggest that reversible Li insertion in Si84 is possible by applying a voltage cutoff before the amorphization reaction. We aim to understand the pathways, reversibility, and kinetics of Li insertion in the empty type II Si framework and evaluate them as Li insertion anodes. Since the Li insertion voltage is 300 mV for Si84, the risk of dendrite formation at higher current rates could be reduced while maintaining higher energy density cell due to a low reaction voltage. These results would be interesting for the future design of anodes that have a lower reaction voltage than the Ti/Nb oxides but still demonstrate rapid, reversible Li insertion.

ES02.08.16
Intercalation Energy Barrier Tuning of MoS2 for Aqueous Zinc Ion Storage
Hanfeng Liang; King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

Aqueous Zn-ion batteries present a low cost, safe, and high-energy battery technology, but suffer from the lack of suitable cathode materials because of the sluggish intercalation kinetics associated with the large size of zinc hydrate. Herein we report an effective and general strategy to transform inactive intercalation hosts into efficient Zn2+ storage materials through intercalation energy barrier tuning. Using MoS2 as a model study, we show both experimentally and theoretically that even hosts with originally poor
Herein, we report that high-energy ball milling (HEBM), which is widely employed in battery research to optimize electrochemical performance of active materials through particle size reduction, is not suitable for VOPO$_4$. Our results reveal that structural distortions and defects introduced in the material during HEBM impede the kinetics of high-lattice formed by the de-intercalation of K from KVOPO$_3$. The synthesis and characterization of these materials were described, together with future opportunities. This work was supported by the DOE–EPRC–NECCES.

Layered Vanadium Oxides as a High Energy Cathode Material for Nonaqueous Magnesium-Ion Batteries

M. Stanley Whittingham, Carrie Siu, Jia Ding and NorthEast Center for Chemical Energy Storage (NECCES) Team; State University of New York at Binghamton, Binghamton, New York, United States.

We have shown that it is possible to reversibly intercalate two lithium or sodium ions into phosphate host lattices without any degradation of the host lattice. Such reactions are highly dependent on the host lattice. We have shown that two lithium ions can intercalate into the e- and b-VOPO$_4$ phases. In these lattices, the first lithium ion intercalates by a slow two-phase reaction VOPO$_4$+LiVOPO$_4$, whereas the second ion intercalates by a fast single-phase reaction, Li$_{1+x}$VOPO$_4$. However, for the larger sodium ion, the expanded lattice formed by the de-intercalation of K from KVOPO$_4$ is required for the intercalation of two sodium ions. The synthesis and characterization of these materials will be described, together with future opportunities. This work was supported by the DOE–EPRC–NECCES.

Tetrahedral polyoxovanadium compounds make up a large family of intercalation cathodes for lithium cathode and solid electrolytes pursuing in next generation lithium batteries. While cathode and solid electrolytes have different requirements on electronic conductivity, high lithium ionic conductivity is of common significance to both electrode materials for high energy density and stable solid state electrolytes for better safety. However, designing a fast ionic transport in tetrahedral polyoxovanadium oxides requires detailed understanding of the interplay of geometric coordination with electronic band structures. This work presents a rational design of high capacity cathode, which utilizes V-doping to simultaneously engineer electronic conductivity and lithium transport in tetrahedral framework silicate, Li$_2$CoSiO$_4$(LCSO). First-principles modeling, in coupling with electrostatic field analysis by Madelung matrix, reveals a profound structural characters of delithiated Li$_2$CoSiO$_4$ (x = 2, 1, 0). However, the calculation indicates that V-doping not only introduces significant gap states that modify both electronic conductivity and redox activity of Li$_2$CoSiO$_4$, but also significantly alter the lithium transportation, which predicts a 0.20 eV lower of the transition barrier. The calculated diffusion coefficient shows that V-doping enhances on transport by three orders of magnitude. A series of Li$_2$Co$_{1-x}$Si$_x$O$_4$ (x = 0.00, 0.05, 0.10, 0.12, 0.16, 0.20) samples have been synthesized to verify and validate the first-principles prediction, combining with characterization by XRD, SEM and Raman spectroscopy studies. Electrochemical testing shows that carbon coating LCSO with 10% V substituted Si delivers an initial discharge capacity of 220.1 mAh g$^{-1}$ with 74% coulombic efficiency and impressive cycling stability. This study may provide a new venue for high performance design of all-solid-state lithium secondary batteries from...
Earth-abundant spinel ferrites are potential low-cost negative electrodes for rechargeable Li-ion batteries because they can undergo reversible conversion reactions upon deep discharge. But iron oxides can also function as positive electrodes provided that a sufficient number of cation lattice vacancies and proton-stabilized oxygen sites are present and accessible for reversible Li+ or Na+ insertion. The challenge is to create these lattice sites in an otherwise vacancy-deficient oxide. We address this challenge and achieve technology-relevant cation–insertion capacities by generating cation lattice vacancies using design strategies that significantly increase the defect nature of the spinel. First, we produce spinel ferrites in aerogel forms (materials with high surface area and through-connected mesoporosity), thus amplifying the surface-to-bulk ratio and providing facile access to vacancies at the inherently disordered surfaces. We then make the oxide highly defective with mild heat treatment in an O2-rich atmosphere that removes synthesis precursors while avoiding crystallization. The defect nature of the spinel is further amplified by substituting a third of the iron sites with high-valent vanadium (V4+ and V5+). We find that choosing thermal treatments that predominantly result in ferrites substituted with V4+ delivers the largest Li+ and Na+ insertion capacities, approaching 130 mAh g−1 and 70 mA h g−1, respectively. We also report on doping the vanadium sites with aluminum (~5%) to improve cycling stability when these spinel ferrites are used as positive electrodes for Li+ insertion.

10:00 AM BREAK

Wenxiang Chen, Xun Zhan, Binbin Luo, Zihao Ou, Hong Yang, Jian-Min Zuo and Qian Chen; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

We study the electrochemical and chemo-mechanical responses of nanoparticles of different sizes as cathode materials in magnesium ion batteries. Distinctive structural phase transition pathways are observed in nanoparticles of different sizes in the Mg ion intercalation as characterized by X-ray diffraction analysis. Small nanoparticles exhibit a single-phase transition while heterogeneous phase evolution is observed in big nanoparticles. Further examination at nanoscale by nano-beam diffraction and energy-dispersive X-ray spectroscopy reveals that the difference in the phase evolutions could be attributed to the short diffusion length and single crystallinity in the small nanoparticles. Our work shows that engineering the nanoparticle size and crystallinity has a direct influence on Mg ion intercalation processes, which rationally guides the design of electrodes with high capacity and high stability.

11:15 AM ES02.10.03

In Silico Investigation of Electrode Materials for Rechargeable Magnesium Batteries Nikhil Medhekar, Mingchao Wang, Jodie Yuwono and Nick Birbilis; Monash University, Clayton, Victoria, Australia.

Rechargeable Mg-ion batteries (MIBs) are rapidly emerging as a plausible alternative to Li-ion batteries (LIBs) in terms of energy density, scalability and operation safety. However, key challenges in addressing the electrochemical stability and cyclability of potential electrodes, such as Mg metal as anode and layered transition-metal dichalcogenides (TMD) as cathode, pose questions regarding their feasibility as electrodes in MIBs. The inadequate understanding of reaction mechanisms during (de)magnesiation process hinders the practical application and optimal design of electrode materials. Here we carry out first-principles calculations to investigate the electrochemical behavior of Mg metal and Group 14 as anodes, as well as layered TMD as cathodes. We find that unexpected self-catalytic behavior of Mg induced by surface hydroxylation can be effectively controlled by impurity enrichment (alloying with Group 14 and 15 elements) and surface oxidation. To replace Mg by Group 14 elements as MIB anodes, comprehensive kinetic and thermodynamic investigations reveal that amorphous Ge and crystalline Sn can work as potentially effective anode materials in Mg-ion batteries. We also find out that a small overpotential is necessary for avoiding aggregation of Mg at anode/electrolyte interfaces during Mg-X reactions. In addition to anodes, our studies demonstrate that the expansion of layer spacing in TMDs (i.e. TiS2 and MoS2) enables faster intercalation and diffusion of MgCl2 species in TMD interlayers owing to the low energy barrier, and further enhancing the theoretical energy capacity of Mg-TMD.

SESSION ES02.11: Multivalent Intercalation—Zn and Beyond

Session Chairs: Benjamin Morgan and Kimberly See

Thursday Afternoon, April 25, 2019

PCC North, 100 Level, Room 126 C

1:30 PM ES02.11.01

Multi-Electron Cathodes for High-Capacity Alkali-Ion Batteries Shyue Ping Ong1, Yuh-chieh Lin1, Marc Hidalgo2, Antonin Grenier1, Natalya Chemova2, Louis F. Piper3, Karena Chapman1 and M. Stanley Whittingham1; 1University of California, San Diego, La Jolla, California, United States; 2Binghamton University, The State University of New York, Binghamton, New York, United States; 3X-ray Division, Argonne National Laboratory, Lemont, Illinois, United States.

Multi-electron cathodes, which utilizes more than one redox couple per transition metal, are a path towards higher capacities and energy densities. In this talk, I will discuss the efforts of the NorthEast Center for Chemical Energy Storage, a DOE Energy Frontier Research Center, in developing multi-electron cathodes for both Li and Na intercalation utilizing the V3+/4+ and V4+/5+ redox couples. I will demonstrate how the integrated application of density functional theory calculations, in operando characterization and
electrochemical measurements has provided deep insights into the relative phase stability and electrochemical performance of the \( \text{e} \), \( \text{f} \) and \( \text{g} \)-polymorphs of VOPO\(_4\), and led to optimized cathodes achieving close to full two electron cycling. Furthermore, we have synthesized all three polymorphs starting from a single precursor – LiVOPO\(_4\)H\(_2\)O – through careful control of the \( \text{O}_2 \) environment and temperature. Finally, I will also highlight our exploration of other VOPO\(_4\) phases with larger alkali ions, e.g., KVOPO\(_4\), for improved Na cycling.

2:00 PM ES02.11.02
High Capacity and Stable Cyclic Performance of 2D MXene Cathodes for Rechargeable Aluminum Batteries
Armin VahidMohammadi and Majid Beidaghi; Auburn University, Auburn, Alabama, United States.

The emerging market of electric vehicles (EVs) has raised the bar for development of safer rechargeable batteries with significantly higher energy densities. Even though currently lithium-ion (Li-ion) batteries are the dominant battery technology for portable electronics and EVs; the scarcity of lithium resources, its high cost of extraction from brines, and safety issues arising from their flammability have further increased the need for batteries beyond Li-ion technologies. Among various battery technologies, multivalent-ion batteries that store and deliver charge by intercalation of divalent (Mg\(^2+\), Ca\(^2+\), Zn\(^2+\)) or trivalent (Al\(^3+\)) ions into layered host materials are of interest as they can potentially deliver higher energy densities at a reduced cost compared to Li-ion batteries. Particularly, rechargeable aluminum batteries that utilize aluminum metal as the anode are considered as one of the most promising alternative energy storage systems for current battery technologies because aluminum is the most abundant metal in Earth’s crust, offers three-electron redox reactions in electrochemical systems, and can be handled in the open air leading to higher safety and facile cell fabrication. Also, it has the highest theoretical volumetric capacity of 8040 mAh cm\(^{-2}\) among all metals and a reasonably high theoretical gravimetric capacity of 2980 mAh g\(^{-1}\). Recently, we reported on rechargeable aluminum batteries utilizing two-dimensional (2D) \( \text{V}_\text{2} \text{C} \) MXenes as intercalation-type cathodes delivering exceptional capacities and rate-capability. \(^1\) MXenes are a family of 2D transition metal carbides and nitrides with a general formula of \( \text{M}_X \text{C}(\text{M} \text{is a transition metal, } X \text{is carbon and/or nitrogen, } n=1,2, \text{ and } 3, \text{ and } T \text{ represents different surface functional groups}) \) that are produced by selective etching of the A layer atoms (i.e., Al) from MAX phases (i.e., \( \text{V}_\text{2} \text{AlC} \)), a large group of layered ternary carbides and nitrides. \(^2\) Despite their high capacities, the MXene cathodes reported in our previous work showed severe capacity decay in over hundreds of cycles. Here, we report the results of our recent research on addressing this problem through a combination of designing new electrode architectures and modifying electrolyte composition. This approach results in achieving highly stable performance for MXene cathodes over hundreds of cycles. We demonstrate the fabrication of freestanding and binder-free hybrid electrode materials based on different 2D MXene compositions with exceptional volumetric capacities and long cycle life. We also present the results of our investigation of thermodynamics and kinetics of Al\(^3+\) intercalation into MXene cathodes through various structural characterizations (XRD, SEM, HRTEM, and XPS) and electroanalytical techniques such as Galvanostatic Intermittent Titration Technique (GITT) and Electrochemical Impedance spectroscopy (EIS). Our research results provide invaluable insights into the mechanism of multivalent-ion intercalation into MXenes. In addition, considering that family of the MXenes now include 20 different compositions, this research guides fabrication of an entire group of cathode materials for rechargeable aluminum batteries based on these 2D materials.

2:15 PM ES02.11.03
Intercalation Host Using Defective FePO\(_4\)-Carbon Composite for Multivalent Rechargeable Battery Cathode
Yuki Orikasa; Kazuaki Kimi; Etsuro Iwama; Wako Naoi; Yusuke Yamaguchi; Yoshihito Yamaguchi; Koji Ohara; Patrick Rozier; Patrice Simon and Katsuhiro Naoi; Ritsumeikan University, Kusatsu, Japan; Tokyo University of Agriculture & Technology, Koganei, Japan; K & W Inc., Kunitachi, Japan; Japan Synchrotron Radiation Research Institute (JASRI, SPring-8), Sayo, Japan; Centre national de la recherche scientifique, Toulouse, France.

Multivalent ion rechargeable batteries are promising candidates as the next generation of rechargeable battery technologies. The advantages of metal anode such as magnesium or calcium are their high theoretical capacity, available stocks and the absence of dendrite formation. However, multivalent ions exhibit slow diffusion kinetics in solid electrodes and intercalation hosts that can operate at room temperature are currently limited to Chevrel structure type compounds.\(^1\)

In this study, we investigated the use of FePO\(_4\)-carbon composite prepared by ultratrefugination (UC) method as multivalent-ion host structure. For nano-hybrid capacitor electrode, the electrode materials prepared by the UC method reported so far are capable of ultrafast lithium-ion insertion and extraction reaction.\(^2\) Therefore, we used the UC method to prepare materials as host electrode for multivalent-ion intercalation. Since the irreversible magnesium ion insertion-extraction reaction in olivine type FePO\(_4\) crystal has been reported,\(^3\) in our study, non-crystalline FePO\(_4\) with carbon composite was used. FePO\(_4\)-carbon composite was prepared by UC process.\(^2\) The composite was mixed with PTFE, with a weight ratio of 9:1. The electrodes were firstly charged in 1M LiPF\(_6\) in a 3:7 volume ratio of ethylene carbonate and diethyl carbonate. Then, a three electrode cell with an Ag/Ag\(^+\)/Mg double junction reference electrode was assembled using the previously charged FePO\(_4\)-carbon composite electrode. The counter electrode was an active carbon, and the electrolyte was 0.5 M magnesium bis(trifluoromethanesulfonfonyl)imide in acetonitrile. Charge-discharge measurements were performed at 25°C. The valence state of Fe and local structure in the charged / discharged electrodes were tracked by X-ray absorption spectroscopy, which was measured in a transmission mode.

Reversible charge / discharge capacity was observed after the first discharge. At 25°C, a capacity of approximately 150 mAh per weight of active material at a rate of 1/20 C was achieved at a potential of about 2 V versus Mg\(^+/\text{Mg}\). From TEM-EDX measurements, FePO\(_4\) particles were found to be embedded in carbon and the intensity of magnesium was observed only in regions where FePO\(_4\) particles exist. X-ray absorption edge at Fe K-edge shifts downward in energy during discharge, reflecting the reduction of iron ions to maintain electrical neutrality upon magnesium-ion insertion in the discharge reaction. In the presentation, we will also report about the charge-discharge characterizations of FePO\(_4\)-carbon composite in calcium and zinc ions based electrolytes.

Real-Time Identification and Understanding of Zinc Compounds in Rechargeable Zinc Electrodes
Brendan E. Hawkins, Damon Turney, Gautam Yadav and Sanjoy Banerjee; The City College of New York, New York, New York, United States.

Rechargeable zinc electrodes are attractive forms of energy storage for commercial applications because of their high theoretical energy capacity and their use of inherently cheap, safe, and environmentally friendly materials. The zinc rechargeable electrode in commercial batteries is historically limited in depth of discharge and cycle life, which has prevented them from being widely used on a commercial scale. This limitation is partly due to irreversible reactions occurring during discharge, which lead to passivation of the zinc electrode. Despite extensive study, the properties of these oxide species and the conditions leading to their formation are not fully understood. In this work, using in-operando optical microscopy, we have identified various zinc oxide morphologies in alkaline electrodes classified as Type I and Type II in the literature as well as other species that have not yet been identified. We will further analyze these zinc compounds using in-operando x-ray diffraction and scanning electron microscopy, and chemically identify these species and the conditions at which they form using in-operando confocal Raman spectroscopy. Identification of zinc species that detrimentally affect zinc rechargeablebility and understanding their formation will promote the design of better zinc electrodes and electrodes, leading to improved cycle life and depth of discharge in zinc batteries.

2:45 PM BREAK
Electrochemical energy storage was an important enabler of the wireless revolution and it is touted as a key component of a society that shifts away from its dependence on fossil fuels. Li-ion batteries are the primary technology when high energy devices are required. However, despite their improved functionality over older systems (e.g. lead-acid car batteries), they do not quite yet meet the emerging energy demands in transportation and grid markets. This roadblock sparked interest in the development of batteries that utilize Mg\(^{2+}\) as ionic carrier. Theoretical predictions indicate that couples exist between a Mg metal negative electrode and oxide positive electrodes that could surpass the current practical limits of current devices. Among the candidate oxides, those showing a spinel structure have been predicted as the most suitable for the reversible intercalation of ions such as Mg\(^{2+}\) or even Ca\(^{2+}\) [1], the critical reaction in the positive electrode. However, experimental validation, while incipient [2], has not been fully achieved. In this talk, we will present the most up-to-date insight into the ability of spinel oxides to diffuse and reversibly intercalate Mg\(^{2+}\). In this task, the ability to synthesize particles at small dimensions is vital, as is the characterization of chemical and physical phenomena using a combination of tools providing information at different scales. We will rely on data from X-ray diffraction, spectroscopy and scattering, electron microscopy and nuclear magnetic resonance to probe the reactions that occur when spinel oxides are used as working electrodes in cells with electrolytes containing Mg\(^{2+}\). The rationale for the choice of techniques and the key pieces they provided to complete the picture will be discussed. Our ultimate aim in the talk will be to establish relationships between crystal-chemistry, charge carrier and outcomes of the electrochemical reaction.

**Measuring and Defining Electrochemical Reactions of Transition Metal Oxides in Mg Electrolytes**

Jordi Cabana; University of Illinois at Chicago, Chicago, Illinois, United States.

Electrochemical energy storage was an important enabler of the wireless revolution and it is touted as a key component of a society that shifts away from its dependence on fossil fuels. Li-ion batteries are the primary technology when high energy devices are required. However, despite their improved functionality over older systems (e.g. lead-acid car batteries), they do not quite yet meet the emerging energy demands in transportation and grid markets. This roadblock sparked interest in the development of batteries that utilize Mg\(^{2+}\) as ionic carrier. Theoretical predictions indicate that couples exist between a Mg metal negative electrode and oxide positive electrodes that could surpass the current practical limits of current devices. Among the candidate oxides, those showing a spinel structure have been predicted as the most suitable for the reversible intercalation of ions such as Mg\(^{2+}\) or even Ca\(^{2+}\) [1], the critical reaction in the positive electrode. However, experimental validation, while incipient [2], has not been fully achieved. In this talk, we will present the most up-to-date insight into the ability of spinel oxides to diffuse and reversibly intercalate Mg\(^{2+}\). In this task, the ability to synthesize particles at small dimensions is vital, as is the characterization of chemical and physical phenomena using a combination of tools providing information at different scales. We will rely on data from X-ray diffraction, spectroscopy and scattering, electron microscopy and nuclear magnetic resonance to probe the reactions that occur when spinel oxides are used as working electrodes in cells with electrolytes containing Mg\(^{2+}\). The rationale for the choice of techniques and the key pieces they provided to complete the picture will be discussed. Our ultimate aim in the talk will be to establish relationships between crystal-chemistry, charge carrier and outcomes of the electrochemical reaction.

* Invited Paper

**TUTORIAL**  
Advanced Soft X-Ray Spectroscopy and Cryo-TEM in Studies of Batteries and Electro catalysts  
Monday Afternoon, April 22, 2019  
PCC North, 100 Level, Room 126 B

This tutorial focuses on the fundamentals and applications of several advanced characterization techniques to understand the atomic and electronic structures of energy materials, especially batteries and electrocatalysts. The tutorial will include detailed explanations of recent advances and developments in soft X-ray spectroscopy, including soft X-ray absorption spectroscopy (XAS), X-ray emission spectroscopy (XES), and high-efficiency mapping of resonant inelastic X-ray scattering (mRIXS) with in-situ operando capabilities. The second part of the tutorial will focus on cryogenic electron microscopy and spectroscopy of energy materials with emphasis on reactive materials and liquid-solid interfaces. Fundamental and practical aspects of cryo-focused ion beam milling (cryo-FIB), cryo-scanning transmission electron microscopy (cryo-STEM), electron energy loss spectroscopy (EELS) and spectroscopic mapping will be discussed. Two invited speakers, Wanli Yang from Lawrence Berkeley National Laboratory and Lena F. Kourkoutis from Cornell University, will highlight examples of these techniques used in their energy materials research in addition to providing details on principles. The tutorial will therefore cover both fundamentals and frontier research, and emphasize the strategies to use proper tools for the studies of electrochemical energy systems under extreme conditions.

1:30 PM  
**Advanced Soft X-Ray Spectroscopy of Energy Storage Materials**  
Wanli Yang; Lawrence Berkeley National Laboratory

This course is intended for chemists, physicists, materials scientists, and engineers with an interest in applying advanced soft X-ray techniques to study a broad variety of electrochemical materials. The highlight will be on the recent developments of high-efficiency mapping of resonant inelastic X-ray scattering (mRIXS) for studying energy materials, but conventional X-ray emission spectroscopy (XES) and five different channels of soft X-ray absorption spectroscopy (sXAS) will be explained in details. The attendee will develop a basic understanding of these modern soft X-ray spectroscopic techniques, the proper data interpretations, and their pros and cons, with plenty of examples on energy storage material studies.

3:00 PM BREAK

3:30 PM  
**Cryogenic Electron Microscopy for Electrochemical Systems**  
Lena F. Kourkoutis; Cornell University

This lecture will cover the principles of cryogenic electron microscopy and spectroscopy of energy materials with emphasis on reactive materials and liquid-solid interfaces. Fundamental and practical aspects of cryo-focused ion beam (cryo-FIB), cryo-scanning transmission electron microscopy (cryo-STEM) and electron energy loss spectroscopy (EELS) will be discussed including signal interpretation, artifacts and limits of each technique. Examples of structural and chemical mapping of processes at solid-liquid interfaces in lithium-metal batteries will be provided and will demonstrate the potential of cryogenic electron microscopy for probing nanoscale processes at intact solid-liquid interfaces in functional devices for energy applications.

**Highly Stable Carbon-Based Catalysts for Bifunctional Oxygen Reduction and Evolution for Reversible Alkaline Fuel Cells**  
Gang Wu; State University of New York at Buffalo, Buffalo, New York, United States.
The intrinsic instability of carbon largely limits its use for the oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) as a bifunctional catalyst in reversible fuel cells or water electrolyzers. Herein, we discovered that Mn doping has a promotional role in stabilizing nanocarbon catalysts for the ORR/OER in alkaline media. Stable nanocarbon composites are derived from an inexpensive carbon/nitrogen precursor (i.e., dicyandiamide) and quaternary FeCoNiMn alloy via a template-free carbonization process. In addition to FeCoNiMn metal alloys/oxides, the carbon composites comprise substantial carbon tube forests growing on a thick and dense graphite substrate. The dense carbon substrate at high degree of graphitization results from Mn doping, while active nitrogen-doped carbon tubules stem from FeCoNi. Catalyst structures and performance are greatly dependent on the doping content of Mn. Various accelerated stress tests (AST) and life tests verify the encouraging ORR/OER stability of the nanocarbon composite catalyst with optimal Mn doping. Extensive characterization before and after ASTs elucidates the mechanism of stability enhancement resulting from Mn doping, which is attributed to (i) hybrid carbon nanostructures with enhanced resistance to oxidation and (ii) the in situ formation of the β-MnO2 and FeCoNi-based oxides capable of preventing carbon corrosion and promoting activity. Note that the improvement in stability due to Mn doping is accompanied by a slight activity loss due to a decrease in surface area. This work provides a strategy to stabilize carbon catalysts by appropriately integrating transition metals and engineering carbon structures.

Interfacial Bonding Layer for High Mechanical and Chemical Robustness of Polymer Electrolyte Fuel Cells for Vehicle Applications Hoe-Tak Kim1, 2, 3, Department of Chemical and Biomolecular Engineering, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Korea (the Republic of); 4Advanced Battery Center, KAIST Institute for the NANOCentury, Daejeon, Korea (the Republic of).

Polymer electrolyte fuel cells (PEMFCs) have been considered a promising mobile energy conversion system to replace internal combustion engines due to high energy conversion efficiency, moderate operating temperature, short fuel charging time, and zero emission. Accordingly, PEMFC is one of the promising candidates for vehicle electrification as exemplified by fuel cell electric vehicle. Even though PEMFC technology has arrived at a commercialization stage, the durability of fuel cell stack needs to be further improved to guarantee reliable operations under harsh conditions. Various degradation modes critical to the durability have been identified, the hydroxyl radical formed by crossover H2 or O2 in the presence of Pt catalyst deteriorates membranes and-ionomers in the catalyst layers; the stress generated during dynamic change in hydration level of the cell leads to a mechanical defect at the membrane/catalyst layer interface or membrane. These chemical and mechanical degradation issues, which eventually result in a cell failure, still remain unsolved. During the past few years, we have addressed the durability problems of PEMFC by engineering the membrane/catalyst layer interface. We witnessed that the interfacial durability between membrane and catalyst layer can be improved by introducing an interfacial bonding layer such as Lego-block structured and ball-socket joint structured interfaces, enhancing the humidity cycling stability. Recently, we find new possibilities that interface material and structure design can also improve the mechanical and chemical durability of membranes. In this talk, we will present our results on how the fuel cell durability under harsh conditions can be improved by advanced interfacial engineering.

11:30 AM ES03.01.03
3D Graphene-Coated Ni Foam Heterostructures as Bipolar Plates of a Polymer Electrolyte Membrane Fuel Cell Yeoseon Sim1, Jinsung Kwak1, Se-Young Kim1, Yongsu Jo1, Seunghyun Kim1, Sung Yoush Kim1, Ji Hyun Kim2, Chi-Seung Lee1, Jangho Jo2 and Soon-Yong Kwon1, Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of); 2Hyundai Motor Group, Yongin, Korea (the Republic of).

The polymer electrolyte membrane fuel cell (PEMFC), which is an energy technology for directly transforming chemical energy into electrical energy by oxidizing hydrogen at the anode and reducing oxygen at the cathode, is a promising way to resolve the energy crisis and environmental pollution. However, realizing their implementation as a practical and highly efficient energy conversion system remains a big challenge because the chemical instability of metal bipolar plates in the harsh acidic (pH ~3-5) and humid operating environment inside PEMFCs leads to decreased performance and durability. To improve the chemical durability of metal plates, various protective layers such as TiC, CrC, and TiN/CrN have been applied to their surfaces.1,2 Even though the corrosion resistance of metal bipolar plates coated with protective layers has been enhanced, their contact resistances remain above the target value for PEMFCs (PEMFC targets for 2020 set by the US Department of Energy (DOE): interfacial contact resistance < ~10 mΩ cm2 and corrosion current density < ~1 µA cm2).1 Besides, another obstacle to commercial utilization of metal bipolar plates is the difficulties in precise machining and designing of flow channels used as a distributor of reactant gases on the metal plate. In this work, we present a novel method for coating highly crystalline multilayer graphene (Gr) as a superficial protective layer (thickness of ~12 nm) onto a 6 × 6 cm2 Ni foam in short growth times (t ≤5 min) via the facile and rapid thermal annealing (RTA) of poly(methylmethacrylate) as a solid-state C source. The synthesized graphene layers have a low defect density and completely cover the three-dimensional (3D)-structured surface of the Ni foam, dramatically improving its corrosion resistance, interfacial contact resistance (ICR), and hydrophobicity. After stability tests in the operating environment of a PEMFC, the optimized Gr-coated Ni foam preserved its exceptionally low corrosion current density of 2.5 µA cm2 with an ICR of 9.3 mΩ cm2 at 10.1 kgf cm2. A H2-air PEMFC fabricated using the Gr-coated Ni foam as bipolar plates showed an exceptionally enhanced maximum power density of ~967 mW cm2, which is the best among those of the reported metal foam bipolar plates. Moreover, all the characteristic values meet the 2020 DOE technical target values for transportation applications of PEMFCs. This study demonstrates that the 3D Gr-coated Ni foam prepared using our proposed new coating method exhibits superior characteristics as an inhibitor for the highly efficient performance of a PEMFC with durability. Our facile coating approach can pave the way to further enhance energy conversion systems through interface engineering.

Reference
100 °C, depending on the thermal management provided in the spacecraft. On the other hand, atmospheric missions and surface missions on inner planets, e.g., Venus, require power technologies that can survive high temperatures up to 465 °C. Another unique requirement for the power sources in NASA missions, especially missions to Jupiter and its moons, is tolerance to high intensity radiation environment of ~10 Mrad. Further, for the missions to Ocean Worlds that are more likely to have extant life, e.g., Europa, Titan and Enceladus, the power sources need to be biologically sterile, which is currently accomplished only by irradiation to about 10 Mrad.

In support of these various missions, we developed, and are still developing in some cases, different primary and rechargeable battery technologies for extreme environments. The primary battery technologies have been developed include lithium-thionyl chloride cells for operations at -80°C, similar lithium oxyhalide chemistries for lower operating temperatures of -100 °C, and lithium-carbon fluoride batteries with high specific energy of >700 Wh/kg and good radiation tolerance. The rechargeable battery technologies that have been advanced include low temperature lithium-ion chemistries operating at low temperatures of -40 to -70 °C and high specific energy candidates offering high specific energy of 220 Wh/kg or higher combined with tolerance to ~20 Mrad of radiation. Finally, we have also focused, to less extent, on high temperature sodium rechargeable molten salt batteries with metal chloride cathode operational at 20-350 °C and lithium molten salt primary batteries that can survive and operate at 465 °C. In this paper, we will briefly describe these technological advances on energy storage technologies for extreme environments in conjunction with the mission descriptions.

Novel Molecular Designing of High-Performance Bio-Based Polybenzimidazoles to Prepare Single-Ion Conducting Solid Polymer Electrolyte
Aniruddha Nag, Md Asif Ali, Raman Vedaranjan, Noryoshi Matsumi and Tatsuaki Kaneko; Japan Advanced Institute of Science and Technology, Nomi, Japan.

Conventional bio-based plastics are usually low performance plastics in terms of thermo-mechanical properties. Here we have successfully synthesized bio-based polybenzimidazoles consist of high thermo-mechanical properties comparable with engineering plastics, owing to strong π-stacking interaction among aromatics and imidazole rings and H-bonding between N-H and N of imidazole ring. Imidazole proton can be easily modified by various substituents. Here we report N-boronation of the PBI via lithiation to be ionically conductive (scheme 1). The PBI was modified by triethylborane substitution to imidazole proton to create boronated PBI (B-PBI) with Li counter ion. Ionic liquid 1-butyl-3-methylimidazolium bis(trifluoromethanesulfonyl)imide (BMIMTFSI) was added to the B-PBI as a plasticizing agent with different concentration to prepare composite solid polymer electrolytes (SPEs). Impedance analysis of various composition SPEs show ionic conductivity with 1.4x10^-2 S/cm at maximum whereas Li-ion transference number was obtained (t_li^+) = 0.623 at maximum. Ionic conductivity, Li-ion transference number, and carrier ion number increased with increasing amount of BMIMTFSI, to show maxima at a certain concentration. Further, charge-discharge measurement was performed by fabricating anode half-cell composed of the highest li-ion conducting composite SPE as electrolyte, Si-electrode as anode, and Li-metal as cathode. The resulting value showed a good reversible capacity at discharge rates ranging 0.1 – 2.0 C and stable solid electrolyte interface formation takes place.

Proton Transport in Solid Electrolytes Under High Pressure
Artur Braun1 and Qianli Chen1,2,3; 1Empa, Dubendorf, Switzerland; 2State Key Laboratory of Metal Matrix Composites, University of Michigan-Shanghai Jiao Tong University Joint Institute, Shanghai, China; 3Physics, ETH Zürich, Zürich, Switzerland.

Protons are the relevant electric charge carriers in the sustainable hydrogen economy [1]. Because of humidity (H2O) in ambient environment and the crystalline imperfections (defects) in materials, water molecules like to enter some materials and settle as hydrates or hydrides structures. Oxygen and protons become part of the structure. Upon thermal excitation, hydroxyl bonds may become hydrogen bonds which eventually “melt”. The protons may then liberate and become electric charge carriers, which lend them a particular function in solid electrolytes as proton conductors. We have in the last couple of years observed and investigated the biography and lifestyle of such protons from localization to de-localization. The proton is an elusive player and not always easy to make out. With a combination of neutron and synchrotron based scattering and spectroscopy methods, along with electroanalytical techniques, we have increased our understanding of the proton dynamics and its structural origin, which is important for super-protonic conductivity. We have investigated the oxygen vacancy filling of engineered oxygen deficient proton conductors by water molecules with impedance spectroscopy and ambient pressure XPS [2], which enabled us to sketch a detailed picture of the correlation of molecular and electronic structure changes, with concomitant onset of proton conductivity at higher temperatures. We thus could design experiments, where the proton-phonon coupling was quantitatively investigated with high pressure and high temperature impedance spectroscopy combined with quasi-elastic neutron scattering [3,4]. Supported by pressure dependent XRD and Raman scattering [5,6] we correlated the proton jumping parameters with the temperature and found that the proton jump times follow a polaron relation [Braun 2017] [7,8,9].

Lithium-Sulfur Batteries—The Next Frontier in Energy Storage
Nikhil Koratkar; Rensselaer Polytechnic Institute, Troy, New York, United States.

Lithium-sulfur (Li-S) batteries offer a theoretical energy density of ~2600 Wh/kg (compared to ~387 Wh/kg for Li-ion technology) and therefore offer great potential as a next generation energy storage device. However there are two major barriers to realization of high performance Li-S batteries: (1) poor cycle stability caused by dissolution of intermediate lithium polysulfides from the S cathode into the electrolyte and (2) nucleation and growth of dendritic structures on the Li metal anode, which can electrically short the battery. In this talk, I will discuss some possible solutions to these problems. Specifically, I will show that two-dimensional (2D) sheets of black phosphorous (i.e. phosphorene) are highly effective as a lithium polysulfide trapping agent. I will further show that the Li dendrite problem can be addressed by using self (Joule) heating to accelerate surface diffusion processes to heal (smoothen) the dendrites in situ. Such advances show potential in enabling the successfully deployment of Li-S batteries with breakthrough improvements in performance as compared to the incumbent Li-ion technology.

Rational Design and Synthesis of Nanostructured Hybrid Cathode Materials for Lithium-Sulfur Batteries
Yanglong Hou, Muhammad Asif and Zeehan Ali; Peking University, Beijing, China.

Lithium-sulfur batteries (LSBs), have been considered as promising power source for future electric vehicles (EVs) due to their high energy and power densities. Thus, many efforts have been made on new electrode materials that can bring the realization of these devices. Despite offering many fascinating advantages over conventional lithium-ion batteries (LIBs), such as low cost of sulfur, the safer operating voltage and in particular non-toxic nature, LSBs are facing numerous challenges, which are currently hindering LSBs from being a serious competitor to LIBs on commercial scale. Among the mainstream challenges, the polysulfide shuttle effect, insulating nature of sulfur, volume expansion, and self-discharge are very crucial factors which need to be resolved urgently to improve the electrochemical performance of LSBs. Moreover, structural disintegration,
limited access to redox sites and loss of electrical contact have long been identified as common reasons for capacity loss and poor cyclic life of these materials. Thus, rational design can inhibit the side reaction by surface protection, make all redox sites accessible by increasing the intrinsic conductivity of the active materials, maintain a continues cycle life of the battery and the charging algorithm will be adjusted accordingly, therefore making the charging algorithm adaptive. This type of charging should help reduce charging time for commercial lithium-ion batteries and also help improve the cycling life of the battery.

4:45 PM ES03.02.09
Microstructural Complexations in Extreme Fast Charging of Li-Ion Batteries Antarsho Mishry and Partha P. Mukherjee; Mechanical Engineering, Purdue University, West Lafayette, Indiana, United States.

Widespread acceptance for electric vehicles is deterred by (i) range anxiety and (ii) recharging time. To be competitive with conventional fuels, battery recharging time must be less than 10 min, which amounts to a very high charging rate (~6C). At such high rates (i.e., extreme fast charge, XFC), a host of anode centric issues arise, namely suboptimal charging capacity, self-heating, and irreversible plating losses. Fundamentally these observations are a result of sluggish kinetic and transport modes at the pore scale. Here in we analyze such complex physicochemical interactions for different commercial graphite electrodes (microstructures are obtained through tomography). Even though the porosity of these structures is spatially quite uniform, the pore and solid networks exhibit considerable variations, both within the sample and across electrodes. Based on these examinations, we outline the guidelines for improving the XFC response via appropriate scaling of structural features.

The Role of Interlayer Structural Water During Ion Intercalation in Crystalline Transition Metal Oxides

Brownmillerite (BM)-structured SrCoO\(_2\) oligomers backbone at the silicon surface is a key factor. Through these studies, we find that the formation of a robust nanostructure SEI made of a Li-ion conductive solid conductor oxide solid fuel cells (H-SOFC) by using Synchrotron Infrared Nanospectroscopy (SINS) and Ambient Pressure X-ray Photoelectron Spectroscopy (AP-XPS) at the Advanced Light Source.

To unravel the mechanism behind an effective Solid electrolyte interphases (SEI) layer on Si anode, we used the unparalleled spatial resolution and surface sensitivity of the near-field IR probe (ca. 20 nm) and chemical selectivity of SINS. We leverage the influence of LiBOB additive to shed lights on SEI’s crucial components and structure at a nanoscale level, which corresponds to the size of the SEI building blocks. Through these studies, we find that the formation of a robust nanostructure SEI made of a Li-ion conductive oligomers backbone at the silicon surface is a key factor.

We also examined proton and oxygen transport at the interface between a standard H-SOFC perovskite electrolyte (BaCe\(_{0.8}\)Zr\(_{0.2}\)O\(_{3-\delta}\)) and the fuel by using Synchrotron Infrared Nanospectroscopy (SINS) and Ambient Pressure X-ray Photoelectron Spectroscopy (AP-XPS).

In Situ Pressure X-ray Photoelectron Spectroscopy (AP-XPS) at the Advanced Light Source.

Performance of electrochemical systems is governed by ion transport through solid/liquid or solid/gas interfaces. Major breakthroughs are then intrinsically linked to a detailed understanding of how molecules, atoms, and electrons behave at these interfaces during operation. Recent progress in the development of ex situ and in situ characterization surface techniques using synchrotron radiation sources has enabled major scientific advancements toward this understanding. In this work, we studied interfacial processes in energy materials such as Li-ion systems or protonconductor oxide solid fuel cells (H-SOFC) by using Synchrotron Infrared Nanospectroscopy (SINS) and Ambient Pressure X-ray Photoelectron Spectroscopy (AP-XPS) at the Advanced Light Source.

It is increasingly recognized that extremely fast charging and discharging, along with long cyclability, will require energy storage materials that are able to respond with minimal mechanical deformation while at the same time storing significant amounts of energy. Our research shows that interlayer structural water in crystalline transition metal oxides appears to play an important role in mitigating the mechanical deformation during electrochemical ion intercalation in a class of model transition metal oxides, layered tungsten oxide hydrates. We investigated the electro-chemo-mechanics of proton intercalation into crystalline WO\(_3\) and crystalline, layered WO\(_3\)\(\bullet\)2H\(_2\)O using operando atomic force microscopy (AFM) dilatometry. The nanoscale deflections of the AFM tip were measured for both WO\(_3\) and WO\(_3\)\(\bullet\)2H\(_2\)O as a function of potential and cyclic voltammogram sweep rate for charge/discharge times on the order of minutes and seconds, pressing the extremes of fast charging and discharging of electrochemical energy storage materials.

Interfacial reaction of LCO in the aqueous electrolyte solution is still superficial however.

Here we present degradation phenomena of LCO electrode in aqueous medium using various X-ray measurement techniques, and suggest the solution to avoid such an irreversible electrochemical reaction. The aqueous solution was prepared with 0.5 M lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) and pH was controlled to ~6.8 and 10. In both cases, there was no evidence for the formation of cathode-electrolyte interphase (CEI) on LCO in contrast to the one with non-aqueous electrolyte solution. The direct contact of aqueous electrolyte solution to LCO surface results in the short-range disorder of LCO structure such as the distortion of octahedral CoO₆.

Since the risk of catch fire using nonelectrolyte aqueous solution, aqueous solution-based rechargeable lithium batteries (ARLB) have been highlighted. However, the conventional positive electrodes of lithium transition-metal oxide such as LiCoO₂ (LCO) and LiNi₀.₅Mn₀.₅O₂ (NMC) have suffered from poor cyclability in aqueous medium. Representatively, the layered two-dimensional structure of LCO shows notably poor stability, possibly due to the surface degradation from water and proton. The understanding of interfacial reaction of LCO in the aqueous electrolyte solution is still superficial however.

Representatively, the layered two-dimensional structure of LCO shows notably poor stability, possibly due to the surface degradation from water and proton. The understanding of interfacial reaction of LCO in the aqueous electrolyte solution is still superficial however.

Here we present degradation phenomena of LCO electrode in aqueous medium using various X-ray measurement techniques, and suggest the solution to avoid such an irreversible electrochemical reaction. The aqueous solution was prepared with 0.5 M lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) and pH was controlled to ~6.8 and 10. In both cases, there was no evidence for the formation of cathode-electrolyte interphase (CEI) on LCO in contrast to the one with non-aqueous electrolyte solution. The direct contact of aqueous electrolyte solution to LCO surface results in the short-range disorder of LCO structure such as the distortion of octahedral CoO₆.

Since the risk of catch fire using nonelectrolyte aqueous solution, aqueous solution-based rechargeable lithium batteries (ARLB) have been highlighted. However, the conventional positive electrodes of lithium transition-metal oxide such as LiCoO₂ (LCO) and LiNi₀.₅Mn₀.₅O₂ (NMC) have suffered from poor cyclability in aqueous medium. Representatively, the layered two-dimensional structure of LCO shows notably poor stability, possibly due to the surface degradation from water and proton. The understanding of interfacial reaction of LCO in the aqueous electrolyte solution is still superficial however.

batteries, achieving 80% state of charge in ten minutes. Next, we rationalize their high performance via cell-level simulations and electrode-level physical characterization. Our results reveal that loss of active material from the graphitic negative electrode is a significant source of degradation, preceding more conventional fast charging degradation modes such as lithium plating. We also identify a critical charge rate beyond which the loss of active material, and thus the overall cell degradation, accelerates. Finally, we study the rate of SEI growth during fast charging via electrochemical methods, identifying a strong dependence on the applied C rate. This work provides novel insight into optimizing and characterizing extreme battery fast charging for time-sensitive applications and suggests avenues to improve both charging times and lifetimes during aggressive battery operation.

High-Performance Electromechanical Device via Controlling Charge Injection Pham S. Nguyen1, Young-hun Seo1, Hong Chul Lim2, Haeun Lee1, Truong Khac Phu Cuong1, Ji-young Lee1 and Ik-Soo Shin1; 1Soongsil University, Seoul, Korea (the Republic of).

Here, we report in-depth study on basic principles of electrochemical devices (ECD) such as their structural design as well as operational method. Electrochemically deposited prussian blue (PB) and tungsten trioxide (WO3) thin films were employed as a working and counter electrode, respectively, and sandwich-type ECDs were fabricated using aqueous electrolyte. Electrochemical devices relying on interfacial charge-transfer and ion transport, normally suffer from a decline of its operational performance which is caused by irreversible redox reaction, ion accumulation or overvoltage at the solution/electrode interface, and it severely curtails the operational lifetime of the devices. After careful investigation of the redox properties of PB and WO3 films and their complementary ECDs, we found that by balancing the charge during on/off switching (regarding bleaching and coloration), the ECD could exhibit improved long-term stability with broad optical modulation and decent coloration efficiency (G.T < 1.7% over 2000 cycles) under mild operational voltage. We expect that the results provide a general overview of the operational conditions and structural design in ECD researches.

1:30 PM *ES03.04.01
Ion Transport and Electrochemistry in Battery Electrolytes Over Wide Range of Salt Concentrations Ole Borodin, Jenel Vatamanu, Travis Pollard and Kenneth W. Leither; U.S. Army Research Laboratory, Adelphi, Maryland, United States.

This presentation will focus on the molecular scale understanding of key factors influencing ion transport, electrochemical stability and decomposition in a wide range of aqueous and non-aqueous electrolytes as a function of salt concentration. No one simulation technique is capable of efficiently capturing all transport and electrochemical properties at interfaces. Therefore, we will utilize a combination of a) density functional theory (DFT) studies of the solvent reactions on cathode surfaces and at the solid electrolyte interphase (SEI) covering lithium metal; b) representative quantum chemistry (QC) calculations performed on the representative small model electrolyte clusters to estimate oxidation and reduction; c) molecular dynamics (MD) using APPLE&P polarizable force field to examine bulk and interfacial properties of electrolytes and electrochemical interfaces. Combined together, information from these modeling studies expands on the previous work and suggests numerous strategies for stabilizing the electrolyte – electrode interfaces for a number of aggressive high energy density cathodes combined coupled with graphite and metal anodes.

High Temperature vs High State-of-Charge—Optimizing the Triad of Energy Density, Cycling Rate and Lifetime Clement Bonniel1,2 and Daniel Steingart1,2,3; 1Mechanical and Aerospace Engineering, Princeton University, Princeton, New Jersey, United States; 2Andlinger Center for Energy and the Environment, Princeton University, Princeton, New Jersey, United States.

Enabling fast-charging capabilities in lithium-ion batteries (LIBs) is critical to the continued development of modern applications such as electric vehicles (EVs), unmanned robots, and grid-leveling applications. However, the current state-of-the-art in commercially available LIBs renders fast charging difficult, especially if energy density, and a long battery lifetime are also desired. While many researchers are currently looking for novel materials to alleviate this issue, this research takes a different approach: can we use currently available materials as an attractive alternative RFB technology because redox active organic molecule materials are synthetically tunable, sustainable, and potentially low cost. The presentation will highlight our research efforts in developing viologen anolyte materials for both anion and cation exchange AORFBs with a variety of catholyte materials including ferrocene, TEMPO, ferrocyanide, and halides. The viologen AORFBs demonstrated outstanding battery performance including a power density up to 120 mW/cm², energy efficiency up to 72% at 60 mAh/cm², and capacity retention up to 99.999% per cycle up to 1000 cycles, representing the state of the art organic RFBs. Particularly, the presentation emphasizes that fundamental understandings of redox active electrolytes at molecular level are crucial to develop new generations of redox flow batteries for large scale and dispatchable

Graphite Lithiation Under Fast Charging Conditions—Atomistic Modeling Insights Juan C. Garcia, Hakim Iddir and Dennis Dees; Argonne National Laboratory, Lemont, Illinois, United States.

The general public reception of electric vehicles (EV) depends, among other factors, on meeting their expectations of similar comfort compared to conventional vehicles. Replicate the convenience of filling a tank of fuel in minutes is a very challenging task when one has to recharge a Li-ion battery. The primary goal of a fast charging protocol must be avoiding Li plating in the anode and maintaining temperature under control. Hence, a deeper understanding of the thermodynamics and kinetics of the anode charging process is crucial to improve the models and subsequently the design of battery cells. In the present work, an atomistic level analysis of Li intercalation and diffusion in graphite have been performed under fast charging conditions. In this presentation, we will show and discuss the effect of fast charging conditions on the intercalation and diffusion mechanism of Li in graphite.

Aqueous Organic Redox Flow Batteries for Large-Scale and Dispatchable Energy Storage Bo Hu, Jian Luo, Camden Debruler, Maowei Hu, Wenda Wu and Tianbiao Liu; Utah State University, Logan, Utah, United States.

Redox flow batteries have several outstanding technological advantages over traditional static batteries (e.g. Li ion and Lead acids) for large scale energy storage including decoupled energy and power, safe energy storage, high current and powerful performance, and scalability. Recently, Aqueous organic redox flow batteries (AORFBs) have emerged as an attractive alternative RFB technology because redox active organic molecule materials are synthetically tunable, sustainable, and potentially low cost. The presentation will highlight our research efforts in developing viologen anolyte materials for both anion and cation exchange AORFBs with a variety of catholyte materials including ferrocene, TEMPO, ferrocyanide, and halides. We report the synthesis of MnVO$_3$ power density, high energy density, and improved charge/discharge rates. Significantly improve the supercapacitor’s performance is the nano-structuring of the electrode material, which considerably increases their surface area. Different morphologies of electrode materials include mesoporous carbon, metal-organic frameworks, and transition metal oxides (TMOs) with a perovskite structure. TMOs store charges electrochemically. Although TMOs are considered the ideal electrode materials for supercapacitors, their fast charge/discharge rates make them the perfect storing devices. However, supercapacitors still face obstacles such as low energy density, performance degradation, and high cost. The active materials of the supercapacitors’ electrodes determine the supercapacitor’s energy storage capacity and electrochemical performance. Accordingly, new materials are being researched every day for the purpose of enhancing the supercapacitor’s performance. Of the most extensively studied materials today are graphene, carbon nanotubes, and transition metal oxide nanofibers (TM OnF) with embedded metal oxide nanoparticles.

Design of Supercapacitors for Wide Temperature Operation

The world’s transition to sustainable energy has been largely accelerated from the transportation field. Thanks to the increasingly wide deployment of charging stations and government incentives, electric vehicles are seeing a fast growth in recent years. Most of them are completely or partially powered by Li-ion batteries, which store and distribute the energy whenever is the need for the operation of the vehicle. The battery pack consists of tens, hundreds, or thousands of individual cells, depending on the size (kWh) of the pack and cell as well as the form factor of the cell. As an EV start up, SF Motors is trying to produce the intelligent EV for everyone. One prominent feature of EV is their fast acceleration. A high power is delivered during fast acceleration, which requires the cell to be discharged at extreme high rates. Simultaneously, extensive heat is generated during fast acceleration, causing cells temperature increase and deteriorating electrochemical performance. For the same reason, the kinetics of the charging/discharging process are more favorable. Typical commercial devices are rated for operation between -40°C and +65°C, with temperature limits set by the nature of the electrolyte solvent. This talk will provide an update on efforts to expand beyond these temperature limits in symmetric devices through selection of suitable electrode/electrolyte materials. In addition, the potential for wider temperature operation in asymmetric cells featuring an intercalation electrode will be discussed.

Free-Standing Graphene Films Prepared via Foam Film Method for Impressive Performance Flexible Supercapacitors

MnVO$_3$/MnO@C Perovskite-like Binder-Free Electrospun Nanofibers as Excellent Electrodes for Supercapacitor Devices
Menna S. Said and Nageh K. Allam; The American University in Cairo, Cairo, Egypt.

Over the past decade, climate change resulted in clean energy being a primary focus in the scientific and industrial communities. With the depleting and polluting effects of fossil fuels rose the need for energy generation and storing technologies for renewable energy sources. The current commercial energy storing devices still face performance limitations, have high maintenance cost, and are not environment friendly. Electrochemical supercapacitors hold the potential of being the next generation of efficient and clean energy storing devices. Their fast charge/discharge rates make them the perfect storing devices. However, supercapacitors still face obstacles such as low energy density, performance degradation, and high cost. The active materials of the supercapacitors’ electrodes determine the supercapacitor’s energy storage capacity and electrochemical performance. Accordingly, new materials are being researched every day for the purpose of enhancing the supercapacitor’s performance. Of the most extensively studied materials today are transition metal oxides (TMOs) with a perovskite structure. TMOs store charges electrochemically. Although TMOs are considered the ideal electrode materials for supercapacitors, as they can provide both high specific capacitance and high energy density, they suffer from low conductivity and in result compromise the electrodes’ power density. Carbon based materials, on the other hand, are characterized by excellent electrical properties and high energy density. Thus, my research focuses on the synthesis of hybrid perovskite-based supercapacitors. Hybrid supercapacitors are those that combine electric double layer capacitor and pseudo-capacitor materials. The outcome should be sustainable, clean supercapacitor electrodes of high power density, high energy density, and improved charge/discharge rates.

We report the synthesis of MnVO$_3$/MnO@C perovskite-like nanofibers with embedded MnO nanoparticles of average diameter size of 400 nm. The electrospun MnVO$_3$/MnO@C electrodes achieve high specific capacitance of 1000 F/g at 5 A/g. A symmetric supercapacitor composed of MnVO$_3$/MnO@C shows an ultrahigh energy density of 23.8 Wh/kg at 5 A/g with a power density of 2500 W/kg. The device shows a superior volumetric energy density, cycle life, and capacity retention.

ES03.05.02
Free-Standing Graphene Films Prepared via Foam Film Method for Impressive Performance Flexible Supercapacitors
Zhu Yuecan and Chunyang Jia; School of Electronic Science and Engineering, University of Electronic Science and Technology of China, ChengDu, China.

Supercapacitor is regarded as the ideal power source in wearable electronic device, the electrode materials of which are always research focus due to it is a key component in the supercapacitor. Among numerous electrode materials, graphene has attracted significant attention for its outstanding electrochemical performance and mechanical properties, which endows graphene films with great potential of applications in future flexible electronics. Therefore, effective preparing methods of graphene films were researched and reported extensively in recent years. Herein, we fabricate a novel graphene oxide (GO) film with excellent mechanical properties via foam film method. Its thickness can be simply regulated by changing the concentration of the surfactant. After chemical reduction, the reduced GO (rGO) films exhibit impressive electrical conductivity of ~172 S cm$^{-1}$. The
supercapacitors based on the fabricated rGO films exhibit satisfied capacitive performance of ~56 mF cm⁻² at 0.2 mA cm⁻² with 6 M KOH solution. Furthermore, the flexible all-solid-state supercapacitors (FSSCs) based on the GO films also show great volumetric capacitance of ~2810 mF cm⁻³ at 12 mA cm⁻³ (~1607 mF cm⁻³ at 613 mA cm⁻³) with polyvinyl alcohol-KOH gel electrolyte, which indicates great rate performance of solid-state devices. Besides, the supercapacitor also show great cycling stability and flexibility: after 10000 cycles and continuously bent to 180° for 300 times, the volumetric capacitance of the FSSC remains at 81.4% and 90.4% of its initial capacitance value, respectively. All the results demonstrate the free-standing rGO films prepared via foam film method in this study could be considered as promising electrode materials for high performance flexible supercapacitors.

**ES03.05.03 Dynamic Processes in Si and Si/C Anodes in Lithium-Ion Batteries During Cycling**
Zheng-Guang Hu, Zhong Lin, Jun Chen, Ruiting Zheng and Guoan Cheng; Beijing Normal University, Beijing, China.

Si is one of the most attractive anode materials because of its extremely high theoretical capacity. In this study, we found that the (111) plane of crystalline Si in the anode is still present after 100 cycles and inferred that it is the intercalation site of Li⁺ ions. We believe that Li⁺ ions are inserted into the tetrahedral sites of crystalline Si, and the (111) plane of Si collapses and decomposes into piled crystallite lamellae; meanwhile, expansion parallel to (220) plane occurs. After full lithiation, the crystalline Si is converted to amorphous silicon. In a Si/ composite anode, although the addition of amorphous carbon improved the cycling performance of the Si anode, the activation process was prolonged as the amount of amorphous carbon increased. We determined that amorphous carbon may reduce the diffusion of Li⁺ ions, which increases the overpotential and results in the lower formation of the saturated Li/Si alloy.

**SESSION ES03.06: Flexible, Stretchable and Adaptive Energy Storage Devices for Versatile Applications**
Session Chairs: Hye Ryung Byon and Yuan Yang
Thursday Morning, April 25, 2019
PCC North, 100 Level, Room 126 B

8:00 AM **ES03.06.01 Flexible Nanocellulose Based Energy Storage Devices**
Zhaohui Wang, Petter Tammela, Ruijun Pan, Maria Stromme and Leif Nyholm; Uppsala University, Uppsala, Sweden.

The strong need for the development of inexpensive, flexible, lightweight and environmentally friendly energy storage devices has resulted in large interest in new cellulose-based electrode materials that can be used in batteries and supercapacitors.[1-3] In this presentation it will be shown that flexible nanocellulose and polypyrrole composites, manufactured by chemical polymerization of e.g. pyrrole on a nanocellulose substrate, can be used as electrodes in charge storage devices containing either water or organic solvent based electrolytes. The aqueous flexible paper-based devices exhibit high charge storage capacities (e.g. 9 Wh/kg) as well as excellent power capabilities (e.g. 3.5 kW/kg) due to the large surface area (up to 250 m²/g) of the nanocellulose and the thin (i.e. 50 nm) layer of polypyrrole present on the nanocellulose fibers. The straightforward (paper-making) composite synthesis approach and the electrochemical properties of the resulting composites will be discussed. It will also be shown that high active mass paper electrodes [4-8] with mass loadings of up to 20 mg/cm² can be employed at high current densities without significant loss of electrochemical performance as a result of the advantageous structure of the electrodes. Devices with unprecedented areal and volumetric cell capacitances (e.g. 5.7 F/cm² and 240 F/cm³) that can cycle for thousands of cycles in aqueous electrolytes can likewise be realized. As the cellulose composites also can be also be used in lithium-ion batteries [9,10], functional (e.g. redox-active) separators [11] for lithium based batteries and in the realization of all-cellulose energy storage devices [12], the present materials provide new exciting possibilities for the development of green and foldable devices for a range of new applications, many of which are incompatible with conventional batteries and supercapacitors.

8:30 AM **ES03.06.02 Extreme Environments for Electrochemical Energy Storage Materials—Inspiration Gained from Implantable Medical Devices**
Amy C. Marschik, Kenneth Takeuchi and Esther S. Takeuchi; Stony Brook University, Stony Brook, New York, United States.

Implantable biomedical applications represent demanding operating environments for electrochemical energy storage materials and systems providing a unique set of challenges for successful design and implementation of such devices. While the capacity and power requirements can vary significantly depending on the specific application, several common challenges become evident. Volumetric rather than gravimetric density is the key consideration. The power source must operate effectively under elevated operating temperature. Reliable function under varied use conditions is essential. Long lifetimes as well as predictive state of charge indicators are essential. Advanced interrogation methods, particularly in-situ and operando approaches, can provide important mechanistic information to elucidate the behavior of the energy storage material. However, it is challenging yet important to design experiments which interrogate the system under application relevant conditions. Progress in investigation of energy storage materials for biomedical applications will be highlighted in this presentation, providing inspiration for design of new electrochemical energy storage solutions for a broad array of demanding applications.

9:00 AM **ES03.06.03 Strain Regulation of Editable Devices for Stretchable Supercapacitors**
Zhisheng Ly and Xiaodong Chen; Nanyang Technological University, Singapore, Singapore.

The ever-growing demands for stretchable electronics in applications of electronic textiles, electronic skins, and wearable health monitors, require concerted stretchability in energy storage devices. As one of the main energy supplies for stretchable and wearable electronics, stretchable supercapacitors are drawing increasing attention in recent years owing to their superior power density and long calendar life under deformation. Although some progress has been made on stretchable supercapacitors, traditional stretchable supercapacitors fabricated by predesigning structured electrodes for device assembling still lack the device-level editability and programmability. To adapt to wearable electronics with arbitrary configurations, it is highly desirable to develop editable supercapacitors that can be directly transferred into customizable shapes and stretchable structure according to application scenarios. Herein, we proposed an editable strategy to fabricate stretchable supercapacitors for regulation of the strain on the electrodes. The editable supercapacitors with customizable structures can regulate the peak strain of the electrodes below the fracture of the electrode materials, which enables a wider range of electrode materials for stretchable supercapacitors. The mechanically reinforced flexible electrode materials for the editable supercapacitors further guarantee the editable process and improve the mechanical stability of customizable devices. Editable supercapacitors for customizable shapes and stretchability using electrodes based on mechanically strengthened ultralight MnO₂ nanowire composites are developed. A supercapacitor edited with honeycomb-like structure shows a specific capacitance of 227.2 mF cm⁻² and can be stretched up to 500% without degradation of electrochemical performance. Taking advantages of these superior properties, the editable supercapacitors are integrated with a strain sensor, and the system exhibits a stable sensing performance even under arm swing. Besides, based on flexible porous polypyrrole composite electrodes, the supercapacitor arrays rearranged into an
expandable honeycomb structure can be further used to fabricate three-dimensional (3D) stretchable supercapacitors with customizable 3D shapes and enhanced areal energy storage performance. Being highly stretchable, easily programmable, as well as connectable in series and parallel, the stretchable supercapacitor with customizable stretchability and shapes is promising to produce efficient energy storage devices to power various portable, stretchable, and wearable devices. Our efficient design strategy provides a new design platform for the electrode materials in the customizable and stretchable electrochemical energy storage devices. Based on it, many other new methods and stretchable electronics could be further developed.

9:15 AM ES03.06.04 Ultra-Extendable Supercapacitors Consisting of Plied and Supercoiled Fibers Changsoon Choi; DGIST, Daegu, Korea (the Republic of).

The demand of stretchable electrochemical energy storage devices that can operate under extreme environments are growing in various aspects of the society requirements. Here, we report on fiber based highly stretchable supercapacitors comprising of nine supercoiled fiber electrodes and quasi-solid-state electrolyte. Each supercoiled fiber was fabricated by inserting a giant twist to supercoiling (coiling of a coiled fiber) a spandex fiber that is helically wrapped by forest-drawn carbon nanotube sheets. Plying these supercoiled fibers enables lower internal resistance, thereby resulting in improved rate-capability (54% retention of maximum capacitance at 1000mV/s scan rate) as well as high areal capacitance (4.23 mF/cm²). Moreover, the nine plied, supercoiled fiber based supercapacitors exhibited ultra-high stretchability in tensile direction (ε = 600%), while conserving 93% of initial capacitance during the reversible stretching. The new structured supercapacitors are posed for energy storage system with special electrochemical and mechanical properties that can work in extreme environments.

9:30 AM ES03.06.05 mm-Thick Soft Hybrid Scaffolds Enabling Wearable Supercapacitors with Ultra-High Energy and Power Densities Jian Shang and Zijian Zheng; Institute of Textiles and Clothing, The Hong Kong Polytechnic University, Hong Kong, China.

The increasing power and energy demand for wearable electronics greatly stimulates the development of wearable energy storage devices with excellent flexibility, robust mechanical property and outstanding energy density. To power the wearable devices in a safe and cost-effective way, fabric-based flexible SCs have attracted intensive attention in both academical and industrial fields due to its significantly mechanical property and inherently safety. However, one major limiting factor regarding the practical application of fabric-based flexible SCs is insufficient areal energy density. The average areal energy density of wearable SCs is only in the range of 0.01 ~ 0.1 mWh cm⁻², which requires hundreds to thousands of square centimeters of SCs to powerly common used wearable devices, such as LED garments, wearable medical care devices and flexible displays.

Therefore, considering the limited surface area of a human body (~ 2 m²), the tremendous challenge for powering future wearable electronics lies on rational fabric-based flexible SCs design for robust areal energy density with prominent wear-ability properties, such as flexible, tailorable, waterproof and fire-retardant.

In this study, we report a new electrochemical fabrication preparation method to fabricate thick and high mass-loading hybrid electrode with superior conductivity and excellent ion diffusion property through successively filtering fresh mixture 1D core-shell pseudo-type materials and 2D rHGO nanosheets on carbon cloth to form a 3D soft hybrid scaffold. By using the afore-mentioned electrode fabrication method, we herein demonstrate the preparation of soft 3D scaffold electrodes with controllable mass loading, increasing from 5 mg cm⁻² to more than 30 mg cm⁻². After cathode and anode pairing and simple vacuum encapsulation, we assemble the 3D soft hybrid scaffold-like electrodes into all-solid-state flexible SCs with ultrahigh mass loading of 68 mg cm⁻² and thickness of 1.05 mm, which delivers a remarkable areal energy density of 1.05 mWh cm⁻² at a power density of 17.07mW cm⁻², along with high electrochemical life (91% retention after 3000 charge/discharge cycles). More importantly, the hybrid 3D scaffolds SC shows outstanding wear-ability properties: excellent mechanical flexibility (only 25% capacitive decay after 4000 bending tests), water-proof property (negligible capacitive decay after immersing in 20 cm deep water for 48 hours), fire-retardant ability (non-combustion-supporting even under butane flame thrower for 34 s) and tailor-abilities, which are critical for wearable applications.

9:45 AM BREAK

10:15 AM *ES03.06.06 UV-Cured Gel Polymer Electrolytes for Advanced Aqueous Li-Ion Batteries Konstantinos Gerasopoulos; Research and Exploratory Development Department, Johns Hopkins University, Laurel, Maryland, United States.

Li-ion batteries are the energy storage source of choice for rechargeable electronics applications due to their high energy density and long cycle life. Despite these benefits, Li-ion batteries suffer from safety concerns associated with the flammable organic solvents that are needed to maintain the high voltage window in the electrolyte. Water emerges as a natural, inherently safe alternative solvent. Its low electrochemical stability window of ~1.23 V limits the available energy density and cycle life of aqueous Li-ion batteries. Recent innovations in aqueous Li-ion batteries have introduced a new class of aqueous electrolytes termed as “water-in-salt” (WiS). In WiS electrolytes, a highly concentrated salt (>21 m) such as LiTFSI is typically used in water. At such high concentrations, water is bound and its electrochemical activity for gas generation is suppressed, extending the electrochemical stability to > 3.0 V.

In this work, significant advancements in WiS electrolytes are discussed, specifically through the incorporation of the WiS in a polymer matrix. When the liquid WiS is combined with a polymer, the need for a separator is eliminated and new form factors with minimal packaging can be realized. Using a high molecular weight polyvinyl alcohol (PVA)-based Gel Polymer Electrolyte (GPE) containing water-in-bisalt (WiBS), a flexible symmetric cell with LiVOPO₄F anode/cathode was built. This cell exhibited long cycle life (4000 cycles) at a 20C rate and continued to operate even after sustaining mechanical damage, such as cutting and exposure to air, immersion in salt water, and subjection to ballistic impact. The GPE properties can be dramatically enhanced when the high molecular weight polymers are replaced by UV cured acrylates. Using a combination of various acrylate monomers, cross-linkers, and photoinitiators, aqueous UV cured GPEs can be fabricated in fully aerobic/ambient conditions in less than 10 minutes with excellent control over thickness and mechanical properties. In addition to simplifying manufacturing, this approach significantly improves electrochemical performance as the UV cured GPEs exhibit an expanded electrochemical stability window (5.0 V) while maintaining ionic conductivity >1 mS/cm and enabled the use of Li₂Ti₃O₁₂ (LTO) as an anode. To further increase cycle stability and Coulombic efficiency, the UV cured GPE can be combined with a dry polymer electrode passivation. This passivation layer, which can be cast or UV cured, further suppresses hydrogen evolution on the anode and expands the stability of LTO-based cells to > 200 cycles at 2C rate. This UV cured passivation concept can be combined with previously demonstrated passivation strategies on graphite to extend the cyclic stability of “4.0 V aqueous Li-ion batteries” to >100 cycles. Finally, in addition to its use in the GPE and passivation layers, acrylate chemistry can also be used to replace the PVDF binder that is typically used in Li-ion batteries. Using a novel cross-linking approach, acrylate binders can be incorporated in battery electrodes with loadings as high as 90%, exhibiting comparable performance to those made with PVDF.

10:45 AM *ES03.06.07 Li-Ion Capacitors with Long Cycle Life and Wide Temperature Range for Military and Space Applications Jim P. Zheng; Electrical and Computer Engineering, Florida State University, Tallahassee, Florida, United States.

As a new generation of supercapacitor, the Li-ion capacitor (LIC) is an advanced energy storage device which consists of an electric double-layer capacitor (EDLC) cathode and a pre-lithiated anode [1], between which the ions shuttle during charge and discharge processes. Because of using pre-lithiated and low surface anode materials, the LIC can be charged to a maximum voltage as high as 4.0 V, which is much higher than that of traditional EDLC. The LIC cell not only retains all the advantages of EDLC such as high specific power (>10 kW/kg and long cycle life >100,000 cycles), but also exhibits a higher specific energy of 15-22 Wh/kg and a higher maximum cell voltage than that of the EDLC [2].

In addition to high specific power and long cycle life, we have also developed new electrolytes for LICs and compared performance of the LICs at various temperatures from 70 to -60 °C. The effects of charging temperature and negative electrode material on the low temperature performance of LICs are also studied [3].

Because of electrodes’ potentials of LIC are comparable to that of Li-ion batteries (LIBs), it allows the LIC and LIB to be assembled in one package as a LIB/LIC hybrid energy storage cell. In this talk, we will also demonstrate a new hybrid energy storage source which combines LIC and LIB. The fundamental difference between the proposed hybrid energy storage supercapacitor and the previous hybrid device (LIC) is that the new hybrid energy storage technology integrates two separate energy storage devices into one by synergistically combining battery and capacitor materials together to form positive (or cathode) and negative (or anode) composite electrodes, and it is rightly named as the “Internal Hybrid” energy source. This new hybrid energy storage device will not require any electric circuits for charge balancing and control. The overall internal hybrid system will be simple, light, compact, and cost effective when compared with the conventional (external) hybrid energy storage source.

Li-ion capacitors (LICs) and Hybrid LICs (H-LICs) are hybrid battery-capacitor energy storage devices that have been proposed as suitable alternative high-power power source technologies for operation in extreme environments with prolonged cycle-life performance. The LICs can accommodate both the non-faradaic (i.e., ion adsorption/desorption) and the faradaic (i.e., Li-ion insertion/extraction) processes of electrochemical double-layer capacitors (EDLCs) and lithium-ion batteries (LIBs) at the same time, respectively. The advantages of the hybrid LIC device includes higher power density and longer cycle life than a LIB and higher energy density than an EDLC. Recently, hybrid composite cathodes that combine capacitor and battery materials have shown promise for enhanced energy/power performance and extended life-cycle. The LICs were assembled as three-layered pouch cells in an asymmetric configuration employing Faradaic pre-lithiated hard carbon anodes and non-Faradaic ion adsorption-desorption activated carbon (AC) cathodes for LICs and lithium iron phosphate (LiFePO₄-LFP)/AC composite cathodes for H-LICs. The room temperature rate performance was evaluated after the initial LIC and H-LIC cell formation as a function of the electrolyte additives. The capacity retention was measured after charging at high temperature conditions, while the design factor explored was electrolyte additive formulation, with a focus on their stability.

References:
Recently, calcium-ion batteries (CIBs) have received attention as one of the post LIBs. The abundance of calcium resources can make CIBs cost effective. Calcium has a standard reduction potential of 0.17 V above lithium ($E^\circ = -2.869$ V vs. SHE for Ca/Ca$^{2+}$) that makes CIBs capable of a higher energy density compared to other multivalent ions such as magnesium, aluminum, and zine. In addition, calcium ion has a lower charge density than other multivalent ions, which may lead to relatively faster diffusion in a host material. 

Recently, Palacin et al. reported the feasibility of calcium plating and stripping using conventional organic electrolytes at elevated temperatures. To use calcium metal as a negative electrode in a cell, suitable cathode materials that store calcium ions are required. However, only a few cathode materials are reported so far to show electrochemical activity in calcium-containing electrolytes, such as V$_2$O$_5$, CaCo$_2$O$_4$, WO$_3$, and Prussian-blue analogues. 

In this presentation, some exploratory experimental results of electrochemical intercalation chemistry of divalent calcium ions will be presented with several host materials in aqueous electrolytes as well as non-aqueous electrolytes.

**Sb$_2$Te$_3$/CNT Composite Anodes for High Performance Sodium Ion Full Cells with Exceptional Energy and Power Densities**

Muhammad Ihsan Ul Haq, Jiang Cui, Baoling Huang and Jang-Kyo Kim; Department of Mechanical and Aerospace Engineering, The Hong Kong University of Science and Technology, Hong Kong, Hong Kong.

Sodium ion batteries (SIBs) are an ideal alternative to lithium ion batteries for grid-level energy storage systems due to the low cost and abundance of Na precursors. The elements, such as SnO$_2$, Sb$_2$S$_3$, and SnS$_2$, undergoing the conversion and alloying reactions with Na hold great promise for high energy density SIBs. However, their large volume changes and low electrical conductivities lead to poor electrochemical performance and sluggish sodiation kinetics. In this work, we report the Na storage performance of a 3D topological insulator (TI), Sb$_2$Te$_3$ phase, and its composites with carbon nanotubes (CNTs) synthesized through a facile, low cost and scalable high-energy ball-milling (HEBM) approach. The composite electrodes exhibit an excellent reversible gravimetric and volumetric capacities of 422 mAh g$^{-1}$ and 1232 mA h cm$^{-3}$, respectively, at a current density of 100 mA g$^{-1}$ with ~97.5% capacity retention after 300 cycles. The roles of HEBM to introduce the Sb-C, Te-C, Sb-O-C and Te-O-C chemical bonds between Sb, Te and functional groups on CNTs are elucidated by combined XPS characterization and the first-principles calculations. Ex-situ TEM analysis reveals the formation of Na$_2$Te and Na$_2$Sb phases after the first sodiation, which are re-combined into Sb$_2$Te$_3$ after the first desodiation, supporting the reversible phase transitions in the composite electrodes. For practical application, the electrochemical performance of a sodium ion full cell (SIFC) consisting of an Sb$_2$Te$_3$/CNT anode and a Na$_3$V$_2$(PO$_4$)$_3$F$_2$ cathode is evaluated. The SIFC delivers a remarkable energy density of ~229 Wh kg$^{-1}$ at 0.5 C and excellent cyclic stability of more than 71% and 66% capacity retention at 5 C and 10 C, respectively, after 200 cycles. Even after fully charged at 40 C in 90 seconds, the SIFC presents an ultrahigh power density of 5384 W kg$^{-1}$. These findings may shed new insight into exploring the unique class of TI quantum materials as anodes for high performance SIFCs.

**Developments of Lithium-Ion Conductors with the LGPS Type for All-Solid-State Batteries**

Ryoji Kanno, Masashi Hori, Kota Suzuki and Masaaki Hirayama; Tokyo Institute of Technology, Yokohama, Japan.

The all-solid-state lithium battery offers an attractive option owing to their potential in improving the safety and achieving both high power and high energy densities. Among the lithium ion conductors proposed for the solid electrolytes, the sulphide LGPS (Li$_x$(GeP$_2$)$_2$) type system is a candidate because of its extreme high bulk ionic conductivity of over 10$^{-5}$ S cm$^{-1}$ at room temperature. To provide the electrolytes suitable for practical usage of the solid-state battery, electrochemical and chemical stabilities are important parameters besides the ionic conductivity. Composition variety of the LGPS type materials provide suitable combinations of the electrodes and the electrolyte. By the host compositions of Li$_x$(GeP$_2$)$_2$, various cation and anion substitutions were examined, and their structures, conduction mechanism and chemical/electrochemical stability will be discussed.

11:00 AM *ES04.01.02*

**Key Parameters for Solid Electrolytes—Learnings from Beta-Alumina and Future Opportunities**

M. Stanley Whittingham; State University of New York at Binghamton, Binghamton, New York, United States.

In the period 1967-1975, substituted beta aluminas [MAl$_2$O$_4$] were the subject of extensive study. These studies identified several key parameters that control the ionic conductivity of such ions as Na$^+$, Ag$^+$, Cu$^+$, Li$^+$, K$^+$, and NO$_3^-$ These parameters include the ionic size, the lattice spacing (diffusion path size), the defect concentration, defect type and diffusion mechanism. Later, similar studies on the WO$_3$, MoO$_3$, TiO$_2$ and VOPO$_4$ materials, all of which exist in several different structures with varying molar volumes, show the criticality of matching the diffusion path size to the mobile cation. The learnings from these studies will be described.
Solid state batteries with alkali metal anodes promise to deliver higher energy densities than conventional Li-ion batteries. However, alkali metal dendrite growth, even at modest rates and even when paired with dense, well-sintered solid electrolytes, leads to short circuits and cell failure. We have investigated the effect of cycling conditions on the formation of dendrites under controlled applied pressure. The results reveal the significance of plating/stripping current densities on cell failure. These results and their implications for the operation of a failure free all-solid-state battery will be discussed.

Cooperative Ion Migration in Li-Ion Conducting Glasses
Donald Siegel and Jeffrey Smith; University of Michigan, Ann Arbor, Michigan, United States.

Sulfur-based glasses have reemerged as promising candidates for use as solid electrolytes in Li-based batteries. Nevertheless, due to their amorphous structure, the ion migration mechanisms that underlie their high Li-ion conductivity remain poorly understood. The present study employs ab initio molecular dynamics to reveal the local structure and migration mechanisms in the prototypical Li-ion conducting glass, 0.75 Li$_2$S - 0.25 P$_2$S$_5$. A computational model of the amorphous structure was generated, and is shown to closely match the measured neutron weighted pair distribution. The structure data indicates that Li-ions experience a range of coordination environments, with typical Li-S coordination numbers between 3 to 5. Lithium is observed to migrate via correlated, 'string-like' events involving multiple adjacent cations. Furthermore, these migration events involve the dynamic participation of the PS$_4$ions, which undergo simultaneous rotation and translational displacements. This behavior contrasts with that of the Li$_2$PS$_5$crystalline analogue, were rotations and translations of the anions during migration events are severely limited. These observations provide direct evidence of the importance of anion dynamics on cation mobility in fast ion conductors.

Simultaneous Topographical and Electrochemical Mapping Using Scanning Ion Conductance Microscopy – Scanning Electrochemical Micoscopy (SICM-SECM)
Wening Shi, Gabriela Mendoza, Byong Kim and Keibock Lee; Park Systems, Santa Clara, Mexico.

Since the inception of scanning tunneling microscopy [1], electrochemists have sought to take advantage of scanned probe microscopy techniques to manipulate the spatial position of a probe with high resolution to facilitate simultaneous high resolution topographical, conductometric, and amperometric/voltammetric imaging of surface and interfaces. Lately, scanning ion conductance microscopy (SICM) [2], has emerged as a versatile non-contact imaging tool and been employed for a variety of applications. SICM has been used to investigate the surface topography of both synthetic and biological membranes, ion transport through porous materials, dynamic properties of living cells, and suspended artificial black lipid membranes. In addition, integration of complementary techniques with SICM has led to many exciting new applications, including scanning near-field optical microscopy and patch-clamping [3]. Powerful as it is, SICM remains insensitive to electrochemical properties, or, in other word, SICM is inherently chemically-blind and has no chemical specificity.

To obtain spatially-resolved electrochemical information, scanning electrochemical microscopy (SECM), also known as the chemical microscope, has been developed. SECM has been widely employed to examine localized electrochemical properties and reactivity of various materials/interfaces, such as electrode surfaces and interfaces, membranes [4], and biological systems. Despite its many applications, SECM, however, lacks reliable probe-sample distance control, and the probe is usually kept at a constant height during conventional SICM scanning. As a result, any variation in surface topography will result in changes in probe-sample distance, and thus leading to convolution to the measured faradaic current, which will complicate the subsequent data interpretation [4]. To address the above-mentioned issues for SICM and SECM, hybrid SICM-SECM techniques have been developed, in which the SICM compartment provides the accurate probe-sample distance control, while the SECM compartment measures the faradaic current for electrochemical information collection.

In this work, we demonstrate the use of an AFM (Park NX10) in combination with an ammeter for concurrent topography imaging and electrochemical mapping. The SICM-SECM probe utilized here consisted of a Au crescent electrode (AuE) on the peripheral of a nanopipette. High resolution probe-substrate distance control was obtained by the ion current feedback from SICM, while simultaneous electrochemical signal collection was achieved via the AuE from SECM. As a proof-of-concept experiment, a Au/Pyre pattern standard sample was imaged with the SICM-SECM technique. The Au bar and the Pyrex substrate were clearly resolved from the SICM topography image, with the bar height and pitch width closely matching the actual values. In terms of the electrochemical property mapping, higher Faradaic current was seen when the probe was scanned over Au bar as a result of redox cycling, while lower Faradaic current was observed when the probe was over the Pyrex substrate due to hindered diffusion. The capability of the SICM-SECM technique described here holds promise of many exciting applications in the field of electrochemistry, material science and battery research.

Raman Crystallography of Superionic AgI Reveals a Connection Between Anharmonicity and Ionic Conductivity
Thomas M. Brennessl1, Christian Gehrmann2, Arun K. Sagotra3, Claudio Cazorla4, David A. Egger5 and Omer Yaffe1; 1Materials & Interfaces, Weizmann Institute of Science, Rehovot, Israel; 2Institute of Theoretical Physics, Universität Regensburg, Regensburg, Germany; 3School of Materials Science and Engineering, University of New South Wales, Sydney, New South Wales, Australia.

Basic understanding of ionic conductivity is critical to the development of new and technologically strategic solid electrolytes. Ionic conduction is fundamentally rooted in transforming vibrational thermal energy into diffusive atomic motion. While methods such as molecular dynamics (MD) can simulate the process accurately computationally, understanding of the process remains rooted in models employing either a harmonic vibrational or quasi-liquid model of the mobile ion. We propose to develop a model of ionic conductivity through the lens of anharmonic lattice dynamics. As a prototypical case we consider superionic AgI, with Ag conductivity > 1 S/cm at 150°C and activation energy of ~0.1 eV. While the Raman spectrum of this material has been studied for decades, using Raman crystallography at low wavenumbers we reveal a novel picture of vibrational motion in superionic AgI: The Raman spectrum in the superionic phase at 170°C is dominated by two first-order modes of symmetry E$_g$ and T$_{2g}$ and a central peak arising from motion with no restoring force. The mode symmetries confirm the accepted structural model of Ag occupying tetrahedral sites and indicate that mobile Ag participates in these modes. The very low phonon lifetimes (~100 fs) of the observed modes and pronounced central peak indicate the presence of strong anharmonicity. The vibrational power spectrum from MD simulations indicates that Ag motion contributes strongly to the observed central peak, and that both I and Ag display strong motion at the frequencies of the observed modes. From these results we hypothesize that anharmonic nuclear motion of both the mobile ion and host lattice is an important factor in ionic conductivity, and possible mechanisms will be discussed.

Mesoscopic Modeling of Microstructural Effects on the Effective Ionic Diffusivity of Solid Electrolytes for All-Solid-State Li Batteries
Tae Wook Heo1, Bo Wang2, Andrew Grieder3, Nicole Adelstein2 and Brandon Wood2; 1Lawrence Livermore National Laboratory, Livermore, California, United States; 2The Pennsylvania State University, University Park, Pennsylvania, United States; 3San Francisco State University, San Francisco, California, United States.
The ion transport kinetics in solid electrolytes is believed to be highly sensitive to the topological characteristics of ion conduction pathways. The conduction mechanisms usually involve concurrent ionic diffusion along a variety of mesoscopic features of internal microstructures such as bulk grain, structural domains, and associated boundaries as well as their network. In addition, inhomogeneous elastic interactions within the electrolyte microstructures are non-trivially coupled with ionic diffusion mechanisms. Due to the complexity of these structural features of the solid electrolytes during operation, it is significantly challenging to experimentally characterize the microstructure-ionic diffusion property relationship for better mechanistic understanding of relevant conduction mechanisms, it is necessary to thoroughly explore the impacts of individual microstructural factors on the overall kinetic properties and performances. In this talk, we will present our development of an efficient mesoscopic computational method for extracting the effective diffusivity of the solid electrolyte containing arbitrarily distributed microstructural inhomogeneities (e.g., differently oriented multiple grains, several structural variants of phase domains, and grain/domain boundaries) and their elastic interactions with Li conduction. Using three-dimensional digital microstructures generated by phase-field simulations as well as the fundamental diffusivity tensors of reference phases and boundaries derived from atomistic calculations as inputs, the developed method enables us to efficiently compute the effective ionic diffusivity tensor of the entire system. We will then discuss the applications of this framework to investigating the relationship between relevant individual microstructural features and effective diffusivity of highly conductive solid electrolytes (e.g., LLTO and LLZO) focusing on the impacts of topological features of grains, internal mesoscopic structures of high- and low-temperature phase domains, and grain phase boundary networks.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

3:15 PM ES04.02.05 Toward Room Temperature Solid State Fluoride Ion Batteries Ani Reddy Munnangi1, Irshad Mohammad1,2 and Maximilian Fichtner1; Helmholtz Institute Ulm (HIU), Ulm, Germany; Tallinn University of Technology, Tallinn, Estonia.

Lithium is an ideal metal to build high energy density batteries owing to its elemental properties. Lithium is highly electropositive (-3.04 V vs SHE), lightweight, monovalent and small ionic radius consequently it possesses high charge density and high mobility. On the other hand, fluorine is highly electromotive (+2.84 V vs SHE), relatively low weight, small in size and monovalent, high charge density and mobility is similar to lithium ions. However, fluorine is a corrosive and toxic gas, which forbid it as one of the electrodes. Nevertheless, fluoride ions can be transported between a metal and a metal fluoride through a fluoride transporting electrolyte, and fluoride-ion batteries (FIB) can be realized [1]. FIB offers high specific energy, high density, thermal stability, and safety. Despite the advantages posed by the FIBs, several challenges need to be addressed to realize its full potential. We have been working on various aspects related to FIB with the aim of developing sustainable fluoride ion batteries [2-4]. So far rechargeable FIBs have been demonstrated only at an elevated temperature like 150 °C and above. Recently, for the first time, we demonstrate room-temperature (RT) rechargeable fluoride-ion batteries using BaSnF$_6$ as fluoride transporting solid electrolyte [5]. BaSnF$_6$ shows high fluoride conductivity (3.5 × 10$^{-6}$ S cm$^{-1}$), but limited electrochemical stability. To be compatible with BaSnF$_6$, we have utilized low electropositive Sn, Zn as anode materials. However, to enable cells with high operating potentials, the electrolyte should be compatible with highly electropositive metals (e.g., Mg, Ce). Towards this, we developed a new interlayer electrolyte that is compatible with highly electropositive metals like Ce and Mg [6]. Further, utilizing the interlayer electrolyte, we demonstrate the operation of first open high potential RT FIB.

3:30 PM ES04.02.06 The Effect of La-Site Dopants on the Microstructure and Ionic Conductivity of the Garnet-Type Li$_{1-x}$M$_{x}$ZrO$_3$ (M=Sm, Dy, Gd, Er, Yb; x=0-0.1-0.1.0) Solid Electrolyte Musah Abdulai, Kamil Burak Dermenci and Servet Turan; Materials Science and Engineering, Eskisehir Technical University, Eskisehir, Turkey.

Solid-state electrolytes are attracting more interest in battery technology due to the recent safety issue brought by the liquid type electrolytes such as flammability, toxicity etc. In recent years, lithium lanthanum zirconium (LLZO) is one of the solid electrolytes which has received attention due to the presence of wide chemical stability window, stability with lithium metal and high ionic conductivity at room temperature. The LLZO has two crystal phase, the stable phase which is the tetragonal and the cubic phase, the unstable phase. The attainment of the cubic phase which has the highest ionic conductivity is challenging as it required higher sintering temperature and dopants. The stabilization of garnet-type LLZO solid-state electrolyte in a cubic phase with appropriate dopants has become essential since they reduced the sintering temperature, sintering time and improved lithium ion conductivity. However, not much data has been reported regarding the role of Lanthanide series elements at the La-site on cubic phase stabilization of LLZO. In the present work, a solid-state electrolyte for the composition Li$_{1-x}$M$_{x}$ZrO$_3$ (M=Sm$_y$, Dy$_{1-y}$Er$_{1-x}$Yb$_x$; x=0-1.0-8) has been synthesized through the solid-state method. High-quality oxide powders were prepared. A stoichiometric weighed quantities of the starting powders were ground and calcined at 1000°C for 10 hours. The calcined powders were pressed into pellets and cold isostatically pressed at 265 MPa. They are sintered in air at 1200°C for 12-18 H using powder bed method. A critical investigation carried out by X-ray powder diffraction and refinement analysis revealed the synthesis of pure cubic LLZO phase. The solubility content of selected ions decreased with smaller size ions. The densities measured by using the famous Archimedes method increases as the ionic content in the garnet framework increased. Pellets having relative densities ranging from 73 g/cm$^3$ to 98g/cm$^3$ out of the theoretical density of LLZO (5.1 g/cm$^3$) were produced. The lattice parameter determined by both the analytical and the refinement technique obey the so-called Vegard’s law. However, the Yb$^{3+}$ exhibits a marginal slope due to the shrinkage that occurred. The SEM images indicate the reduction of porous microstructure with an increase in ionic contents which is consistent with the measured density values. EDS analysis confirmed the presence of the mentioned ions at this content. Lastly, the smaller ionic radius ions were observed to produced higher ionic conductivity of the garnet-type solid electrolyte.

3:45 PM ES04.02.07 Correlation Between the Activation Energy and Pre-Exponential Factor in Solid-State Li-Ion Conductors Sokisela Muy1, John C. Bachman2 and Yang Shao-Horn1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Mechanical Engineering, California State University, Los Angeles, Los Angeles, California, United States.

The correlation between the pre-exponential factor and the activation energy in the Arrhenius equation, variously known as compensation law or Meyer-Neldel rule, is ubiquitous in almost all physical/chemical systems whose kinetic is thermally activated. In this talk, we focus specifically on the origin of Meyer-Neldel rule observed in solid-state Li-ion conductors by systematically investigating the ionic conductivity in the model system Li$_x$PO$_4$-Li$_{2-x}$VO$_3$-Li$_2$GeO$_3$. We found that the activation energies and pre-exponential factors exhibit a strong correlation as expected from Meyer-Neldel rule. However, the series of compound with and without partial lithium occupancy were shown to fall into two distinct lines with a similar evolution with melt temperature, entropy theory, we were able to relate the slope to the inverse of the energy scale associated with phonon in the systems and the intertest to the Gibbs free energy of defect formation. Compiled data of pre-exponential factor and activation energy for commonly studied Li-ion conductors shows that this correlation is very general, implying an unfavorable trade-off between high pre-exponential factor and low activation energy needed to achieve high ionic conductivity. Understanding the circumstances under which this correlation can be violated might provide a new opportunity to further increase the ionic conductivity in Li-ion conductors.

4:00 PM ES04.02.08 Strain-Induced Effect on Defect Formation in Cubic Li$_{1-x}$A$_x$La$_{2}$ZrO$_6$: Solid Electrolyte Ashkan Moradabadi1,2 and Payam Kaghazchi3; 1Physikalische und Theoretische Chemie, Freie Universität Berlin, Berlin, Germany; 2Material Science, Technical University of Darmstadt, Darmstadt, Germany.

Rate performance of all-solid-state batteries (ASSB) depends strongly on the structure of electrolyte/electrode interfaces.

This page includes text that is not formatted as a block of text. The text is scattered and does not form a coherent natural text representation. The content appears to be a mix of headings, references, and possibly other types of text that are not clearly legible or organized in a standard manner. This makes it difficult to extract a coherent and readable representation of the document's content. The text includes references to various research papers and authors, indicating a focus on materials science and battery technology. The content seems to be discussing the synthesis, properties, and applications of solid-state electrolytes, particularly those based on lithium, and their use in battery systems. The pages contain references to specific studies, methodologies, and experimental results, which are typical of scientific or technical literature. However, due to the formatting issues, it is challenging to provide a clear and readable text representation without further context or clarification.
Lattice-mismatch-induced interfacial strain is an important parameter to control conductivity and thereby the rate performance of ASSB. In the present study, we have investigated the defect chemistry in unstrained and strained Li$_8$Li$_2$Al$_{25}$La$_{25}$Zr$_{25}$O$_{121}$ (Al-LLZO) as a promising solid electrolyte. We employed Coulomb-energy analysis and density functional theory (DFT) calculations to find the most favorable structures. Thermodynamics of defects were applied to determine type and concentration of defects as functions of $\mu_\text{Li}$ and $\mu_\text{O}$.

We also used the "elastic dipole tensor" method to analytically describe the effect of applied strain on defects thermodynamics in an efficient way.

At first, all possible Li and Al arrangements in Al-LLZO were explored and the minimum energy structures of pristine and defective Al-LLZO were determined. Afterwards, the range of chemical potential of constituent elements where Al-LLZO is thermodynamically stable were specified. Defect formation energy plots show that in the oxygen rich limit, combination of charged Li vacancy and Li interstitial (a Frenkel-like pair) has the lowest defect formation energy. In the oxygen poor limit, however, combination of 2-Li vacancy ($V_\text{Li}$) and 1-O vacancy ($V_\text{O}$), a Schottky-like pair, has the lowest formation energy which is followed by the Frenkel-like pair of Li as well as charged La interstitial. The low formation energy of the Schottky defect is due to a strong interaction between $V_\text{Li}$ and $V_\text{O}$.

Interaction is also evident when lattice strain is applied to the system. The effect of lattice strain on charged O vacancy formation is more significant compared to charged 2-Li vacancies and this effect is opposite between these two cases. According to our findings, ionic conductivity can be enhanced by controlling lattice mismatch at electrolyte/electrode interfaces in ASSBs.

4:15 PM ES04.02.09
Solid-State Electrolytes with SiS$_2$ as a Glass Former

Ran Zhao, Guantai Hu, Steven J. Kmiec, Ryan Gebhardt and Steve Martin; Iowa State University, Ames, Iowa, United States.

The most widely studied sulfide-based solid electrolytes are P2S$_5$-Li$_2$S glasses and their analogs, which show conductivity as high as 10-3 S/cm. However, due to the volatility of P2S$_5$, the atmospheric pressure synthesis method of P2S$_5$-Li$_2$S was limited to the high energy plenary milling, as a result, scientists started to investigate the ionic conductive glasses based on SiS$_2$. In 1985, Kennedy et al. reported a variety of oxide-sulfide glasses in the systems Li$_2$S-SiS$_2$-Li$_x$MO$_{2-y}$ with high conductivity and stability against crystalization. However, to the best of our knowledge, none of the studies have investigated the critical current density and the cyclibility of the glass solid electrolyte material when cycling pure lithium metal, and those important properties of the SiS$_2$ based glasses as a solid electrolyte is still unknown.

In this work, we demonstrate three glasses systems with SiS$_2$ as a glass former. First, Li$_2$S-SiS$_2$-P$_2$S$_5$ glass system was synthesized by mechanical milling and the mix glass former effect was investigated, the material were characterized using XRD, Raman and NMR, and tested in symmetric cells with lithium metal as electrodes. Next, to improve the glass stability in contact with lithium, Li$_2$S-SiS$_2$-P$_{20}$S$_5$ was made and tested in symmetric cells for electrochemical impedance spectroscopy and cycling, to address the high solid-solid interfacial resistance and short-circuiting dendrite problems, we demonstrate a simple strategy to engineer the lithium-GSE interface by forming an in-situ interlayer via a heat treatment. Then, Li doped Li$_2$S-SiS$_2$-P$_{25}$S$_5$ was made and melt-quenching technique and superior electrochemical properties were observed. These results provide a promising group of glass with SiS$_2$ as glass former that can be applied to lithium metal battery and other energy storage application as solid-state electrolytes.

4:30 PM ES04.02.10

Ionic Conductivity and Short Range Order Structures of Sodium Oxy-Thio Phosphate Glasses

Steven J. Kmiec, Adriana Joyce, Ran Zhao and Steve Martin; Iowa State University, Ames, Iowa, United States.

Sodium thio-phosphate glasses exhibit extraordinary high ionic conductivities, and have received a lot of attention as potential electrolyte materials in solid state batteries. However due to the poor chemical and electrochemical stability of sulfide materials efforts have been made to improve these properties though the incorporation of oxygen. The short-range order (SRO) structure of glasses were characterized using FT-IR, Raman and $^{31}$P Magic Angle Spinning NMR (MAS NMR) spectroscopies to identify the role of oxygen in the glass structure. Evidence suggests that the addition of oxygen causes a disproportionation reaction to occur in the structure through the formation of mixed oxy-sulfide tetrahedra. These units allow for greater uptake of sodium ion to the system leading to a large change in the physical properties, most notably in ionic conductivity.

SESSION ES04.03: Solid-State Cell Integration and Architecture

All-Solid-State Lithium Metal Batteries Utilizing Solid Polymer Electrolytes

Lauri Imholt¹, Gunther Brunklau²,³, Jijiehs Nair¹, Johannes Knasctcheew¹, Isidora Cekic-Lashovic¹ and Martin Winter¹,²
¹Helmholtz-Institute Münster, Forschungszentrum Jülich GmbH, Münster, Germany; ²MEET Battery Research Center / Institute of Physical Chemistry, University of Münster, Münster, Germany.

All solid state batteries in principle allow for a reduction of the net weight and volume of the battery, greater energy output, and better ion transport while affording small self-discharge, minimal wear and tear, and a more uniform output voltage [1]. Materials that can reversibly store Li$^+$ to create capacity are potentially good anode materials, among which lithium offers a particularly high theoretical specific capacity, though lithium metal in contact with liquid electrolytes often leads to formation of high surface area metallic lithium structures upon repeated recharge and charge [2]. Solid electrolytes can be made compatible with lithium metal and allow to almost suppress lithium deposits rendering them a viable alternative, including advantages in terms of mechanical stability, operational safety and simplicity of cell design [3]. Solvent-free electrolytes require further improvement of achievable lithium ion conductivities at ambient temperatures, e.g. via design of nanostructures that facilitate directional pathways for Li$^+$ transport [4]. Polyoxotanate and ethylene oxide (EO) based polymeric electrolytes exhibiting impressive ionic conductivities and excellent oxidation stability at potentials higher than 5.5 V vs. Li/Li$^+$ will be discussed, highlighting interesting characteristics in terms of specific capacity, cycle life and Coulombic efficiency. In addition, Polysulfonamide based single ion conducting blend polymers that other than dual ion conducting electrolytes offer excellent transference numbers will be considered. The polymer blend electrolyte has superior oxidative stability and long-term stability against lithium metal, hence enabling operation in Li(Ni$_{1/3}$Mn$_{1/3}$Co$_{1/3}$)$_2$O$_{2}$/lithium metal cells at 20 °C and 60 °C, respectively [5]. Moreover, considerable improvements of sulfidic-based ceramic electrolytes will be discussed in view of challenges associated with materials processing and reproducibility aspects, in this way providing a reasonable basis for systematic exploration of electrode/electrolyte interfaces.

Garnet-Based Advanced Solid-State Batteries

Liangbing (Bing) Hu; Department of Materials Science and Engineering, University of Maryland, College Park, Maryland, United States.

I will start by giving an overview of active research activities in my research group located at University of Maryland Energy Research Center, including wood materials toward sustainability, 3000K high temperature materials and processing (Science 2018), wood nanotechnologies (Nature 2018), beyond-Li ion batteries (solid state, Na-ion). Then I will focus on our recent development on garnet-based solid-state Li-metal batteries including interface engineering to improve the wetting between Li metal anode and Garnet solid-state electrolyte (Nature Materials 2016; Advanced Materials 2017; Science Advances 2017); Garnet based 3D Li ion conductive framework (bilayer, triayer) toward high energy density Li-S batteries (EES 2017); Garnet nanofiber based flexible, hybrid electrolyte with a high Li ion conductivity (PNAS 2016), and in-situ neutron depth profiling technique in understanding Li-garnet and CNT-garnet interfaces (JACS 2016).

8:00 AM *ES04.03.02
Prospects and Challenges of Solid Electrolytes in Lithium Rechargeable Batteries

Ratnakumar V. Bugees, William C. West, Erik Brandon, Keith J. Billings and Simon C. Jones; Jet Propulsion Laboratory/Caltech, Pasadena, California, United States.

Solid electrolytes have been successfully developed for use in high temperature energy devices, e.g., Ytria stabilized zirconia (YSZ) as oxide ion conductors in solid oxide fuel cells operating at ~800°C, and sodium b-alumina solid electrolyte in Na-S and Na-Metal chloride (Zebra) batteries operating at 300-400°C. Excellent performance and lifetimes have been demonstrated in these devices. The b-alumina solid electrolyte separator enabled successful implementation of molten anode and cathodes in Na-S cells, and with a molten salt electrolyte for the Zebra batteries, without the issues of any (Na) dendrites during cycling. Development of room temperature Li-conducting solid electrolytes has been the topic of intense research in the last few years, mainly guided by the potential to replace the flammable organic electrolytes in current Li-ion cells for enhanced safety.

Additionally, these solid electrolytes can improve energy characteristics beyond the current Li-ion cells with the use of Li anode and high voltage cathodes. A noteworthy success was reported by Bates et al with a new solid electrolyte, LiPON (Lithium Phosphorus Oxynitride), which has a moderate ionic conductivity of 10^-4 S/cm at 25°C, but impressive interfacial stability against Li and cathodes. One difficulty with this material is its method of synthesis, i.e., reactive sputtering directly on cathode layers, which is not amenable for scale up. At JPL, we utilized this electrolyte in the development of micro-batteries with Li/LiCoO2 cells and demonstrated excellent cycle life at ambient temperatures and also at high temperature with cells fabricated by Front Edge Technologies.

The search for new Li-solid electrolytes has proceeded more rapidly in recent years, with improved conductivity of some of the recent systems, approaching and even surpassing that of liquid electrolytes. Room temperature conductivities of around 1 mS cm^-1 have been shown in lithium garnet oxides. These systems typically require co-sintering to obtain good contact between the electrode and electrolyte, which is important for battery performance. More recently, new sulfide superionic conducting materials have emerged with higher conductivities and with mechanical properties amenable for better physical contact with electrodes. These include Li2GeP2S6 (LGPS), with a conductivity of 12 mS/cm at 25°C, and Li2PSi11, a glass-ceramic with a conductivity of 27 mS/cm at 25°C. The challenges associated with these high conductivity solid electrolytes are: 1) Poor interfacial stability of almost all the solid electrolytes towards Li or cathode materials, which warrants intermediate buffering layers (e.g., Al2O3) and ii) Need to have sufficient solid electrolyte as part of cathode, i.e., composite cathode, for a good utilization of cathodes of nominal thickness. Often, a hybrid system is preferred, where the solid electrolyte is utilized to protect Li anode and is used in conjunction with a conventional liquid electrolyte. In this paper, we will review the status of this technology and also present the results of our studies on the interfacial stability of some of these solid electrolytes towards Li anode and various cathodes.

Wet Chemical Processing of Lithium Garnets—Previous Challenges, A New “Solution”

Zachary D. Hood1 and Jennifer L. Rupp1, 2, 3; 1Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Lithium solid electrolytes are expected to improve next-generation energy storage technology on the basis of energy density, safety, cost, amongst other parameters. However, there has been limited success in growing oxide-based solid electrolytes, such as Li3xAlxLa2-xZr2O7 (LLZO), into thin films between 200 nm and 5 μm in thickness using scalable solution-based techniques. Several vacuum-based2 and sol-gel-derived3 methods have shown promise in making thin garnet-based solid electrolyte films with relatively high ionic conductivity (~10^-3 ~ 10^-4 Scm^-1 at room temperature), yet lithium loss during the post annealing can alter the phase as well as significantly affect the lithium ion conductivity. Only a recent report4 has overcome this issue by using an alternative ceramic processing strategy establishing lithium reservoirs directly in lithium garnet-based films (through LiN multilayers) that allow for lithiated and fast-conducting cubic solid state battery electrolytes at unusually low processing temperatures using pulsed laser deposition. Still, the exploration of scalable fabrication techniques is of special importance to develop thin films of garnet-based solid electrolytes with high ionic conductivity. Here, we present a new solution based on spray pyrolysis for growing garnet-based thin films. We show that the crystallization and the phase transformation can be modulated to lower temperatures (~750 °C) by tuning the concentration of cations and the boiling point of the solvents used in the spray solution. Also, by altering the chemistry of the spray solution and the post-annealing conditions, we show that the surface roughness can be modulated while still maintaining dense and continuous membranes of LLZO. Our results highlight a new opportunity for manufacturing garnet-based solid electrolytes with tunable electrochemical surface areas. The insights from this work are expected to serve as fundamental guidelines for future optimization toward solution-based processing of thin film superionic garnet-based materials for next-generation lithium metal batteries.

Solid-State On-Chip Energy Storage Devices Based on Photopatternable Ionogel Solid Electrolytes

Christopher S. Choi1, Kevin Brousseau2, Patrice Simon1 and Bruce S. Dunn1; 1University of California, Los Angeles, Los Angeles, California, United States; 2Materials Science department - CIRIMAT, Université Paul Sabatier,, Toulouse, France.

While microfabrication techniques have been used extensively to form the complex circuitry of modern microelectronic devices, its application in the fabrication of electrochemical energy storage (EES) systems has not been considered traditionally. However, the microfabrication approach can open new routes for minimizing the dimensions...
of EES devices and for directly incorporating them with integrated circuits, sensors, MEMS devices, and various other Internet-of-Things components. In particular, the photopatterning of mechanically robust solid electrolytes offers several potential advantages, such as the spatial control with micron and sub-micron resolution in complex designs, ease of co-packaging with other integrated circuits, and high-throughput wafer-scale fabrication of EES arrays.

This presentation will review our work on the fabrication and characterization of a photopatterning, ionically conducting solid electrolyte. Electrolyte materials consist of the epoxy-based photopattenable polymer matrix that confines an ionic liquid, thus providing an appropriate source of ions and measureable ionic conductivity of 0.4 mS cm⁻¹. This ionogel solid electrolyte possesses excellent mechanical integrity, demonstrates good electrochemical stability, and can be photopatterned with micrometer-scale resolution. To validate its electrochemical performance and on-chip integration, fabrication of all-solid-state micro-supercapacitor devices was demonstrated using microfabrication methods that are fully compatible with current semiconductor processing. The interdigitated electrode designs were optimized to minimize the ion transport distance, compensating for the modest ionic conductivity of our solid electrolyte. The resulting TiC-derived-carbon micro-supercapacitor devices with 15-μm electrode spacings demonstrate a high areal capacitance and long-term electrochemical stability. In addition, the potential range and total capacitance of micro-supercapacitor devices can easily be tailored through modifying the device arrangements in series or parallel configurations.

Thin Film Technology—Opening New Frontiers for 3D Solid-State Energy Storage Gary Rubloff, Keith Gregorczyk, David Stewart, Blake Nuwayhid, Angelique Jarry, Nam Kim, Jake Ballard and Sang Bok Lee; University of Maryland, College Park, Maryland, United States.

Solid state batteries (SSBs) can be fabricated using thin film processing techniques like those which dominate major high-tech markets such as semiconductors, displays and optoelectronics. In particular this approach - profoundly divergent from today’s Li ion battery mainstream - enables controlled patterning of electrode and electrolyte shapes and connectivity that opens the door to simultaneous high energy and high power, 3D nano/micro configurations exploiting conformal high aspect ratio geometries, and flexible form factors for integrating SSBs into multifunctional systems. We have made substantial progress in realizing these benefits in conformal 3D vertical interdigitated nanobattery arrays, forming SSB layers in high aspect ratio nano/micro pores, affording the opportunity to project performance. We are also pursuing a contrasting lateral design that promises similar benefits. We compare the vertical and lateral designs in terms of projected performance and associated synthesis and fabrication challenges, and we highlight key scientific challenges at the levels of nanoscale interfaces and mesoscale architectures.

11:15 AM ES04.03.07
Advanced Sulfide Solid Electrolyte and Battery Design for 5V Cathode Xin Li; Harvard University, Cambridge, Massachusetts, United States.

Ceramic sulfide solid electrolyte can show high lithium conductivity, while the voltage stability was reported as an issue in many previous literatures. We show in this talk a new way to improve the voltage stability of sulfide solid electrolyte materials by microstructure and battery designs. The improved battery performance and voltage stability are shown by electrochemical test. A combination of first principle simulation and transmission electron microscopy imaging techniques are used to understand the principle behind the phenomenon.

Specifically, sulfide Li-Si-P-S has been synthesized, characterized and tested to show an improved voltage stability window up to 3.1 V and quasi-stable voltage window up to 5V from a combined thermodynamic modeling and DFT simulation understanding the principle behind this promising result. A new design principle and theory is proposed and discussed systematically for tuning the voltage stability of solid electrolyte, giving the guidelines for the design of advanced sulfide electrolytes. All-solid-state battery using 5V cathode materials based on sulfide solid electrolyte is demonstrated in our experiment.

Thin-Film Battery Architecture Approaches for High Power and Energy David M. Stewart, Blake Nuwayhid, Keith Gregorczyk, Angelique J. Jarry and Gary Rubloff; University of Maryland, College Park, Maryland, United States.

Producing battery materials by thin film deposition techniques provides many benefits for future solid state batteries (SSB) and opens up new possibilities for on chip energy storage in microelectronics applications operating in harsh environments and with high power demands. We have recently demonstrated that a fully 3D thin film based SSB can be produced by atomic layer deposition (ALD) into an array of nanopores etched into an inert substrate, with potential to scale capacity to rival that of modern lithium ion batteries. Such extreme 3D architectures apply certain constraints to the selection of materials and deposition techniques, and effectively limits us to using ALD, not to mention limiting the ways in which we wire these 3D TFSSB to the rest of the device.

Experiments on an alternative TFSSB architecture, simpler and more efficient in many regards, are presented which relaxes many of these constraints, while retaining the same capacity scaling performance. In this architecture, the battery layers are deposited in a planar way using magnetron sputtering, and the processing is repeated to produce multiple layers of TFSSB in the same space. Once electrode connections are completed, this multibattery architecture alleviates many of the concerns raised from the previous 3D battery, while presenting other issues (e.g., annealing steps required to produce the desirable phase in the cathode).

We will describe and compare our measurements on these two distinctly different approaches to 3D battery architectures for high power-energy solid state electrochemical energy storage, considering such aspects as mesoscale synthesis, performance scaling, flexibility in form factor, and integration into multifunctional systems.

Interfacial Engineering of Solid-State Batteries Using Atomic Layer Deposition Neil P. Dassargues; Department of Mechanical Engineering, University of Michigan, Ann Arbor, Michigan, United States.

Solid-State batteries have experienced a recent explosion in research and development, owing to their potential to improve safety and enable higher energy density electrode chemistries. However, it has been widely recognized that all solid-state interfaces present unique challenges compared to traditional liquid electrolytes, including reduction of high interfacial impedances (which can evolve during cycling), accommodation of mechanical stresses due to solid-solid interfacial contact with active materials, and (electro)chemical instabilities that can arise from localized gradients in ionic and electronic concentrations.

To address these challenges, our group focuses on gaining new fundamental insights into the coupled phenomena occurring at interfaces, and applied this knowledge to rationally design interfacial chemistry to address the root cause of performance limitations. The key enabling technology that will be discussed in this talk for surface modification is Atomic Layer Deposition (ALD). This is a gas-phase deposition process capable of conformally coating high aspect-ratio structures with sub-nanometer control in thickness. This atomic-scale modification of surfaces allows for precise control of interactions at heterogeneous interfaces, including (electro)chemical stability, interfacial kinetics, wettability, and mechanical load transfer.

In this talk, examples will be presented in both bulk solid-state battery interfaces, and thin film electrolytes deposited by ALD. By studying interfacial chemistry across length
The advent of solid-state batteries has spawned a recent increase in interest in lithium conducting solid electrolytes, especially in the lithium thio phosphates. While current lithium electrolytes provide fast-ionic conduction to fundamentally study solid-state batteries, their ionic conductivities are not sufficient for thick electrode configurations, which will really allow high energy densities to be achieved. In this presentation, we show how an understanding of the structure-transport properties of the lithium argyrodites Li$_x$PS$_{4-x}$ can help tailor the ionic conductivity. We show that an anion site disorder between $S^2$ and $X$ is beneficial for the activation barrier and that an induction of the site disorder in Li$_x$PS$_{4-x}$ leads to a significant improvement of the conductivity. Having achieved the fastest lithium argyrodite so far with $\sim 18$ mS/cm, solid-state batteries with thick electrode configurations (150 – 350) can be built. Due to the optimized solid electrolyte, the solid-state battery can be cycled even at 1C with no capacity fade over 150 cycles. This work shows that optimizing solid electrolytes helps to achieve stable cycling at high rates in solid-state batteries with thick electrodes. Finally, we will show how tuning the lattice polarizability in ionic conductors affects the ionic transport due to a softening of the lattice. Our work shows that the idea of the “softer, the better” needs to be revisited. Lastly, we show how volume changes, induced by electrochemical (de-)intercalation, affect the performance in solid state batteries providing an understanding of the underlying mechanochemical influences in solid-state batteries.\(^{(1)}\) (1) Janek, J.; Zeier, W. G. A Solid Future for Battery Development. Nat. Energy 2016, 16141.

All solid-state batteries have become the focus of next-generation Li-ion battery research and development to meet the ever-growing demands on safe and high-energy-density storage systems. Replacing conventional electrolytes with solids mitigates issues associated with flammable organic liquid and makes safer battery systems. Solid electrolytes which are stable against lithium and resistant to Li dendrite penetration could enable the use of metallic lithium anode, offering a promising pathway to deliver lithium-ion cells with energy densities that significantly exceed 350 Wh/kg. While each main class of solid electrolytes has their intrinsic challenges, integrating different groups of solid electrolytes such as polymers and ceramics has the potential of bringing their individual advantages together and overcoming their drawbacks. In this study, we fabricated a group of hybrid polymer/ceramic electrolytes made from commercially available materials. Their ionic conductivity, electrochemical stability, interfacial stability towards metallic lithium, thermal property, processability and mechanical strength were systematically investigated. Finally, we develop a metrics to screen these hybrid solid electrolytes and identify promising candidates which are most relevant to electric vehicles (EV) applications. Our study illustrates the importance of component integration in developing high-performance solid-state electrolyte. This work serves as a guide to select the appropriate solid electrolytes that can power future electric vehicles.

Si Doped Flexible Self-Supporting Comb Like Polyethylene Glycol Copolymer (Si-PEG) Film as Polymer Electrolyte for All-Solid-State Lithium-Ion Battery

Dandan Li1,2 and Dean Shi1,2; 1Hubei University, Wuhan, China; 2Materials Science and Engineering, Hubei University, Wuhan, China.

Self-supporting comb like Si-PEG copolymer with flexible Si-O-C bonds in the main chain and pending short PEG chains as the side chain was synthesized to improve the low temperature performance and overcome the dilemma between good mechanical and electrochemical properties of polymer electrolyte in lithium ion battery. The tensile strength of Si-PEG polymer electrolytes (SPH15) is 0.8MPa at 30°C, which is strong enough to inhibit the growth of lithium dendrites. The ion conductivities of Si-PEG (SPH15) are 1.2×10-4 S/cm at 30°C and 3.2×10-7 S/cm at 10°C, respectively, which are one order higher than those for PEG based copolymer electrolytes without Si doping. Assembled LiFePO4/SPH15/Li half batteries can deliver specific capacities of 84 mAh/g at 10°C and present 75% capacity retention after 500 charge-discharge cycles at 0.5C.

ES04.05.01
Ionic Liquid Embedded Poly(methacrylate)-Comb-Copolymer Electrolytes for Solid-State Supercapacitor
Jadjun Lee and JongHak Kim, Yonsei University, Seoul, Korea (the Republic of).

We report a highly ionic conductive gel polymer electrolyte for supercapacitor, composed of poly[2-[3-(2H-benzotriazol-2-yl)-4-hydroxyphenyl] ethyl methacrylate]-poly(oxyethylene methacrylate) (PBE) copolymer and 1-Ethyl-3-methylimidazolium dicyanamide ionic liquid. When incorporated with EMIM DCA, selective interaction between ether groups and EMIM DCA induced micro-structured morphology, observed by (TEM). Structured morphology effectively suppressed aggregation of EMIM DCA and provide ion transport pathway, which led to fast diffusion of mobile ions. The PBE/EMIM DCA electrolytes showed gel-like morphology, which is suitable to fabricate solid-state, leakage-free supercapacitor. The best performance of supercapacitor using PBE/EMIM DCA electrolytes exhibited higher capacitance (125.1 F g-1) than that of reference PVA/H3PO4 electrolyte (39.5 F g-1) due to its high ionic conductivity and good affinity with electrode.

ES04.05.02
Stabilizing Lithium Electrodedeposition in Solid Polymer Electrolyte through Introducing Polymeric Ionic Liquid
Xiaowei Li and Christopher Li, Drexel University, Philadelphia, Pennsylvania, United States.

Development of practical high-energy-density lithium metal batteries (LMBs) remains a grand challenge due to uneven lithium deposition and uncontrollable lithium dendrite growth. Hence, to further stabilize lithium electrodeposition, polymeric ionic liquid (PIL), poly(diallyldimethylammonium) bis(trifluoromethanesulfonyl)imide (PDDA-TFSI) with TFSI- as the anions, is introduced in the cross-linked poly(ethylene glycol) (PEG) solid polymer electrolyte to form an interpenetrating polymer network (IPN) in order to homogenize the anion concentration and reduce the local space charge-associated large electric field during the electrolyte cycling. Galvanostatic cycling and polarization measurements of symmetrical lithium cells show that introducing proper amount of PIL could improve the lithium dendrite resistance at relatively low current density, and reduce anion depletion velocity and extend Sand’s time when polarized at high current density, indicating the improved lithium electrodeposition stability. Calculations from the Chazalviel model reveal that the improvement derives from elevated ionic conductivity and ionic concentration when PIL is introduced. The results demonstrated here represent a facile way for stabilizing lithium electrodeposition in high-performance LMBs.

Mixed Electronic and Ionic Conduction Properties of Reduced Lithium Lanthanum Titanate
Michael Wang and Jeff Sakamoto, University of Michigan, Ann Arbor, Michigan, United States.

Solid state electrolytes have garnered significant interest in recent years due to their potential to enable high energy-density Li-metal batteries. Because solid electrolytes have the potential to physically stabilize the Li-metal/electrolyte interface, significant emphasis has been placed on understanding the kinetics and stability of the Li/electrolyte interface. As significant progress is made in stabilizing the Li/electrolyte interface at higher current densities, there is an increasing need to develop and improve compatible cathodes for all solid-state architectures. Currently, achieving a combination of facile ion and electron transport through the cathode thickness is emerging as a challenge toward high-rate cycling. It has been proposed that a method of introducing charge transport in the cathode is introducing a mixed electronic and ionic conductor (MEIC) which can reduce the amount of net
conductive additive required. This study focuses on the perovskite Li_{12}La_{2/3}Zr_{12}O_{41} (LLTO) as a model MEIC system. The physical and charge transport properties for LLTO are measured in the oxidized and reduced state. Furthermore, the effects of P2O5 and grain size on the transport properties are examined. Overall, this work will motivate the further study and development of MEIC materials in the context of solid-state batteries and may improve the potential for high-rate cathodes for solid-state architectures.

ES04.05.05
A Novel De-Coupling Solid Polymer Electrolyte via Semi-Interpenetration Network for Lithium Metal Battery Yongwei Zheng, Xiaowei Li and Christopher Li; Drexel University, Philadelphia, Pennsylvania, United States.

Solid-state lithium metal battery attracts lots of interest for its high theoretical capacity and less flammability. Poly (ethylene oxide)-based solid polymer electrolyte (SPE) has been proved to be successful in lithium metal battery. However, the Li-ion transference number which restrains the battery working is at high current rate. Herein, a novel SPE combined poly (ethylene oxide) and poly (propylene carbonate) and with semi-interpenetration network structure is reported. The synthesis of the SPE is based on the crosslinking of octakis(3-glycidoxypropyldimethylsiloxyl) octasilsequioxane and amine-terminated polyethylene glycol while adding linear poly (propylene carbonate) with controlled concentration. The optimized SPE could be stably cycled for over 300 hours at current density of 1.5 mA cm−2 during the galvanostatic symmetrical cell plating/stripping experiment. Lithium ion transference number could reach 0.38 which is almost double to the single network SPE. Scanning electrical microscope (SEM) revealed that the involvement of poly (propylene carbonate) could effectively suppress the lithium dendrite growth. X-ray photoelectron spectrum (XPS) found Li plating/stripping experiment. Lithium ion transference number could reach 0.38 which is almost double to the single network SPE. Scanning electrical microscope (SEM) revealed that the involvement of poly (propylene carbonate) could effectively suppress the lithium dendrite growth. X-ray photoelectron spectrum (XPS) found Li.

ES04.05.06
Compositional Dependence of Structural, Thermal and Electrochemical Properties of Lithium Oxythio-Silicophosphate Glassy Solid-State Electrolytes Guantai Hu, Ran Zhao, Steven J. Kmiec, Ryan Gehbardt and Steve Martin; Iowa State University, Ames, Iowa, United States.

Hazards associated with the utilization of organic liquid electrolyte has created a growing concern while the number of lithium rechargeable battery (LRB) applications has been increasing over the last two decades. Glassy solid-state electrolytes (GSSEs) have been considered as a safer alternative credited to its promising thermal stability and physical durability. In addition to this, the elimination of fire and explosion risks provides the chance to adopt high-energy-density metallic lithium as anode material, leading to drastic improvements in overall energy density of LRBs. However, few papers have been reported on lithium oxythio-silicophosphate (LiPSiSO) GSSE, and the compositional dependence on structural, thermal and electrochemical properties are not clear yet.

In our research, LiPSiSO GSSE materials were synthesized via melt-quench method, and the structural and thermal properties were characterized using differential scanning calorimetry, Raman, infrared, nuclear magnetic resonance spectroscopies. The electrochemical properties have been tested via electrochemical impedance spectroscopy and direct-current cycling methods, for which powdered LiPSiSO GSSE was pressed into thin pellets (~1mm). The experimental results showed the structural, thermal and electrochemical properties of our GSSE are highly composition dependent. This insight allows for the correlation among those properties, and helps optimize the performance of LiPSiSO GSSEs by composition adjustment during synthesis.

ES04.05.07
Solid State Li-La-Zr-O2–Polymer Composite Electrolyte for All–Solid–State Lithium Batteries Parisa Bashiri1, Prasad Rao Talakonda1, Vaman Naik2 and G. Abbas Nazri1,2; Wayne State University, Detroit, Michigan, United States; 1University of Michigan–Dearborn, Dearborn, Michigan, United States.

Current lithium-ion batteries contain flammable organic-based electrolyte with limited voltage stability. A promising solid state electrolyte has been proposed to improve safety and limited voltage stability of the current lithium-ion battery. A global research activity is underway to develop a safe solid-state electrolyte with high conductivity and high voltage stability to replace the organic liquid electrolyte.

The polymer-salt complex electrolytes have been investigated in the past. However, this class of electrolyte exhibits low ionic conductivity (10−6 – 10−7 S cm−1) at room temperature due to their high degree of crystallinity at low temperatures and a high degree of ion-pairing that limits salt solubility. These issues have been addressed by adding plasticizers such as ethylene carbonate (EC), propylene carbonate (PC), etc., or using inorganic fillers. In this research, we have studied PEO based polymer electrolyte with inorganic filler, Li-La-Zr-O2 (LLZO), which is also a Li-ion conductor. We have shown that the ionic conductivity of PEO-LLO composite electrolyte increases by one order of magnitude upon adding LLZO (20 wt%) and EC (20 wt%) and lowering the activation energy from 0.6 eV to 0.4 eV with high (5V) voltage stability. The results of a detailed study of electrochemical properties of PEO-LLO composite electrolytes using electrochemical impedance spectroscopy, linear sweep voltammetry, and chronoamperometry will be presented.

ES04.05.08
High-Capacity Slurry-Coated Sheet-Style Tin Anodes for All-Solid-State Lithium-Ion Batteries Nathan A. Dunlap; Mechanical Engineering, University of Colorado - Boulder, Boulder, Colorado, United States.

High capacity all-solid-state Li-ion battery anodes were prepared using an industrially scalable solution coating processes. Employing commercially available polyacrylonitrile as a mixed conducting binder, we have demonstrated stable cycling, high capacity electrodes with large mass loadings of tin active material. This is, to our knowledge, the first time a high capacity lithium-alloying material has been utilized in a slurry-coated sheet-style all-solid-state Li-ion battery anode. Optimization of this new electrode architecture resulted in a sheet-style anode capable of retaining an electrode specific capacity of 643.5 mAh g-1 after 100 charge-discharge cycles at a 0.1C rate. We believe that this work represents a step forward for slurry-coated electrodes and that the continued development of these high capacity sheet-style anodes will be critical to the commercialization of the all-solid-state Li-ion battery.

ES04.05.10
Atomic-Level Understanding of Thermal Management for Superionic Conductor Battery Materials Ming Hu; University of South Carolina, Columbia, South Carolina, United States.

The importance of clean and efficient energy storage has grown enormously over the past decades, driven primarily by concerns over global warming, diminishing fossil-fuel reserves, and increasing demand for portable electronics and grid storage systems. The performance of energy storage devices depends crucially on the properties of their component materials. Rechargeable lithium ion batteries (LIBs), due to their high energy density superior to all other secondary batteries, have become instrumental in powering nearly all of our small, portable electronics. However, LIBs have their drawbacks. One of the most pressing challenges for LIBs is overheating. During charging, a tendency for growth of small Li filaments, known as dendrites, occurs. The dendrites can short-circuit the cells and trigger a process known as thermal runaway, which can lead to violent overheating reactions. When a LIB overheats, the components inside are at risk of decomposing and undergoing a series of reactions that can generate even more heat and gaseous products. This will induce the liquid electrolyte that comprises organic chemicals to combust. In order to extend the battery life between charges and create a smaller, higher-energy battery, today’s LIBs have twice as much active material and tinier separators, setting the stage for a new generation of heat-triggered recalls. Despite many safety mechanisms have already been incorporated into batteries to prevent inadvertent charging and excessive current, there is little research focusing on exploring the fundamental mechanism of heat transport in LIBs in both stationary and charging conditions and how the excess heat is generated. In this work, by performing first-principles and molecular dynamics simulations, for the first time we give a robust and detailed explanation of the thermal transport mechanism in superionic material LiSi. At the temperature range in which the system can be regarded as a solid, the large hopping of Li is found to be responsible for phonon thermal conductivity’s deviation from the traditional 1/T relationship. At the high temperature range, the contribution of convection and liquid-phonon interaction increase significantly due to the fluidization of Li ions. Furthermore, there is an interplay between the enhanced phonon scattering and the increased forced hopping between neighboring atoms as temperature arises, which results in a dip in the evolution of the virial term around 1200K. When the temperature is higher than 1200 K, the virial thermal conductivity increases with temperature due to the contribution of vibrations with extremely short
mean free path (diffusons). At 1300 K, more than 46% of the heat carried by the S sublattice is contributed by the carriers with mean free path smaller than a few angstroms, which is the typical hopping distance. Our study provides a clear physical map of the heat transport in superionic battery materials and describes the key mechanisms to guide the design of thermal management in battery electrodes.

ES04.05.11
Investigation of LiPON Thin Films Grown by Pulsed Laser Deposition for Application as a Solid-State Electrolyte Thomas C. Callaway, David Beckwitt, Nick Rogers and Saibal Mitra; Physics, Astronomy, and Materials Science, Missouri State University, Springfield, Missouri, United States.

Modern lithium batteries use liquid electrolytes as the source for lithium ions in batteries and electrochromic devices. However, liquid electrolytes present its own set unique problems. Lithium ion batteries are prone to runaway thermal reactions and a loss of performance due to dendritic growth in the electrodes. Lithium phosphorous oxy-nitride (LiPON) is a solid-state material with good lithium ion conductivity that should address some of these challenges. In this work, we investigate the growth of LiPON films using pulsed-laser deposition (PLD) on pristine and copper-coated soda-lime glass. The goal of this work is to optimize the growth parameters for the development of highly conductive LiPON films that can be used in both solid-state lithium ion batteries and electrochromic devices. A lithium phosphate (Li3PO4) target was abladed in a nitrogen atmosphere using a Quantel Q-Smart 850 laser with a neodymium-doped yttrium aluminum garnet (Nd: YAG) crystal and a laser fluence of 20 J/cm². Two sets of films were deposited at room temperature and at 400°C. For each set of films the nitrogen pressure was varied from 10⁴ to 10⁶ mbar to 10⁻⁴ mbar. The target to substrate distance was held constant at 5.5 cm and the thickness of the films was controlled by the number of shots on the target. The films were studied both as-deposited and with a post deposition anneal of 30 minutes. We characterized the films using a number of techniques including x-ray diffraction, electron microscopy, Raman spectroscopy and electrical measurements. The detailed results will be presented.

ES04.05.12
Flexible Lithium-Air Batteries Based on Polymer Gel Electrolytes Lie Wang, Ye Zhang and Huisheng Peng; Fudan University, Shanghai, China.

The development of high-performance and flexible energy storage devices is critical while it remains challenging for wearable electronics. The lithium-air battery has been proposed as the next-generation energy-storage device with a much higher energy density compared with the conventional lithium-ion battery. However, they are designed into a rigid bulk structure that cannot meet the flexible requirement in the modern electronics. Besides, lithium-air batteries currently suffer enormous problems including parasitic reactions, low recyclability in air, degradation, and leakage of liquid electrolyte. Herein, a new family of all-solid-state lithium-air batteries was developed with high electrochemical performances and flexibility by designing a polymer gel electrolyte and an aligned carbon nanotube sheet air electrode. The battery exhibited a high discharge capacity and could stably work with long cycles in ambient air; its electrochemical performances were well maintained under bending and after bending, which is particularly desirable for portable and wearable electronic devices.

ES04.05.13
Combinatorial Study on Lithium-Ion Conductivity of Amorphous Li-La-Zr-O Thin-Films with Sol-Gel Processing Myung-Gil Kim; Chung-Ang University, Seoul, Korea (the Republic of).

The sol-gel process was successfully implemented for combinatorial investigation of amorphous Li-La-Zr-O (a-LLZO) electrolyte. With unlimited compositions of the amorphous structure, the combinatorial approaches were systematically developed to seek for optimal composition and optimized experimental condition (400 °C annealing temperature). The amorphous structures were displayed by GIXRD analysis. The electrochemical impedance study reveals that the ionic conductivity considerably improved with composition optimization, specifically from 4.8 x 10⁻⁸ S cm⁻¹ to 1.18 x 10⁻⁷ S cm⁻¹. Exceptionally, the LLZO-coated LiCoO2 (LCO) coin cell showed a greater cycling performance compared to bare-LCO coin cell at the optimum ratio of LLZO. We believe that a-LLZO is a promising material for solid electrolyte battery.

ES04.05.14
Highly Dense Composite Nanostructured Electrode for Flexible Supercapacitor Application Sangram K. Pradhan, Julien C. Niyogishima, Sangeeta Rout, Christian Carvajal, Bo Xiao and Messaoud Bahoura; Norfolk State University, Norfolk, Virginia, United States.

A high demand of energy storage devices has boosted researchers for fabricating ultra-efficient capacitor with better energy density and cycling stability. Supercapacitor made up of organic and inorganic nanostructured electrode showing better performance in terms of flexibility, light weight, and electrochemical stability. The supercapacitor made up of composite nanostructured electrode operates at higher voltage and exhibits excellent retention behavior with a very little loss of capacity even after few thousands of charge and discharge cycles. The composite electrode shows excellent flexibility without changing any sheet resistance even after few tens of bending mode. FESEM images reveals the formation of high dense nanostructure of different size with diameter vary from few tens to few hundreds of nanometer. The asymmetric supercapacitor shows energy density, power density of 0.47 mW h/g, and 35.2 mW h/g respectively. This device exhibits a high areal Csp of more than 6F/g. These energy storage unit holds a great potential for the use in future flexible electronic device.

Glucose-Intercalated NiMn LDH@NiCoS2 Heterostructures Supported on Carbon Fiber Cloth for High Performance Flexible Supercapacitors Shixia Chen¹ ² and Shuguang Deng¹; ¹School for Engineering of Matter, Transport and Energy, Arizona State University, Tempe, Arizona, United States; ²School of Resource, Environmental and Chemical Engineering, Nanchang University, Nanchang, China.

Weearable energy sources are under urgent demand due to the rapid development of wearable electronics. Supercapacitors possess a high power density and long cycle lifetime, thus developing flexible high-performance supercapacitors is a promising route to meet the demand for wearable energy sources. The realization of high-performance flexible supercapacitors strongly relies on the electrical properties and mechanical integrity of the constitutive materials and their ingenious assembly into free-standing and binderless structure. Pseudocapacitive metal (e.g., nickel, cobalt, and manganese) hydroxides/oxides provide multiple oxidation states for reversible Faradaic reactions which have been extensively pursued to realize efficient supercapacitors devices. However, the faradaic nature of bulk pseudocapacitive material with limited diffusion length restrains the capacitance contribution within the surface and near the surface of the material. Thus, a method to control the structure of the material should be found to improve the charge and ion-transfer efficiency of the flexible pseudocapacitive material. Core–shell structure with different pseudocapacitive materials can provide more electroactive sites, higher electrical conductivity, faster ion-electron transport, which might lead to unprecedented electrochemical performance. Herein, we design and fabricate a new and hierarchically core-shell structured hybrid of electroactive material coating (NiMn-glucose-LDH) on in situ grown NiCoS2 nanotube arrays on a flexible carbon fiber cloth (CFC), denoted as NiMn-G-LDH@NiCoS2. Highly conductive NiCoS2 nanotube arrays grown on a flexible CFC, which can serve not only as a superior pseudocapacitive material but also as a three-dimensional (3D) conductive scaffold for loading additional electroactive materials. Glucose intercalated NiMn LDH (NiMn-G-LDH) could significantly improve the ion diffusion coefficient with the expansion of the interlayer distance. Inheriting the merits of NiMn-G-LDH and NiCoS2 nanotube, the free-standing NiMn-G-LDH@NiCoS2 hybrid could synchronously achieve the excellent rate performance and cycle stability. The electrochemical investigation shows that the NiMn-G-LDH@NiCoS2 have a significantly enhanced specific capacitance (1,793 F g⁻¹ at 1 A g⁻¹), rate capability (~70% retention at 20 A g⁻¹) and cycling performance (keep ~82% after 1000 cycles) that far exceed those of the reported individual NiCoS2 and NiMn LDH electrodes.

Polymer-Mineral Composite Solid Electrolytes Bo Wang; Imerys, San Jose, California, United States.

Polymer-mineral composite solid electrolytes have been prepared using lithium ion-exchanged natural bentonite and mineral derived NASICON materials as solid electrolyte fillers in the polyethylene oxide (PEO) polymer containing LiTFSI salt. The mineral based solid electrolyte fillers not only increase ionic conductivity but also improve thermal and mechanical stability. The flexible and stretchy polymer-mineral composite solid electrolyte films can be used in the all-solid-state batteries.

1D Nickel-Cobalt Composite Oxides and Polypyrrole Decorated Stainless Steel Yarns for High-Performance Fiber-Shaped Flexible and Wearable Asymmetric

School for Engineering of Matter, Transport and Energy, Arizona State University, Tempe, Arizona, United States; 2School of Resource, Environmental and Chemical Engineering, Nanchang University, Nanchang, China.
Flexible and wearable supercapacitor (SC) has drawn a great attention for the potential in powering smart and wearable electronics. Particularly, 1D fiber-shaped flexible devices can be directly knitted or sewn into conventional textiles. Here, an electrodeposition strategy is devised to purposefully fabricate nickel/cobalt composite oxides and polypyrrole (PPy) decorated stainless steel yarns (SSY) as the positive and negative electrodes, respectively. The nickel/cobalt composite oxides based SSY positive electrode showed the highest volumetric capacitance of about 166.5 F/cm³ at the current density of 0.4 A/cm². Asymmetric all-solid-state supercapacitors (AASs) were then successfully developed and assembled by wrapping a PPy coated negative electrode on the as-prepared positive electrode in conjunction with the PVA/KOH gel electrolyte, showing competitive flexibility and electrochemical properties owing to the flexible SSY substrate and the highly pseudocapacitive materials. The as-obtained AASs exhibited a wide voltage window of 0-1.5 V, and the highest volumetric capacitance was nearly 13.88 F/cm³ at the current density of 20 mA/cm², and the maximum energy density was 2.95 mWh/cm³ at a power density of 17.68 mW/cm². Furthermore, the highly flexible AASs were then directly sewn into a conventional textile fabric, exhibiting great electrochemical stability under 6,000 charging/discharging cycles. Collectively, the work uses the highly pseudocapacitive materials and facile methods fabricated flexible AASs with enhanced electrochemical properties, which showed a decent potential in designing and exploring the next-generation wearable and portable SC devices.

SESSION ES04.06: Alkali Metal/Solid-Electrolyte Interface

Interfacial Engineering of Solid-Solid Interfaces to Enable All Solid State Batteries Y. Shirley Meng; University of California, San Diego, La Jolla, California, United States.

Solidifying the components of a Li-ion battery consisting of a high energy capacity oxide cathode (e.g. NMC, NCA), a Li metal anode, and a sulfide-based glass ceramic solid electrolyte (SE), is a pathway to overcome the challenges of liquid electrolyte, namely dendrite growth and safety concerns without compromising high energy density. Even though the conductivity of a few sulfide solid electrolytes (SSEs) surpasses that of liquid electrolytes, multiple interfacial phenomena at both the cathode and anode interfaces play a crucial role in affecting efficient battery performance. Such phenomena include solid-electrolyte interphase (SEI) formation and mechanical deformation; the SEI forms due to poor chemical and electrochemical stability of SSEs while mechanical deformation arises from volume changes experienced by the cathode during cycling and also the rigid nature of SSEs. In the past several decades, tremendous effort has been made to study the SEI for SSEs, however, the properties of cathodic and anodic SEIs and their effects on long-term All Solid State Battery (ASSB) cycling are still not well-understood. In this work, we use multi-modal characterization and computation modeling tools to understand and elucidate the reaction mechanisms at the solid-solid interfaces. Interfacial engineering through coating of active electrode materials can be an effective method to enable ASSB at room temperature.

9:00 AM *ES04.06.02
Growth and Properties of Lithium Thin Films for Solid State Batteries Nancy Dudley1, Andrew S. Westover1, Erik G. Herbert2 and Jeff Sakamoto3; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Material science and engineering, Michigan Technological University, Houghton, Michigan, United States; 3University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

The lithium for many batteries comes packed in the cathode, so little is needed to seed the lithium anode and form the current collector. For this we grow the lithium films by vacuum thermal evaporation. This presentation will describe conditions and control of the film growth and the resulting morphology and properties of the films deposited onto a variety of solid electrolytes. Initial studies will also address how the lithium properties, structure and its interfaces evolve as functions of the rate and depth of the cycling.

Acknowledgement: The research was supported by the Advanced Battery Materials Research and Battery500 Consortium programs of Vehicles Technology Office within the US DOE’s Office of Energy Efficiency and Renewable Energy; and by the IONICS program of the Advanced Research Program Agency for Energy (ARPA-E).

9:30 AM ES04.06.03
Evaluating Changes at the Li-Metal/Solid-Electrolyte Interface Under Dynamic Stack Pressure Conditions Michael Wang and Jeff Sakamoto; University of Michigan, Ann Arbor, Michigan, United States.

Solid state electrolytes have the potential to enable safe, high energy-density Li metal batteries by serving as a physical barrier against unstable Li plating. Because of the tendency for Li filaments to propagate through the solid electrolyte and short circuit the cell at high current densities, significant emphasis has been placed on studying the kinetics and mechanisms of the plated Li-electrolyte interface. However, as the mechanics of the Li-metal/solid-electrolyte interface are drastically different from conventional Li-ion batteries, there is a continued need to understand the behavior of both Li metal stripping and plating. The present work evaluates the electrochemical behavior at the interfaces under dynamic stack pressure conditions. Using a novel mechanical testing apparatus in an inert environment, symmetric Li-electrolyte cells are studied under dynamic loading and electrochemical cycling conditions. Li₂La₂Zr₂O₇ (LLZO) garnet electrolytes are used as a model system, given the ability to achieve low interface resistances (~10Ω cm²) and stably plate Li at relatively high current densities. Using a combination of AC and DC methods, it is demonstrated that deviation from Ohmic behavior during constant current cycling occurs at a “critical stack-pressure” and is a result of surface roughening primarily at the Li stripping electrode. Changes in the interfacial resistance on the Li stripping electrode suggest the presence of Kirkendall voids which form when there is insufficient stack pressure to replenish the supply of Li being dissolved at the interface. The results further motivate the need to understand the coupled electrochemo-mechanical behavior of the Li-metal/solid-electrolyte interface and identifies stack pressure as an important design parameter for future solid-state batteries.

9:45 AM ES04.06.04
Garnet Based Solid Electrolyte Lithium-Ion Battery for Safe Energy Storage Application Samuel Dantuah, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, Chesapeake, Virginia, United States.

Fast-ion-conducting garnet-type solid electrolyte could influence solid-state battery chemistries with desirable performance and safety. In addition, it is environmentally stable and has an electrochemical window wide enough to overpower surplus electronic transport. However, high interfacial resistance at the electrode/solid electrolyte interface makes it more challenging for commercial use, which consequently, hinders the fast charging and discharging behavior of the battery. This work investigates the reduction of the high interfacial resistance at the electrodes/solid electrolyte interface using a garnet material Li₆La₂Zr₂(CO₃)₂Zr₂Ti₅Nb₂O₁₉ (LLCNN) synthesized by a wet chemical technique and ultrathin hafnium oxide (HfO₂) by atomic layer deposition technique. A remarkable reduction of the interfacial impedance was noticed at room temperature. The structure and surface morphology of LLCNN and HfO₂ were characterized by X-ray diffraction (XRD) and FESEM respectively. Interestingly, field emission scanning electron microscope (FESEM) images show the porosity of the electrolyte which helps for the easy movement of charged ions through the electrolyte. The electrochemical performance of the battery shows outstanding performance with large charge storage capability. The battery shows improved capacitance with higher number of charging and discharging cycles. This improvement in the rate ability is a result of the reduction in the interfacial impedance. This work is supported by the NSF-CREST (CREAM) Grant Number HRD 1547771, and NSF-CREST (CNBMD) Grant number HRD 1036494.

Unexpected Opportunities in Stabilizing Lithium Metal Anodes Using Soft Solid-Ion Conductors Brett Helme1, Chengyin Fu1, Andrew Ellis1, Zeeshan Ahmad2, Victor Venturi2 and Venkat Viswanathan1; 1Lawrence Berkeley National Lab, Berkeley, California, United States; 2Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.
The realization of a low-cost, safe, reversible, high-area capacity lithium metal electrode for solid-state batteries has remained elusive despite ongoing advances in anode protection using ion-conducting ceramics and glasses as well as organic and inorganic passivating layers. Here, we will outline a framework to understand the successes and failures of these differentiated materials platforms on the basis of their mechanical properties, transport properties, and partial molar volume considerations for solid-ion conductors relative to the lithium anode. Within this framework, I will also highlight an unexpected opportunity for suppressing lithium metal dendrites using soft solid-ion conductors. I will then detail the extent to which these predictions deliver on their promise, from early-stage discovery science and in-depth synchrotron hard x-ray techniques to platform maturation from coin cells to pouch cells.

10:45 AM ES04.06.06
Dendritic Growth in Lithium-Based Batteries Aarun Jair
Sang Im Woo, Karra S. Vikrant and Edwin Garcia; Purdue Univ, West Lafayette, Indiana, United States.

Lithium dendrite growth is one of the grand challenges in the design of high energy rechargeable lithium-ion batteries. “Dendrites” are undesired elongated metallic nanostructures that form on the anode during fast charging. Upon battery cycling, they grow towards the cathode causing short-circuits and other catastrophic failures (including fires) in portable electronic devices and electric vehicles. A computational framework based on the Phase Field Method has been developed to couple lithium electrodeposition kinetics on the anode with the inherent mechanical behavior of metallic lithium. The framework provides a means to provide detailed insight on the time-dependent, spatially heterogeneous electrical, chemical, and mechanical driving forces during electrodeposition that are otherwise difficult to visualize through experiments. The different mechanisms observed during classical electrodeposition and those previously unidentified are predicted and rationalized through this framework as a stepping stone to design safer, high energy density devices.

11:00 AM ES04.06.07
Mechanisms of Critical Current Densities in Solid Electrolytes for Preventing the Lithium Metal Penetration Peng Bai and Jizhao Guo; Washington University in St. Louis, St. Louis, Missouri, United States.

Li-ion batteries are currently the most energy-dense battery technology. If the intercalation anode (e.g. graphite) can be completely removed and Li ions stored in the intercalation cathode can be reduced into a thin film of Li metal anode during recharge, the energy density of the state-of-the-art Li-ion battery will be nearly doubled. However, the formation of Li metal anode in liquid electrolytes has been plagued by the dendrite penetration and low cycling efficiency for decades [1,2]. While solid electrolytes in principle could solve both problems, recent studies revealed that Li metal dendrites can easily penetrate the garnet Li$_2$Zr$_2$O$_7$ (LLZO) solid electrolyte at current densities lower than 1 mA cm$^{-2}$ [3-12]. This relatively low critical current density (CCD) prohibits the battery using solid electrolyte from fast charging, therefore will significantly limit the application, especially for electric vehicles. Accurately understanding the mechanisms of CCD has become an urgent need for designing high-rate, dendrite-proof solid electrolytes. In this study, we first analyzed 16 sets of reported experimental data, and discovered for the first time a linear relationship between the CCD, $J_{lim}$, and the thickness of the solid electrolyte pellet, $L$, i.e. $J_{lim} \propto \sigma_{metal}/L$. This linear relationship resembles the proved limiting current in liquid electrolytes, i.e. $J_{lim} \propto D_{L,L,L}/L$ [1], suggesting that the solid electrolyte may also have a limiting current, even though prevailing understandings prefer that the near unity transference number ensures an infinitely high limiting current. Inspired by the electrochemical methods used in studying lithium electrodeposition in liquid electrolytes, further investigations of the transport properties of LLZO solid electrolytes led to the discovery of the limiting current in the $L$-$V$ curve, which is consistent with the CCD discovered from the standard constant current cycling. Quantitative explanations and a simple mathematical model were provided to better understand the mechanisms of the CCD.

Mechanical Properties of Metallic Sodium and Metallic Lithium Anodes Coleman D. Fincher, George M. Pharr and Matt Pharr; Texas A&M University, College Station, Texas, United States.

Room temperature metallic anodes possess potential to enable batteries with enormous capacity. Lithium metal is known as the “holy grail” of anode materials, as it has the highest theoretical capacity, lowest density, and most negative electrochemical potential of known anode materials for rechargeable batteries. However, dendrites of lithium form during repeated cycling, posing a significant safety hazard. Sodium has similar safety concerns and a much larger sized ion than lithium (1.02 Å versus 0.59 Å), leading to generally comparatively worse kinetic performance. Despite their issues, sodium metal anodes have recently received increased attention due to sodium’s natural abundance and relatively low cost. A comprehensive understanding of both lithium’s and sodium’s mechanical properties is vital in designing solid-state electrolytes to mitigate dendritic growth. Through nanoindentation and bulk tensile testing, we explore the mechanical properties of the metallic sodium and lithium anode.

11:30 AM ES04.06.09
Mechanistic Origins of Lithium Plating with Solid Electrolytes Aashutosh Mistry and Partha P. Mukherjee; Mechanical Engineering, Purdue University, West Lafayette, Indiana, United States.

Solid electrolytes are advocates for next-generation lithium batteries given their conformity against lithium metal anodes. Intuitively the mechanical stiffness of the solid electrolytes should discourage irregular lithium deposition. However, often lithium dendrites are found to form in solid electrolytes. We find that the solid electrolytes defy the conventional wisdom of electroplating. An irregular lithium dendrite leads to a misfit strain which alters both the reaction kinetics and transport in the solid electrolyte. These competing mechanisms give rise to an interfacial instability, which marks the onset of dendrite formation. Here in we discuss the regimes to promote uniform deposition.

SESSION ES04.07: Solid-Solid Interfaces
Session Chairs: Juan Carlos Gonzalez-Rosillo and Juergen Janek

1:30 PM *ES04.07.01
Enabling All-Solid Lithium-Sulfur Batteries Timothy Arthur; Toyota Research Institute of North America, Ann Arbor, Michigan, United States.

To meet the future demands of future hybrid, plug-in hybrid, and all electric vehicles, advances in energy storage for transportation is indispensable. Additionally, energy diversification is vital to tailor electrification requirements to optimize the cost, range and size of the application. Recently, post Li-ion batteries, such as Li-O$_2$, multivalent and anion batteries, have garnered much attention. The lithium-metal/sulfur (Li-S) battery is an exciting system due to its high theoretical capacity (1673 mAh/g) and the potential of low cost. However, realizing Li-S batteries relies on solving key challenges such as dissolution and shuttling of polysulfides, low sulfur utilization at high-areal loading levels,
lithium metal dendrite formation, and continuous electrolyte decomposition on the Li metal surface. The potential benefits of solid-state electrolytes, such as polymer electrolytes, gel electrolytes and ion-conducting ceramics electrolytes, are wide-operating windows, active material dissolution prevention and metal dendrite inhibition. However, low ionic conductivity and interfacial stability require continued development to achieve a viable energy storage system. Recently, ionic conductivities rivaling liquid based-systems have been observed for the sulfide-based, glass-ceramic Li2O/GeS2/LGPS, encouraging continued research into solid-state batteries using sulfide-based solid-electrolytes. Tatsumisago et al. illustrated and impressively initial cycling results using lithium-iodium alloy anode, a lithium iodide/lithium sulfide solid-solution cathode, and a solid sulfide electrolyte: over 1000 mAh/g at 2C cycling for over 2000 cycles. Inspired by the results, developing all solid Li-S (AS-LiS) batteries presents hope for a high-energy density battery.

The major road-block to enabling AS-LiS batteries lies is the capability to utilize lithium metal. Researchers have recently observed the decomposition of sulfide electrolytes in contact with lithium metal, as well as the tendency for the active metal to plate within the electrolyte layer and create electrical shorts. The realization of lithium metal for solid-state batteries will provide the energy needed for future mobility. Here, we will discuss protection strategies to inhibit undesired reactions at the anode-electrolyte interface; including lithium metal surface modification, and additives for the solid-electrolyte separator layer as potential solutions. Realizing lithium metal for solid-state batteries will provide the energy needed for future mobility.

Solid-state batteries (SSBs) have been regarded as promising next-generation Li-ion batteries (LIBs), and promising solid electrolytes (SEs) with higher Li-ion conductivities have been found. However, the high interfacial resistance of Li-ion transport at the electrode-SE interface remains a crucial bottleneck. Although interposing a buffer layer into the interface has been used to remedy this problem in practice [1], the fundamental mechanism is still under considerable debate. We have been exploring the atomistic understanding of this interfacial resistance mechanism with DFT-based calculation approaches [2-3]. So far we have devised some systematic ways for the solid-solid interfaces and discussed possible origins such as the space-charge layer and the reaction layer. However, the sufficient sampling of the solid-solid interface configurations is too cumbersome for deducing any significant statistical and general features of the interfacial Li-ion transport. Hence, we utilized the CALYPSO structure prediction method [4,5] as a calculation technique for the interface structure search, to be combined with mismatch treatment, lateral shift etc.

Here as representative model systems, we applied the above DFT-based calculation technique Li/LCO (LCO = LiCoO2), Li/LPS (LPS = Li3PS4), and Li/NbO2 (LNO) acting as a cathode, a sulfide electrolyte, and a buffer layer, respectively. For the LCO/LPS interfaces, we sampled over 20000 configurations and found several stable disordered structures involving ionization and anion exchange, leading to the formation of a reaction layer. On the other hand, Li-ion sites that can be preferentially depleted upon charging always exist around the cathode-SE interfaces irrespective of the interfacial order/disorder. Therefore, we conclude that the dynamic Li-ion depletion is likely to be a major cause that prevents successive Li-ion transport, leading to the resistance. Through investigating the buffer layer effects and the interfacial electronic states, we also deduced a probable origin for the interfacial Li depletion and a mean to suppress this problematic behavior. In the talk, we will also discuss the related works on anodes and SEI interfaces.

Modeling the Origin of the Interface Resistance in Solid-State Batteries Yue Qi, Michael Swift and Hong Kang Tian; Michigan State University, East Lansing, Michigan, United States.

The major bottleneck for the all-solid-state batteries lies at the high interfacial resistance, which is due to two main factors, physical contact and chemical effect, both will be evaluated via modeling in this talk. First, we devise a model, incorporating atomic electrochemical potentials, thermodynamic stability of bulk electrolyte phases, and point defect formation energies to yield quantitative profiles of the electrostatic potential, lithium chemical potential, and electronic energy levels. This model complements direct microscopic and macroscopic simulations by rigorously and simultaneously determining the potential drop, electrostatic dipole, and space-charge layer at the interface. The application of this model to the Li/LiPON/LixCoO2 system leads to the important discovery that the space-charge layer varies with the state of charge (i.e. Li concentration in LixCoO2). This new physics insight unifies the seemingly contradictory experimental observations and leads to new device design rules to promote interfacial ion transport in future solid-state-batteries. Secondly, we combined contact mechanics with 1D Newman battery model to capture the effect of imperfect electrode/electrolyte interfacial contacts, which can be formed during cell fabrication and worsened due to cycling of solid-state-batteries. Constant current discharging processes at different rates and contact areas were simulated to correlate the capacity drop with the contact area loss. Furthermore, the model suggested how much pressures should be applied to recover the capacity drop due to contact area loss.

Low Temperature Processing Innovation and Structure Design of Li-Garnets for Solid State Batteries and Environmental Sensing of Chemicals Juan Carlos Gonzalez-Rosillo and Jennifer L. Rupp; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Next generation of energy storage and sensors may largely benefit from fast Li+ ceramic electrolyte conductors to allow for safe and efficient batteries and real-time monitoring anthropogenic CO2. Recently, Li-solid state conductors based on Li-garnet structures received attention due to their fast transfer properties and safe operation over a wide temperature range. Through this presentation basic theory and history of Li-garnets will first be introduced and critically reflected towards new device opportunities demonstrating that these electrolytes may be the start of an era to not only store energy or sense the environment but also to emulate environmental data and information based on simple electrochemistry device architecture twists. In the first part we focus on the fundamental investigation of the electro-chemo-mechanical characteristics and design of disordered to crystallizing Li-garnet structure types and their description. Understanding the fundamental transport in solid state and asking the provocative question: how do Li- amorphous to crystalline structures conduct? New insights on degree of glassy to crystalline Li-garnet thin films are presented based on model experiments of the structure types. Here, the thermodynamic stability range of maximum Li-conduction, phase, nucleation and growth of nanostructure is discussed using high resolution TEM studies, near order Raman investigations on the Li-bands and electrochemical transport measurements. In a second part, we focus on new processing opportunities to Li-garnet thin films in crystalline state and to assure cubic and fast conducting garnet structures for thin film form. For this we will review the field of thin film processing and structure-property for garnet type thin films and reflect our recent new processing routes based on vacuum and wet-chemical techniques. The insights provide novel aspects of glass and ceramic thin film processing and material structure designs for both the Li-garnet structures (bulk to films) and their interfaces to electrodes, which we either functionalize to store energy for next generation solid state batteries or ... make new applications such as Li-operated CO2 sensor tracker chips which we present in a final part.

An Analysis of Kinetics at the Solid Polymer Electrolyte/Lithium Lanthanum Zirconium Oxide Electrolyte Interface Arushi Gupta and Jeff Sakamoto; University of...
Polymer-Lithium Lanthanum Zirconium oxide (LLZO) composites have gained traction as a promising candidate to be used as electrolytes for solid state batteries. They can exhibit high ionic conductivity and suitable mechanical properties owing to the complementary characteristics of the ceramic and polymer respectively. However, without intervention, the polymer-ceramic interface is highly resistive. Thus, to achieve facile ion transport across the polymer-ceramic interface it is necessary to minimize the interfacial resistance. We hypothesize that two important factors which limit the interfacial kinetics between the two electrolyte faces: 1) surface impurities on the LLZO electrolyte and 2) a large disparity in charge carrier concentration the polymer electrolyte (Polyethylene oxide (PEO)-LiTFSI) and LLZO.

Firstly, we studied the effect of the LLZO heat treatment (HT) temperature on the interfacial impedance between LLZO and PEO-LiTFSI (27:1 [EO]/[Li]+ ratio) using a trimilaniar PEO-LiTFSI/LLZO/PEO-LiTFSI cell configuration. We determined that the interfacial impedance decreased exponentially with increasing LLZO HT temperature. Secondly, we believe that by increasing the Li concentration we would facilitate charge transfer at PEO-LiTFSI/LLZO interface. For this we studied the effect of Li salt concentration in the polymer electrolyte on the interfacial impedance, observing that the interfacial impedance decreases with increasing salt concentration. We achieved an interfacial impedance value of ~390 Ohms cm² at the optimal [EO]/[Li]+ salt concentration.

With the results from the two studies, we believe we can further lower the interfacial impedances, achieve facile Li ion transport across the PEO-LiTFSI/LLZO interface and thereby, enable the development of composite electrolytes with high room temperature ionic conductivities.

4:00 PM ES04.07.06
Degradation Mechanisms in All-Solid-State Li-S Batteries with LiPSCl and Their Optimization Sanevuki Ohno, Georg Dewald, Juergen Janek and Wolfgang Zeier; Justus Liebig University Giessen, Giessen, Germany.

While the demand for batteries with a high energy density is rapidly growing, the currently commercially available Li-ion battery chemistry is approaching a theoretical limit. To overcome this issue, Li-S batteries exploiting the conversion reaction between sulfur and Li+S have been attracting significant attention as a promising candidate for next-generation batteries. The history of the development of conventional Li-S batteries has involved the fight against the notorious shuttle effect caused by polysulfides dissolved in the liquid electrolyte. However, employing solid electrolytes as a separator can mitigate the occurrence of this polysulfide shuttle. Indeed, solid-state Li-S batteries composed of Li-ion conducting thio-sphosphates (e.g. Li5PS4Cl), exhibit no evidence of the shuttle effect.

Nevertheless, there are still several major challenges hindering the development of batteries exhibiting a high capacity and good capacity retention. In this study, the mechanisms of short-term and long-term capacity fade within solid-state Li-S batteries employing LiPS2Cl are investigated. The cause of a crucial capacity loss observed after the initial discharge is elucidated and overcome using a facile cathode processing method, thereby resulting in a specific capacity of over 1000 mAhg−1. The degradation process affecting the battery performance during long-term cycling are also investigated. Using the results from our investigations toward the optimization of the aforementioned battery architecture, we were able to achieve a specific capacity of 700 mAhg−1 after 100 cycles. A deeper understanding of the underlying chemistry influencing crucial degradation mechanisms will enable further enhancements of both the capacity and cyclability of solid-state Li-S batteries.

Interface Stability Between Solid-State Electrolytes and Cathodes in Lithium-Ion Batteries Jung-Hyun Kim1, Chan-Yeop Yu1, Jun-Bin Choi2 and Venkataramani Anandar1; 1Mechanical and Aerospace Engineering, Center for Automotive Research, The Ohio State University, Columbus, Ohio, United States; 2Energy Storage Research Department, Ford Motor Company, Dearborn, Michigan, United States.

Although lithium-ion (Li-ion) battery is one of the most successful energy storage devices, especially for electric vehicle (EV) applications, it retains a thermal runaway risk that stems from the presence of flammable liquid electrolytes made of organic solvents. To overcome this challenge, significant research efforts have been recently devoted on the development of new ceramic electrolytes that can replace the flammable liquid electrolyte and yield an all-solid-state Li-ion batteries. Among various solid electrolytes investigated, Li1.25Al0.75La2Zr1/3Ta1/3O2 (LLZT) with garnet structure and Li1.25Al0.75Ti1/3P0.5 (2P0.5) (LATP) in NASICON family showed great promises due to their stabilities in air, high-voltage stability, good mechanical properties, and reasonable Li-ion conductivity (10−2 − 10−3 S/cm).

Despite the significant progress in discovering new ceramic electrolytes with promising Li-ion conductivity, a ceramic-based solid-state battery is not commercially available today. The main barrier for a scale-up of solid-state batteries as practical power sources is the instability of electrode-ceramic electrolyte interface and the consequent premature cell-failure. In particular, the fabrication processes of solid-state batteries involve high-temperature heat-treatment to obtain good adhesions between ceramic components. During the sintering process, unwanted elemental inter-diffusion between the electrodes and electrolytes can occur and form secondary phases at interfaces, which often impede the transportation of Li-ions at the interfaces.

In this presentation, we will report our recent systematic study on the interface stability between solid-state electrolytes (e.g., LLZT or LATP) and conventional cathodes in Li-ion batteries including various chemical compositions and crystal structures (e.g., LiCoO2, LiNiO2, LiNi0.05Co0.95Mn0.03O2, LiNi0.5Mn0.15O2, and LiFePO4). First, we investigated high-temperature phase stabilities between solid-electrolyte and cathode composites, characterized by X-ray diffractionometer (XRD) and Rietveld refinement in a temperature range of 500 – 900°C in air. By identifying crystalline phases at each temperature, we can find (1) on-set temperatures of unwanted side-reactions between solid-electrolytes and cathodes, (2) types of secondary phases and their evolutions depending on temperature, and (3) fundamental reaction mechanisms between different types of solid cathodes and electrolyte materials. In addition to the thermodynamic stabilities at interfaces, we will present the effect of interface stability and microstructure on the electrochemical performances at cathode/solid-electrolyte interfaces. From electrochemical impedance spectroscopy (EIS) and adhesion test combined with scanning electron microscopy (SEM), increasing a sintering temperature offers a trade-off between good adhesion of cathodes and interface stability, which significantly impacts the electrochemical performances of solid-state Li-ion batteries. Therefore, by exploring the phase stability – microstructure – electrochemical performances relationship, we can find the optimal sintering conditions of cathode/solid-electrolyte interfaces.

The results from our systematic study will be essential in determining processing parameters of solid-state Li-ion batteries. Moreover, understanding the fundamental reaction mechanisms between solid-electrolytes and cathode materials will be a prerequisite for a design new solid electrolyte – cathode interfaces in future studies.

4:30 PM ES04.07.08
Enhanced Grain Growth Kinetics in Polycrystalline Li5.25Al0.75La2Zr1/3Ta1/3O2 Solid Electrolyte Regina Garcia-Mendez and Jeff Sakamoto; Materials Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States.

The demand for vehicle electrification has created the impetus to develop energy storage technology beyond Li-ion. One approach involves the use solid electrolytes to enable metallic Li anodes, pushing energy densities to 1200 Wh/L. However, the ability to plate Li metal at relatively high current densities (~3 mA/cm²), has not been demonstrated using solid electrolytes. Moreover, it was reported [1] that in polycrystalline solid electrolyte such as Li5.25Al0.75La2Zr1/3Ta1/3O2 (LLZO), Li preferentially deposits intergranularly. We hypothesize that the maximum Li plating rate (or critical current density – CCD) is strongly correlated to the existence of microstructural defects, such as grain boundaries, as
interest in solid-state electrolytes has grown rapidly in recent years owing to the desire to utilize Li metal anode for improved specific energy density and the inherent safety advantage of a non-flammable solid state electrolyte. A practical solid electrolyte for energy storage must be a fast ion conductor, have negligible electronic conductivity, high relative density and adequate chemical and electrochemical stability with electrodes. For ease of manufacturing and potentially higher power capability we have focused research on oxide ceramic electrolytes. This work will cover our work on the synthesis and characterization of NASICON, perovskite, garnet and newly emergent structural families including how to stabilize the most conductive phase and maximize the ionic conductivity through substitutional chemistry. We will discuss materials synthesis, ionic/electronic conductivity, mechanical properties, Li/water stability and the results will be compared and contrasted for varied structural families of Li-ion solid electrolyte conductors.

**Adapting Materials Processing and Structure Toward Improved NaSICON-Based Sodium Ion Conductors**

Creating new, high conductivity, zero-crossover solid state separators is central to the advance of emerging solid state and other high energy density batteries. In particular, we are synthesizing sodium ion conductors could enable new classes of low cost, high performance systems. Here, we focus on recent progress advancing sodium ion conductors based on materials such as NaSICON or β'-alumina, which typically require elevated temperatures (~250-350°C) for optimal ionic conductivity. Lowering the usable temperature of these materials makes them much more practical for applications such as solid-state batteries. NaSICON ceramics, in particular, are recognized for potential as room temperature sodium ion conductors, and here we highlight our efforts to tailor the composition and structure of NaSICON-based solid state separators for use in ambient or near-ambient applications. We not only explore how variations in NaSICON chemistry can affect conductivity, but also how processing these materials into hybrid architectures and composite materials promises improvements in separator conductance and overall separator performance. We specifically discuss material design, processing, and characterization of separator properties, focusing not only on ionic conductivity, but also on challenges to mechanical behavior and chemical stability of these materials that affect battery safety and long term performance. These emerging solid state separators offer great promise toward a new class of robust and reliable energy storage technologies.

**On Thin-Film LLZO Electrolytes for All-Solid-State Batteries**

Jordi Sastre-Pellicer¹, Agnieszka Priebe², Ayodhya N. Tiwari³, Yaroslav E. Romanyuk⁴ and Stephan Buecheler¹; ¹Laboratory for Thin Films and Photovoltaics, Empa - Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, Switzerland; ²Laboratory for Mechanics of Materials and Nanostructure, Empa-Swiss Federal Laboratories for Materials Science and Technology, Thun, Switzerland.

The concept of all-solid-state Li-ion batteries has gained broad attention in recent years as it has the potential to overcome the energy density and safety limitations of the nowadays widely used Li-ion batteries based on liquid electrolytes. Thin film manufacturing opens up the possibility of further enhancing volumetric and gravimetric energy densities by reducing the amount of inactive materials, lower the costs of production, and enable new applications, like on-chip batteries.

Garnet-type Li₁₀.₃La₂Zr₂O₁₂ (LLZO) electrolyte is a promising ionic conductor, for the development of all-solid-state thin-film batteries. While high ionic conductivities (above 1 mS/cm) have been demonstrated for bulk material in pellet form, processing LLZO in the form of thin films still poses some challenges. Ionic conductivities reported so far are generally much lower than those of the bulk material, densities and conformability are difficult to achieve at the limited sintering temperatures required.

In our work we investigated LLZO thin films deposited by co-sputtering from LLZO, Li₂O and Al₂O₃ targets, and subsequently annealed under a controlled oxidizing atmosphere. In this work, the LLZO thin films were sputtered onto 200 μm thick Si wafers at 100 °C, and annealed in a muffle furnace at 300 °C, 500 °C, and 700 °C. The thickness of the LLZO thin films was measured using a surface profilometer. The density of the LLZO thin films was determined using Archimedes’ method. The ionic conductivity of the LLZO thin films was measured using a four-point probe technique.

In our contribution we will present successful approaches to increase the ionic conductivity of LLZO thin films above 10⁻² S/cm and achieve higher density, uniformity and surface stability, which are key attributes necessary for the implementation of a LLZO-based thin-film battery with a metallic Li anode. In particular, we will discuss how we tackled common challenges in the fabrication of thin-film ceramic Li-ion electrolytes: the stabilization of highly conductive phases at room temperature, the compensation of Li losses during annealing, the densification of the films at relatively low temperatures, and the mitigation of moisture-induced surface degradation.

route to obtain garnets with both particle size and high ionic conductivity. Acting as high temperature solvents, molten salts present a large design space wherein the properties of the salt melt can be finely tuned to present desirable properties in the as-synthesized material. Further, modifying the basicity of the salt melt enables simultaneous substantial reduction in the formation temperature of complex oxides, which is expected to drastically lower the energy cost of synthesis of lithium conducting garnets. However, the increased complexity of chemistry in molten salts presents a non-trivial challenge, requiring finer tuning of both the molten salt medium and precursors to take full advantage of the benefits offered by MSS to obtain pure material. In particular, relative solubility of reagents as well as the stability of LLZO in a given salt melt have substantial implications on crystal chemistry, phase purity, and performance. The work described herein explores a wide range of salt media including ‘neutral’ media (e.g. molten halides) and basic media (e.g. molten oxoalts), as well as the effect of certain additives, in the synthesis of lithium conducting garnets. Design principles for formation of doped and co-doped LLZO are discussed, wherein salt and reagent composition have direct effects on the formation temperature, particle size, particle size distribution, and electrochemical performance of the as-synthesized material. Depending on the choice of salt medium, powders consisting of single-crystals of LLZO with tunable particle size between 0.5 to 20 μm can be obtained at temperatures as low as 500 °C, while maintaining high ionic conductivity, demonstrating the versatility of the MSS approach for this crucial class of ionic conducting materials.

9:15 AM ES04.08.05 Computational Study of Lithiation of Ba-Doped Type I Si/Ge Clathrates Xiaohong Peng1, Andrew Doplilka1, Qun Wei1,2 and Candace K. Chan1; 1Arizona State University, Mesa, Arizona, United States; 2Physics and Optoelectronic, Xidian University, Xi'an, China.

Types I and II Si and Ge clathrate materials have recently been studied for their electrochemical properties as anodes for lithium-ion batteries due to their unique cage structures and ability to incorporate extrinsic guest atoms. First-principles density functional theory (DFT) calculations were performed to investigate the type I Si and Ge clathrate compounds with and without the guest Ba atoms to understand the optimal structural configurations of small degrees of lithiation and Li diffusion paths inside the clathrates. The studied structures include Si60, Li,Na16Si64, Li,Na16,As8,Na16 and Li,Na16Ge43. The results showed that Li insertion into framework or Ba vacancies could stabilize the clathrate structures. Substitution of Si network atoms by Al lowered the formation energies of the lithiated compounds and mitigated the calculated volume increase upon lithiation. The results also showed that it is energetically feasible for multiple guest atoms to be placed in the Si60 cages. For Ba-doped Ge clathrates, it was found that Li insertion into the three framework vacancies in BaGe43 is energetically favorable, with a calculated lithiation voltage of 0.77 V versus Li/Li+. However, the high energy barrier (1.6 eV) for Li diffusion between vacancies and around Ba guest atoms suggests that framework vacancies are unlikely to significantly contribute to lithiation processes unless the Ba guest atoms are absent. The results from this study can elucidate the preferred structural configurations for Li in type I, Ba-doped Si and Ge clathrates and also be informative for efforts related to understanding the structures obtained after electrochemical insertion of Li into the clathrates.

9:30 AM BREAK

10:00 AM ES04.08.06 Electron Microscopy for All-Solid-State Batteries—Addressing Challenges at Atomic Scale Miaofang Chi; Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

All solid-state batteries are considered as one of the primary battery configurations that offers cost-effective and efficient energy storage. Recently, several solid electrolyte materials have been developed that exhibit ionic conductivities that are equivalent to that of organic liquid electrolytes. Low ion conductivities that were previously believed to be the major issue impeding the use of solid electrolytes are no longer the bottleneck. Rather, their interfaces are frequently found to limit the performance of all solid-state batteries. These interfaces include both internal interfaces such as grain boundaries and the interfaces between two electrolytes if the solid electrolyte is a composite or a multilayered material. The associated challenges now include electronic conductivity, mechanical integrity, chemical, and electrochemical instabilities that result in limited current densities, inadequate cyclability, and dendrite growth. These phenomena, however, are challenging to characterize and understand since they are often spatially confined and embedded. Owing to its atomic-level spatial resolution for both imaging and spectroscopy, scanning transmission electron microscopy (STEM) is now a primary technique for addressing the challenges in such studies. This talk will focus on introducing how we use state-of-the-art atomic-resolution STEM and electron energy loss spectroscopy (EELS) to understand the complex phenomena at interfaces in all solid-state batteries. I will also introduce emerging STEM techniques, such as 4D-STEM based differential phase contrast (DPC) imaging and vibrational spectroscopy, and discuss how these methods can benefit research of solid-state ionic materials. I will touch on the importance of understanding synthesis mechanisms regarding interfaces by highlighting examples of our recent work aimed at elucidating synthesis and processing mechanisms of solid electrolytes using in situ electron microscopy and neutral scattering. This work was sponsored by the U.S. Department of Energy (DOE), Office of Science, Basic Energy Sciences, the Materials Sciences and Engineering Division, and was performed at ORNL’s Center for Nanophase Materials Sciences (CNMS), which is an Office of Science User Facility.

10:30 AM ES04.08.07 Green Synthesis of Size-Controlled Li,S Nanocrystals for Use in Solid State Batteries Yangzhi Zhao, Kristen Hietala, Yongan Yang and Colin A. Wolden; Colorado School of Mines, Golden, Colorado, United States.

Lithium sulfide (Li,S) nanocrystals (NCs) are critical materials used to produce solid-state electrolytes and cathodes for emerging battery technologies. Li,S is typically produced by high temperature carbothermal reduction that creates powders, which then require extensive ball milling to produce the nano-sized materials desirable for battery applications. We have recently developed a solution-based synthesis of Li,S nanocrystals by contacting metalorganic solutions with hydrogen sulfide at ambient temperature, employing bubble columns for scalable production. Additional benefits include complete abatement of H2S and recovery of the valuable H2 stored within. Control of nanocrystal size and uniformity is demonstrated through choice of solvent and manipulation of processing conditions such as precursor concentration and solvent evaporation rate. X-ray diffraction (XRD), small angle X-ray scattering (SAXS), and scanning electron microscopy (SEM) were used to quantify crystallinity, particle size distribution (PSD), and morphology, respectively. These complementary techniques confirmed the production of anhydrous, phase-pure Li,S nanocrystals with tunable size (5-40 nm) and narrow PSDs. Mild annealing conditions were identified that provide the purity required for battery applications, while retaining the original PSD. These materials were used to synthesize simple cathodes and solid-state electrolytes to validate their electrochemical properties. Li,S cathodes fabricated using NCs (<10 nm) achieved capacities approaching the theoretical limit (1166 mAh/g), exhibiting good rate capability and promising stability. Control of size is also expected to provide many benefits for solid-state electrolyte production including reduced thermal budgets, improved ionic conductivity, and minimized interfacial resistance. Studies are underway to fabricate Li,S-P,S cathode electrolytes, where it has already been shown that the use of NCs dramatically shortens the ball mixing time required to create the glassy phase relative to commercial powders. We will report on the electrochemical performance of these electrolytes and the integration of these materials in solid-state architectures.

10:45 AM ES04.08.08 Unusual Temperature Dependent Li-ion Conductivity and Influence of Air Exposure on NASICON-type Solid Electrolyte Hirotoshi Yamada1, Taiki Nakamura1, Eiisuke Magome2 and Tomoko Ito1; 1Nagasaki University, Nagasaki, Japan; 2Saga Light Source, Tosu, Japan.

Some of lithium-ion conducting solid electrolytes with rather high ionic conductivity exhibit high sensitivity to air. It is well known that sulfide-based ones hydrolize. Even oxide-based ones, garnet-type lithium ion conductors react with air, resulting in formation of LiOH and Li2CO3 on their surface and deterioration of conductivity. Among them, NASICON-type solid electrolytes, such as LiAl1/2Ti1/2(PO4)3 (LATP), have been supposed to be stable in air. In this study, we have found that unusual temperature-dependent ionic conductivity of LATP: ionic conductivity showed negative activation energy from 0 to ~15°C on cooling. Detailed studies using high-frequency electrochemical impedance spectroscopy and synchrotron X-ray diffraction confirmed that the unusual temperature-dependence is due to the change in grain boundary resistance, while bulk (inner grain) resistance exhibits monotic temperature dependence. In addition, this unusual temperature dependence of the grain boundary resistance disappeared after the specimen was annealed in inert atmosphere. Based on all results, it is proposed that the atmosphere dependent grain boundary resistance was due to the depletion layer formed on the surface and along the grain boundary. This work conclude that even NASICON-type solid electrolytes is not stable in air.

11:00 AM ES04.08.09 Dense, Melt Cast Sulfide Glass Electrolyte Separators for All-Solid-State Li Metal Batteries Thomas A. Yersak, James R. Salvador, Nicholas P. Piesczonka and Mei Cai; Chemical and Materials Systems Lab, General Motors Global R&D, Warren, Michigan, United States.
According to consulting firm, Wood Mackenzie Power & Renewables, more than $500 million was invested in solid-state battery technology in 2018; double that of all previous years combined [1]. At the moment, it may be argued that sulfide solid-state electrolytes (SSEs) have the best combination of performance and manufacturability. Accordingly, ongoing work at General Motors Global R&D is concerned with the development of processing technology for sulfide SSE separators and evaluating how different processing methods affect SSE separator performance. In this presentation, we will compare the properties and performance of sulfide SSE separators made by cold pressing versus melt casting.

The manufacture of prototype bulk all-solid-state Li-ion batteries by a conventional slurry casting method has already been demonstrated [2]. However, the promise of doubling energy density with solid-state technology will only be realized with a Li metal anode. Unfortunately, the slurry cast/cold pressed separators used in all-solid-state Li-ion batteries may have upwards of 10 - 15 % porosity since they are analogous to green-tape ceramics. It has been shown that Li deposits penetrate porous cold compacted sulfide SSE separators, which results in cell failure by shorting [3,4]. Consequently, robust charging of bulk all-solid-state Li metal batteries is limited to elevated temperature and/or low C-rate.

LiF dopants have been shown to improve the resistance of cold-compacted sulfide SSE separators towards Li penetration [4]. However, Porz et al. suggest that dense sulfide glass SSE may fully block Li deposits [5]. The data presented here are the first to show, at a device scale, that dense sulfide glass SSE separators are effective at blocking the penetration of Li metal deposits. Monolithic glass wafers 4-5 cm² in diameter and 400-500 microns thick with a nominal composition of (Li₂S₀.6(Si₂S₆)₀.4(P₂S₇)₄) were made by melt casting. This glass composition was chosen as a compromise between glass formability and stability versus Li metal; the Si₂S₆ co-former reduced melt volatility while the P₂S₇ co-former increased the glass’ stability versus Li metal. Symmetric Li | SSE | Li cells were made to measure separator ionic conductivity and critical current density (CCD), the current density at which shorting failure is evident. The resulting melt cast glass had an ionic conductivity of 1.8 mS/cm and a CCD of 1,800 μA/cm² at room temperature. For comparison, porous separated formed by cold compaction of the same glass powder have an ionic conductivity of 0.81 mS/cm and a CCD of only 400 μA/cm² at room temperature. The lower conductivity of the cold compacted separator suggests that percolation and interparticle impedance of sulfide glass electrolytes is significant. Consistent with previous findings, the primary cause of shorting for the cold compacted separator was deposition of Li metal through interparticle porosity. On the other hand, the primary cause of shorting for the melt cast glass wafer was stack pressure induced macroracking and subsequent Li deposition through the crack. Our work suggests that dense sulfide SSE separators may prove appropriate for Li metal batteries so long as Li/SSE interfacial contact can be maintained at low stack pressures.

Designing Polymer/Ceramic Composite Electrolyte for Solid–State Lithium Batteries Yuan Yang; Columbia University, New York, New York, United States.

Solid state batteries are attractive for next-generation energy storage as they could provide better safety and higher energy density. There are two major categories of solid electrolytes: ceramic electrolytes and polymer electrolyte. While ceramic electrolytes have high ionic conductivity, they have large interfacial resistance with electrode materials. On the other side, polymer electrolyte has low ionic conductivity, but compatible with state-of-the-art manufacturing process. An attractive approach is to combine polymer and ceramic electrolyte together to combine advantages of both. In this talk, I will discuss recent work in my group to enhancing performance of composite electrolyte-based solid state batteries, which includes 1) vertically aligned ceramic electrolyte in PEO Polymer electrolyte, which enhances ionic conductivity by more than a factor of 3, and reasonable density at which shorting failure is evident. The corresponding LiFePO4/Li cell can be cycled for over 400 cycles with high capacity retention. 2) stabilization of PEO with 4V layered oxide cathode. By optimizing surface coating and electrolyte composition, the cycle life is significantly improved compared to bare layered oxides.

SESSION ES05.01: Heterogenous Catalysts
Session Chair: Huiyuan Zhu
Tuesday Morning, April 23, 2019
PCC North, 100 Level, Room 122 B

10:30 AM *ES05.01.01
Metal-Support Cooperativity in Highly Dispersed Re Catalysts for Olefin Metathesis Susannah Scott¹, Fan Zhang², Mostafa Taoufik², Kai Szeto³, Régis Gauvin¹ and Laurent Delevoye;¹University of California, Santa Barbara, Santa Barbara, California, United States; ²CPE-Lyon, Lyon, France; ³Université de Lille, Lille, France.

Heterogeneous olefin metathesis catalysts are made by dispersing a mid-transition metal oxide on an "inert" support such as silica-alumina or alumina. However, the support is an essential part of the catalyst; no metathesis is observed in its absence. Moreover, the activity and stability of the catalyst depends strongly on the choice of support, including its
crystallinity and Lewis/Bronsted acidity. The origin of the cooperativity between support and active site was investigated by spectroscopic characterization of dispersed Re(VII) sites, including advanced NMR characterization methods. The number of active sites is limited by the availability of certain strong Lewis acid sites which are identified as five-coordinate Al centers. The lifetime of these sites is a function of their distance from hydroxyl groups, both terminal and bridging. A rapid deactivation process is attributed to the presence of local hydroxyls, while a slower deactivation process is associated with mobility of the active sites which brings them into proximity with hydroxyl groups. These insights allow us to design more effective metathesis catalysts with greatly improved activity and productivity.

11:00 AM ES05.01.02
Generation of Subnanometric Metal Species in Zeolites and Their Catalytic Applications
Lichen Liu and Avelino Corma; Instituto de Tecnología Química, Valencia, Spain, Spain.

Single metal atoms and metal clusters have attracted much attention thanks to their possibility as heterogeneous catalysts.[1,2] However, the generation of stable single atoms and clusters on a solid support is still challenging.[2] Recently, we report a new strategy for the generation of single Pt atoms and Pt clusters with exceptionally high thermal stability, formed within purely silicious MCM-22 during the growth of a two-dimensional precursor of the zeolite into three-dimensional structure.[4] These subnanometric Pt species are stabilized in the zeolite, even after treatment in air up to 540 °C. Furthermore, we have studied the dynamic structural transformation of those subnanometric Pt species during reduction-oxidation treatments and under reaction conditions (CO+O2, water-gas shift, NO+CO and NO+H2) by environmental transmission electron microscopy (ETEM).[5]

The Pt/MCM-22 was prepared by the transformation of 2D into 3D zeolite, using purely silicious H-ITQ-1 as precursor. In situ electron microscopy experiments were performed using a Titan 80-300 Environmental Transmission Electron Microscope at the Centre for Functional Nanomaterials (CFN), Brookhaven National Laboratory. Subnanometric Pt species are finely dispersed in MCM-22 crystals. With the help of aberration-corrected electron microscopy, we are able to directly measure the size of those Pt species and figure out their position in the zeolite. Some of the Pt atoms and clusters are located in the surface “cups” of MCM-22 and some of them are anchored to the zeolite framework. Nevertheless, a large part of subnanometric Pt species are located in the internal space of the structure, which is confirmed by the size-selective hydrogenation of propane and isobutane. The exceptional high stability of the encapsulated subnanometric Pt species has also been reflected in the propane dehydrogenation reaction to propylene, showing higher activity and stability than Pt nanoparticles prepared by conventional impregnation method.

Furthermore, using Pt@MCM-22 material as a model system, we have studied the evolution of Pt single atoms and clusters during reduction-oxidation treatments and under reaction conditions by ETEM. Pt nanoparticles and clusters will disintegrate into smaller clusters or even single atoms after calcination in O2. And single atoms and clusters will agglomerate into small particles after reduction by H2. Besides, it can be a general phenomenon that subnanometric metal species will undergo dynamic structural evolution under reaction conditions. For the same reaction, the states of metal species are dependent on the temperature and atmosphere. Our synthesis strategy can also be applied for preparation of Au@MCM-22 and Pd@MCM-22 materials, with subnanometric Au and Pd species encapsulated in MCM-22 zeolite. Those subnanometric metal clusters show unique catalytic behavior for selective aerobic oxidation of cyclohexane to KA-oil and low-temperature combustion of CH4, respectively.

Subnanometric metal species (single atoms and clusters with a few atoms) with exceptional high stability can be generated and stabilized in MCM-22 zeolite. Those subnanometric metal species show dynamic structural transformation during reduction-oxidation treatments and under reaction conditions and also show unique catalytic properties for various reactions.

Oxidation and Hydrolysis of Small Molecules and Organophosphorous Compounds via Thermal and Photocatalytic Pathways at Oxidation-Stable, Plasmonic Cu/TiO2 Aerogels

We stabilize plasmonic Cu nanoparticles by establishing extensive interfacial contact between photodeposited Cu and an anatase TiO2 aerogel support. The three-dimensional (3D) interfacial contact between sub-5-nm Cu nanoparticles and the covalently networked ~10-nm TiO2 particulates that create the aerogel framework stabilizes Cu against oxidation to an extent that preserves the plasmonic behavior of the nanoparticles, even after long-term exposure to ambient air. The Cu nanoparticles entrained in the TiO2 aerogel comprise a metallic Cu core with a shell featuring high fractions of Cu2+ and Cu3+ species, with a small fraction Cu+.

Both the plasmonic character and low oxidation-state speciation of Cu prove critical to several thermal and photochemical oxidation and hydrolytic degradation pathways. The Cu/TiO2 aerogels catalyze oxidation of carbon monoxide (CO) at temperatures as low as ~75 °C at rates comparable to those observed at nanostructured Au/TiO2 materials. Varying the relative amounts of Cu0, Cu+, and Cu2+ in the supported Cu nanoparticles determines the activation energy (Ea) for CO oxidation, with the lower oxidation states driving more efficaciously faster kinetics. In contrast, depositing Cu nanoparticles on commercial anatase powders results in Cu oxide nanoparticles with no detectable Cu+, and much higher fractions of Cu2+: Cu+ than observed when supporting Cu on TiO2 aerogels, resulting in poorer CO oxidation rates.

The Cu/TiO2 composite aerogels also fully hydrolyze the chemical warfare (CW) simulant dimethyl methylphosphonate (DMP) under aerobic and anaerobic conditions. In situ diffuse-reflectance infrared spectroscopy (DRIFTS) shows that all initial reactants and final hydrolysis products identified are bound to TiO2, however, aerogel-expressed anatase TiO2 alone does not hydrolyze DMPM. Excess surface concentration of OH species at Cu/TiO2 aerogels created near Cu/TiO2 junctions drives DMPM hydrolysis.

Finally, we describe the thermal and hydrolytic and oxidative degradation of the organophosphorous chemical warfare (CW) agents Sarin (GB) and Soman (GD) and the enhancement of their degradation by visible-light-driven photoelectrochemical oxidation of methanol under visible-light illumination, which is contrast is not observed for Cu photodeposited at non–networked anatase TiO2 nanoparticles.[1] The Cu/TiO2 aerogels enable us to apply a suite of thermal and photochemical degradation pathways for CW agent decontamination in one composite multifunctional material.

The exceptional activity for Cu-catalyzed oxidations and hydrolysis at a 3D Cu/oxide interface characteristic of aerogel supports highlights the importance of the interfacial design motif on both preserving plasmonic Cu and on driving oxidation and hydrolysis reactions in the dark—conditions requiring most of the promoting effects of the active support oxide to occur in very close proximity to the Cu/oxide interface.

11:30 AM ES05.01.04
Two-Dimensional Transition Metal Carbides as Supports for Tuning the Chemistry of Catalytic Nanoparticles for Effective Shale Gas Dehydrogenation
Yue Wu; Iowa State University, Ames, Iowa, United States.

Supported nanoparticles are broadly employed in industrial catalytic processes, where the active sites can be tuned by metal-support interactions (MSIs). Although it is well accepted that supports can modify the chemistry of metal nanoparticles, systematic utilization of MSIs for achieving desired catalytic performance is still challenging. The developments of supports with appropriate chemical properties and identification of the resulting active sites are the main barriers. Here, we develop two-dimensional transition metal carbides (MXenes) supported platinum as efficient catalysts for light alkane dehydrogenations. Ordered Pt/Ti and surface Pt/Nb intermetallic compound nanoparticles are formed via reactive metal-support interactions on Pt/Ti2C2T and Pt/Nb2CT catalysts, respectively. MXene supports modulate the nature of the active sites, making them highly selective toward C-H activation. Such exploitation of the MSIs makes MXenes promising platforms with versatile chemical reactivity and tunability for facile design of supported intermetallic nanoparticles over a wide range of compositions and structures. This work is recently published online at Nature Communications on December 10, 2018.
Fischer-Tropsch to olefins (FTO) synthesis has drawn significant attention due to the high demand of light olefins as building blocks for the chemical industry, the desire to reduce the dependence on petroleum cracking for these chemicals, and the need for improving environmental sustainability. Iron-based catalysts have emerged as promising FTO catalysts because of their low cost and excellent catalytic performance. We have designed a promising nanocatalyst of porous interconnected carbon nanosheets supported iron oxide nanoparticles for FTO synthesis. The catalysts demonstrate an extremely high iron time yield (FTY) of 1882 μmol/g cata./h with 41% selectivity for light olefins and excellent stability (>100 h time on stream). Our FTY value is found to be one of the highest FTYs and in particular, in 50 to ~1300 times higher compared with those catalysts exhibiting similar light olefins selectivity reported in literature. Mössbauer characterization demonstrates the presence of catalytically active iron carbide species after FTO reaction. *Ex situ* XAFS measurements reveal that the carbon nanosheets support stabilizes metallic iron during the initial catalyst reduction step, which leads to more carbon uptake under FTO reaction conditions to more efficiently form highly active iron carbide phase. In contrast, a control sample with carbon nanotubes as the catalyst support exhibits oxidized iron in the catalyst after removal from H₂ reduction pretreatment, suggesting a substantially reduced stabilizing effect of carbon nanotubes towards supported metallic iron nanoparticles. This results in inefficient formation of iron carbide species under FTO conditions. Additional XAFS results further confirm the buildup of iron carbide phase as a function of time on stream in the carbon sheets supported catalysts, whereas a much smaller portion and negligible growth of iron carbide phase was observed in the carbon nanotube supported catalysts under the same reaction conditions.

Electrocatalysts I

SESSION ES05.02: Electrocatalysts I

Session Chair: Shaojun Guo and Dong Su

Tuesday Afternoon, April 23, 2019

PCC North, 100 Level, Room 122 B

1:30 PM *ES05.02.01 Getting to the Core of the Matter—A Comparison of Core@Shell Nanocatalysts Built from Random Alloy and Intermetallic Seeds Sara E. Skrabalak; Chemistry, Indiana University - Bloomington, Bloomington, Indiana, United States.

Pt catalysts are widely studied for the oxygen reduction reaction (ORR), but their cost and susceptibility to poisoning limit use. A strategy to address both problems is to incorporate a second transition metal to form a bimetallic alloy; however, the durability of such catalysts can be hampered by leaching of non-noble metal components. Here, we show that random alloyed surfaces can be stabilized to achieve high performance and durability by depositing the phase on top of intermetallic seeds. Specifically, random alloyed PtCu shells were deposited on PdCu seeds that were either the atomically random face-centered cubic phase (fcc A1) or the atomically ordered phase (CsCl-like B2). Precise control over crystallite size, particle shape, and composition allowed for comparison of these two core@shell PdCu@PtCu catalysts and the effects of the core phase on electrocatalytic performance. Indeed, the nanocatalysts with intermetallic cores saw only an 18% decrease in activity after stability testing, whereas the random alloy core catalyst saw a 58% decrease. Although many random alloy and intermetallic nanocatalysts have been evaluated, this study is the first to directly compare random alloy and intermetallic cores for electrocatalysis and will facilitate the design of electrocatalysts with high activity and durability.

2:00 PM *ES05.02.02 Heterostructure Interface-Promoted Oxygen Electrocatalysis for Renewable Energy Applications Sen Zhang and Zhiyong Zhang; University of Virginia, Charlottesville, Virginia, United States.

Developing efficient energy storage and conversion devices with low environmental impact is central to our ability to secure the society’s energy and environmental sustainability. Oxygen electrocatalysis is the cornerstone for many renewable energy devices, including PEM fuel cells, metal-air batteries and water electrolyzers. In this talk, I will highlight the critical role of heterostructure interfaces in exploiting and optimizing the kinetics of oxygen electrocatalysis: oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) in alkaline and neutral electrolytes. Associated with the formation of abundant oxide/sulfide interfaces over mixed spinel oxide nanosheets, the catalyst’s oxygen binding energy can be effectively tuned to enhance the OER and ORR activities, as revealed by the density functional theory (DFT) calculations. In 0.2 M phosphate buffer solution (PBS), the sulfurred zinc oxide present an excellent oxygen electrocatalytic activity and stability, with much lower OER and ORR overpotentials than single component oxide or sulfide, and with negligible performance decay in accelerated durability testing. As a result, it can be used as air electrode for both neutral/alkaline rechargeable zinc-air batteries. The relevant theoretical calculation, wet-chemical synthesis and structure/electrochemical analysis will be discussed.

2:30 PM *ES05.02.03 Ethanol Electro-Oxidation Using Pt3Sn Nanoparticles Yifan Liu and Chao Wang; Johns Hopkins University, Baltimore, Maryland, United States.

Direct ethanol fuel cell (DEFC) is a promising electrochemical energy conversion device. Its application, however, is hindered by lack of efficient catalysts for complete oxidation of ethanol into carbon dioxide. Here we report the study of ethanol electro-oxidation on Pt3Sn alloy nanoparticles. Electrochemical studies and product analysis were conducted comparatively on Pt3Sn/C, commercial Pt/C as well as Pt3Sn/C with surface tin species removed via KOH treatment. Our investigation reveal the dual role of Sn in Pt3Sn/C for ethanol electro-oxidation: surface SnOx species facilitate oxidation of *CHx to *CO while subsurface Sn species enhances oxidative removal of *CO.

2:45 PM *ES05.02.04 Tuning Hybrid Low-Dimensional Nanostructures for Efficient and Selective Electrochemical Reduction of Carbon Dioxide Sehmos Ozdemir1, Tristan Asset1, Samuel Garcia1 and Plamen Atanassov2,1; 1 Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 2 Department of Chemical and Biological Engineering, The University of New Mexico, Albuquerque, New Mexico, United States; Department of Chemical and Biomolecular Engineering, University of California, Irvine, Irvine, California, United States.

The ability to directly produce fuels by consumption of carbon dioxide (CO₂) is one of the promising solutions that would have a transformational impact on both global energy and environmental sustainability. The success of this groundbreaking technology depends on products that form from consumption of CO₂, and hence it is important to develop effective catalytic materials for facilitating the CO₂ conversion process. However, existing catalysts do not exhibit high efficiency and good selectivity, which is leading to multiple products. Major reported CO₂ reduction catalysts are limited with formation of CO and formate that is two-electron reduced products. The formation of hydrocarbon products, which involve multiple proton and electron transfers still remain one of the major scientific challenges that needs to be addressed. Presently, there is no known catalyst that can facilitate CO₂ conversion to hydrocarbon fuels with both good efficiency and high selectivity mainly because of the little mechanistic understanding. Here, we will discuss tuning the hybrid structure of metal-oxide nanoparticles and two-dimensional (2D) layered materials as an efficient and selective CO₂ reduction electrocatalyst with the density functional theory calculations, which reveals the unusual electrocatalytic properties of hybrid structure creating intrinsic chemical and electronic coupling and assist to understand the mechanism beyond the process.

3:00 PM BREAK

3:30 PM *ES05.02.05 Synthesis of Novel Two-Dimensional Nanomaterials for Electrocatalysis Hua Zhang; Nanyang Technological University, Singapore, Singapore.

In this talk, I will summarize the recent research on synthesis and characterization of two-dimensional nanomaterials in my group, which include graphene-based composites, transition metal dichalcogenide (TMD)-based composites, single- or few-layer metal dichalcogenide nanosheets and hybrid nanomaterials, the large-amount, uniform, ultrathin
metal sulfide and selenide nanocrystals, and other 2D nanomaterials, nanodots prepared from 2D nanomaterials, etc. Then I will demonstrate the applications of these novel 2D nanomaterials in electrocatalysis.

4:00 PM ES05.02.06
Formation of CoO4/Co2O3 Heterolayered Nanotubes Electro catalysts for Efficient Oxygen Evolution Bocheng Qu and Yang Chai; The Hong Kong Polytechnic University, Hong Kong, Hong Kong.

Electrochemical splitting water into hydrogen and oxygen provides alternative way to reduce the current reliance on fossil fuels and thereby mitigate net carbon dioxide emissions.[1] The oxygen evolution reaction (OER) in water splitting process typically requires noble-metal-based catalysts to reach the desired current density of 10 mA cm–2 with a substantial overpotential.[2] Unfortunately, the high overpotential to drive the reaction significantly reduces the conversion efficiency of water splitting. Furthermore, it is difficult to fabricate these precious metal catalysts in mass production owing to their high cost and low elemental abundance. To solve these problems, considerable efforts have been devoted to explore low-overpotential, stable and earth-abundant OER catalysts. Given that transition metal compounds, including oxides, sulfides, phosphides, and nitrides, inevitably transform into their corresponding oxides after OER,[3] the transition metal oxides are the most promising alternatives owing to considerable stability and theoretical activity. In particular, cobalt oxide (Co3O4) holds great promise to substitute for rare precious metal based catalysts due to its low cost and earth abundance. However, the utilization of Co3O4 as an OER catalyst is limited by poor mass-transfer ability. Co3O4, with the flexible switch between Co2+ and Co3+ oxidation states, shows reversible surface oxygen ion exchange, high oxygen-storage capacities, and good electronic/ionic conductivity,[4] which offers the opportunity to generate strong electron interactions with other materials. Therefore, Co3O4 is expected to modulate the electronic structure and adsorption property of Co3O4 effectively.

We develop heterolayered CoO4/Co2O3 nanotubes catalysts by using Cu2O nanowires as templates. The CoO4/Co2O3 nanotubes exhibit superior activity for oxygen evolution in comparison with pristine Co3O4 nanotubes. Our density functional theory (DFT) calculations show that CeO2 can systematically modulate charge density of Co3O4, which provides near-optimal adsorption energies at Co catalytic sites for various OER intermediates simultaneously, and substantially enhances OER performance of Co3O4. This work underscores the importance of modulating the electron density of catalytic sites, and provides the guidance to implement more targeted strategies for developing highly efficient OER catalysts.

4:15 PM ES05.02.07

Given the crucial role of catalysis science in our society, understanding how to design catalyst structures for desired catalytic activity and selectivity becomes a grand challenge. Core-shell nanostructured materials hold the promise of being active, cost-effective, and stable catalysts. I will demonstrate how we understand the structure-performance correlation at the atomic-scale level through a set of computational approaches and apply it to address the catalyst challenge in the fields of energy conversion and storages. Computationally, we designed heterostructured perovskites for electrochemical water splitting, which were experimentally synthesized, characterized and validated(Figure 1). This sets the stage for the future design of core-shell oxide nanoparticles and their use for chemical reactions under harsh chemical environments. I will provide an understanding of the activation mechanism of the heterostructures based on first principle simulations (Figure 2). Finally, I will bridge core-shell architected oxide and transition metal systems and discuss our vision of potential design strategies.

SESSION ES05.03: Poster Session I: Electro catalysts
Session Chair: Huiyuan Zhu
Tuesday Afternoon, April 23, 2019
5:00 PM - 7:00 PM
PCC North, 300 Level, Exhibit Hall C-E

ES05.03.01

Many researchers are eager to achieve novel systems for the synthesis of fuels or organic substances from CO2 under solar irradiation in an effort to help alleviate global warming and fossil fuel shortages. If CO2 can be reduced by utilizing water as an electron donor, then this would constitute an ideal reaction that would mimic photosynthesis in plants. We have previously reported CO2 reduction with very low overpotential and high reaction selectivity in an aqueous medium using abundant manganese complex polymer ([Mn-McN]2) catalysts.[1] Moreover, as a catalyst for oxygen evolution reaction, we have developed akaganeite-type iron oxyhydroxide surface-modified with amorphous nickel hydride (β-FeOOH:Ni/a-Ni(OH)2).[1-3] In this presentation, we demonstrate photocathodeelectrochemical CO2 reduction to CO with a solar-to-chemical conversion efficiency (ηCO2) of 3.7% by combining the earth-abundant catalysts wired with a cheap poly-crystalline silver photovoltaic cell (poly-Si cell) as a light absorber. Over 80% of current efficiency for CO production was observed in a one-compartment reactor, even in the presence of both oxygen gas and protons. We have also successfully conducted the reaction in neutral aqueous solution by formation of a Ni(OH)2/NOH redox system by pre-treatment of the β-FeOOH:Ni/a-Ni(OH)2. A photocathode composed of [Mn-McN] and triple junction amorphous silicon connected with a β-FeOOH:Ni/a-Ni(OH)2 anode also achieved ηCO2 of 1.0%, which suggests a future possibility to realize an ultimately-simplified monolithic artificial photosynthesis device to produce only gaseous products through the use of earth-abundant catalysts and a photosorbber.[4]

References
Interface engineering is one of the important schemes to optimize the intrinsic electronic structures of electrocatalysts and thus enhance the activity of the oxygen redox reactions for the applications of energy conversion devices such as fuel cells and metal-air batteries.\(^{(1)}\) When two different materials come to contact, charge transfer takes place at the interface due to the discrepancy between two Fermi levels. As a result, the excessive charge would boost the ORR process.

In our work,\(^{(2)}\) we take Mn-based mullite and perovskite as the prototype oxides to examine the interface tuning effect on the ORR performance. It is known, for individual either mullite or perovskite, only very limited ORR performance could be achieved.\(^{(3)}\) But, fundamentally, for Mn-based mullite, it contains two different crystalline fields,\(^{(3)}\) i.e. the Mn-centred pyramid\((3)-1\) and octahedral\((-4). The pyramid field \((\text{Mn}^{3+})\) introduces the \(d^{2}\) unit occupancy in the Fermi level region, which results in the ORR catalytic activity. For the octahedral field, it does not satisfy the requirement of the \(e_g\) unit occupancy. Thus, only one type of Mn is utilized. In order to maximize the active sites Mn, it is insightful to convert partial Mn\(^{3+}\) to Mn\(^{4+}\) to increase the \(e_g\) orbital occupancy. Through interfacing with n-type perovskites with higher Fermi levels, electrons will transfer to mullite side and achieve the conversion of Mn\(^{4+}\) to active valance Mn\(^{3+}\).

Based on the above arguments, we synthesized the heterogeneous catalysts, \((\text{AMn}_x\text{Mn}_y\text{O}_{z}\text{A}=\text{Ca, Sr, Ba, }x=0-0.5), i.e. \text{Mn-based mullite oxide interfacing with the IIA-group perovskies}, via the facile one-step co-precipitation method. We do find that the mixed-phase oxides display higher ORR performance. Among the three perovskites (\(\text{AMn}_x\text{Mn}_y\text{O}_{z}\text{A}=\text{Ca, Sr, Ba}), Ba-perovskite ultimately causes the band bending of mullite and thus leads to the highest half-wave potential \(-0.79\text{ V (vs. RHE)}\) in regards to individual mullite and Ba-perovskite, boosted by the accumulated electrons distributed in the mullite side at the interface. This work provides a strategy to rationally design the heterogeneous electrocatalysts via interface engineering.

Redox Polymer Mediated Electrochemistry of Oxygen Reduction Reactions
Arneet Rajput, E. C. Montoto and Joaquin Rodriguez-Lopez; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Achieving high theoretical energy densities in alkalai metal-air batteries is still practically limited and is an inefficient process.[1] The low performance of these batteries is a result of combination of unwanted side reactions and the consequent formation of precipitates on the electrode surface. These discharge products, in turn, passivates the electrode surface and reduces the discharge capacity of the alkalai battery.[2] Two use of solution-based catalysts in systems such as lithium-oxygen batteries have been reported to drive the formation of precipitates away from the electrode. This results in the enhancement of energy density and cyclic stability of batteries.[2, 3] In recent years, redox-active polymers (RAPs) have gained vast interest because of their multiple redox active sites. This nature of RAPs can be employed for multi-electron mediation. In our laboratory, we are currently investigating RAPs as potential oxygen reduction catalysts in different alkalai metal-air batteries. Our electrochemial results represent the mediating property of RAPs and demonstrate their electro-catalytic performance, specifically in regard to substrate and ion type. These results are coherent with the ability of RAPs to tune mechanism via conformation.[4] Nevertheless, we are still limited on the kinetic information of these poly-electrolyte systems.

In this report, we will present the redox and catalytic behavior of RAPs in different alkalai-air environments. Additionally, voltammetric simulations will be presented for understanding kinetic mechanisms involved at the electrode interface and in the polyelectrolyte solution. We present the voltammetric simulations of polyelectrolyte behavior for different electrolyte concentrations and ions. These simulations provide a deeper insight on feasible chemical pathways and the complex kinetics involved in this system. In summary, our studies aim to investigate and expand the horizon of RAPs-mediated electrochemistry for interfacial protection and to study further interfacial charge transfer reactions.

species embedded into carbon-based networks are efficient active species for the OER. In this work, we developed a hybrid ORR catalyst through the coordination of Co-based organometallic molecules to N-doped multiwalled carbon nanotubes (MWCNTs). Notably, our method offers a room-temperature reaction pathway for the formation of a stable catalytic complex through the exploration of N-doped structures. The hybrid ORR catalyst shows excellent catalytic performance with an onset potential of 0.95 V (RHE), superior durability, and good methanol tolerance. Chemical and structural characterization after many reaction cycles reveals that the Co-based organometallic species maintained the original structure of cobalt(II) acetylacetonate with coordination to the carbon-based materials. Also chemical and morphological characterization demonstrate after many reaction cycles reveals that a molecular well-dispersed active species at the surfaces of the carbon-based materials.

ES05.03.06
Synthesis of Ultrathin Wall CuO Nanotubes for CO Oxidation Yiwei Yu1, Na Ta1, and Jingyue Liu1; 1School for Engineering of Matter, Transport and Energy, Arizona State University, Tempe, Arizona, United States; 2Department of Physics, Arizona State University, Tempe, Arizona, United States.

Ultrathin nanostuctures with ultrathin walls provide readily accessible, high specific surface area for heterogeneous catalysis and sensing applications [1]. We report here the development of a room temperature synthesis process that produces tubular CuO nanowires with ultrathin wall (<10 nm). The synthesis process consists of using pre-formed Cu nanowires as templates, rapid annealing to oxidize the outside layers of the Cu nanowires, and a final well-controlled electrochemical corrosion process to obtain the final tubular structures. Characterization of the fabricated tubular structures by XRD and electron microscopy revealed that the morphology of the tubular structure conforms to the template Cu nanowires and that the crystalline tubular structure consists of CuO single phase. The synthesized CuO nanotubes have an average inner radius of 29 nm, outer radius of 35 nm and wall thickness ranging from 4 nm to 9 nm. After conditioning of the fabricated CuO nanotube catalyst during the first cycle of low temperature CO oxidation it demonstrated high activity with 100% CO conversion at 150°C in the following cycles, probably due to in situ reconstruction of the nanotube surface structures. The activation energy, stability and the structural evolution of the CuO nanotube catalyst during low temperature CO oxidation will be discussed [2].

Nickel-Containing Species Molecularly Immobilized on the Carbon Nitride as Hybrid Electrocatalysts for the Oxygen Evolution Reaction Sujin Seok, Dawoon Jang, Sunghee Park and Sungjin Park; Inha University, Incheon, Korea (the Republic of).

Water electrolysis is a type of oxygen electrochemistry that has been studied as a sustainable and effective energy conversion and storage device. The reaction occurring at the cathode electrode of the water electrolysis is referred to as HER (hydrogen evolution reaction), and the reaction occurring at the anode electrode is referred to as OER (oxygen evolution reaction). The OER reaction is slow because of the four-electron reaction, which is a major cause of the efficiency degradation. There is a need to develop new catalysts that allow the OER reaction to occur rapidly.

Precious metal oxides such as IrO2 and RuO2 exhibit great electrocatalytic activity for OER in acidic and alkaline conditions. However, because of high cost and scarcity of the precious metal elements, cost-effective and Earth-abundant metals, such as Fe, Co, and Ni. Among them, Ni-containing materials, show excellent electrocatalytic performances in alkaline medium.

Carbon materials are applied to various fields such as catalytic reaction, adsorption reaction, battery, and energy storage material. It has been known that bonding of nitrogen to such carbon materials can improve the properties of carbon materials, and much research has been conducted. Among them, carbon nitride (g-C3N4) is what we made in this experiment. In the case of C3N4, the synthesis method is simple and not toxic, and it has a band gap of about 2.7 eV, which is applied in various fields. Particularly, in the case of the most stable form of C3N4, graphitic carbon nitride (g-C3N4) is attracting attention as a catalyst which does not use metal as a material having a two-dimensional structure.

Hybrid catalytic materials containing single atoms or molecule-based active species fixed on nano-materials have been suggested as advanced catalyst for various reactions. In this study, we compared the OER performance of Ni-C3N-x (x = 10, 30, 50, 70, 100, 200) according to the composition of g-C3N4 and nickel. Novel hybrid system consisting of molecularly dispersed Ni-based materials on a g-C3N4 framework show excellent electrocatalytic performance for the OER.

We concentrated on Ni-C3N-200 because it shows the best catalytic performance for the OER. Chemical analysis revealed that Ni-C3N-200 contained Ni-based molecular species that were not aggregated in the porous g-C3N4 network and did not interfere with the network structure of C3N4. As calculated using BET data, the pore size of Ni-C3N-200 powder was 70 nm of diameter and surface area of Ni-C3N-200 was found to be 25.7 m2/g. EXAFS analysis investigated the local structure around Ni, Ni-C3N-200 shows the main peak at 1.6 A indicating the presence of Ni-N bonds.

In addition, electrochemical characterization results suggest dispersed Ni-containing molecular entities are active species for the OER. The Ni-C3N-200 sample exhibits the best electrocatalytic activity with an onset potential of 1.54 V (vs. RHE), which is less positive by 80 mV relative to g-C3N4. Not only the reduced onset potential, but also the kinetics, of the OER is enhanced by the attaching of the Ni-containing species on C3N4. The corresponding tafel slopes of IrOx, Ni-C3N-200, Ni-C3N-100, g-C3N4, and pristine GCE are 86, 60, 88, 230, and 470 mV/s, respectively. In test duration, the CV curves after 500 and 1000 cycles were almost like the initial curve and the chronoamperometry (CA) shows Ni-N bonds.

ES05.03.08
Fabrication and Photocatalytic Activity of Noble Metal(Ag, Au) Coated Fe3O4@TiO2@Fe3O4@TiO2 Nanomaterials Jin-Seung Jung; Gangnung-Wonju National University, Gangnung, Korae (the Republic of).

With the development of industrial technology, the amount of organic pollutants is constantly growing. In particular, water pollution produced by printing and textile factories has seriously affected the environment and caused severe consequences, such as aesthetic pollution, toxicity, and perturbation of aquatic life. Recently, with growing demand for clean and comfortable environment, purification technologies with high efficiency and low cost to reduce the pollutants of wastewater are urgently needed. Heterogeneous Fe3O4@TiO2@Au,Ag nanocomposites have an average inner radius of 29 nm, outer radius of 35 nm and shell thickness of 25 nm. The Fe3O4@TiO2@Au,Ag nanocomposites can be easily collected by applying external magnetic field due to the magnetic property of core Fe3O4 particles. The noble metal(Au,Ag) coated Fe3O4@TiO2@Au,Ag nanocomposites exhibited high photocatalytic activity in the degradation of rhodamine B (RhB) and methylene blue (MB) under visible light. The Fe3O4@TiO2@Au,Ag nanocomposites possess a relatively large specific surface area induced by noble metal(Au,Ag) nanoparticles, magnetic behavior for easy reuse, and enhanced photocatalytic efficiency caused by metal-semiconductor charge transfer or energy transfer. The increased photocatalytic activity of the Fe3O4@TiO2@Au,Ag nanocomposites is related to the increase in the electron–hole separation, caused by the interparticle charge transfer or energy transfer between TiO2 and noble metal(Au,Ag). The photodynamic process of TiO2 rapidly generates reactive oxygen species (ROS) as for instance superoxide anion radical (O2−), hydrogen peroxide (H2O2), singlet oxygen (1O2), and hydroxyl radical (OH). Thus, detection methods and generation mechanisms of the intrinsic reactive oxygen species (ROS), in photocatalysis, were surveyed comprehensively. The renewable photocatalytic activity of the photocatalyst was also examined.

ES05.03.09
Theoretical Study and Atomic-Scale Synthesis of Pt/Mn2 Interface for Bifunctional CO Oxidation Bin Shan and Rong Chen; Huazhong Univ of Science and Technology, Wuhan, China.

CO oxidation is a widely used model system for understanding fundamental aspects of heterogeneous catalysis. While platinum (Pt) continues to be a reference material for CO oxidation catalysis, poisoning of Pt catalysts presents a critical issue that blocks reaction sites and impedes subsequent reaction steps. Fabrication of CO poison-free Pt catalysts remains a great challenge due to its co-phile nature. Hence, we conduct a theoretical study of a bifunctional Pt/Mn-trimer interface that can effectively eliminate the CO poisoning effect. The Pt/Mn2 trimer structure is demonstrated irrespective of Pt cluster’s size, which can provide spatially separated sites for CO adsorption and O2 dissociation.
The binding strength of CO at the interfacial Pt sites is in the optimal range due to the charge transfer from Pt clusters to oxide, while the stronger polarization of Mn dimers induced by Pt clusters with stable three-dimensional morphologies can lower the energy barrier of O2 dissociation. Aroused by our theoretical results, we have synthesized the proposed structure via atomic layer deposition that tightly anchors subnanometer Pt clusters onto SmMn2O3 mullite facets, and with cluster configurations modulated by controlling key deposition parameters. Superior CO oxidation activity is observed with room temperature light off and turnover frequency rivaling the best in its class. The in-situ diffuse reflectance infrared Fourier transform spectroscopy analysis and oxygen isotope experiments confirm that the Pt/Mn2 structure’s activity originates from the bifunctional Mn2 components providing active oxygen atoms sources.

ES05.03.10
Ternary MnO/CoMn Alloy@N-Doped Graphitic from Bi-Metal Pigment for Bifunctional Electrocatalsis
Chen Deng; The University of New South Wales, Sydney, New South Wales, Australia.

Developing highly efficient bifunctional electrocatalyst for both oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) is of great importance in fuel cells and metal-air batteries. Among all candidates, non-precious transition metal composite materials with appropriate components and nanostructures might be promising for ORR and OER. Herein, we synthesized a composite containing CoMn alloy coated with N-doped carbon and MnO by a facile strategy of annealing Prussian blue analogues (PBA). The derived heterogeneous composite Mn2Co3-900 includes the merits of CoMn alloy, N-doped carbon and MnO, showing a low onset potential of 0.91 V, positive half-wave potential of 0.76 V and large limiting current density of 5.8 mA cm-2 among controlled samples. We proposed the enhanced ORR activity attributed to the optimal surface electronic configuration of alloy beneficial to dissociate intermediates and heterojunctions favoring charging transfer from alloy and oxide. In addition, this catalyst also shows promising activity for OER with onset potential of 1.53 V and low potential of 1.65 V at 10 mA cm2. This work therefore highlights the importance to construct alloy and oxide composite catalysts for superior electrocatalytic reaction.

ES05.03.11
An Etching-Assisted Route for Fast and Large-Scale Fabrication of Non-Layered Palladium Nanosheets
Yaming Liu; Xi’an Jiaotong University, Xi’an, China.

To date, great progress has been made in the shape-controlled synthesis of noble-metal nanocrystals. However, there still exists a major gap between academic studies and industrial applications due to the inability to produce nanocrystals in large quantities while retaining their uniformity. To help fill this gap, herein, we provide a new route to scale up and accelerate the production of non-layered palladium nanosheets (Pd NSs) by incorporating etching while retaining effective capping during the synthesis. The key to this rapid synthesis is the etching induced by selected etchants (e.g., Fe3+/Fe2+, Cl2/O2, Br2/O2, and F2/O2). Specifically, this synthesis can be accomplished within 3 min, reaching a yield as high as 7.2 g L−1 h−1. The thickness of Pd NSs can be tuned to 1.6, 2.0, 2.3, and 3.5 nm by controlling the etching and reducing rates via choosing different type of etchants. Moreover, these non-layered Pd NSs are fabricated in an aqueous solution without the addition of any organic compounds; therefore, the surface of these NSs is extremely clean. When used as a catalyst for the formic acid oxidation reaction, the as-prepared non-layered Pd NSs exhibit a mass activity as high as 1350 mA mg−1, which is 3.7 times higher than that of commercial Pd/C, due to their much larger electrochemical surface area (66.2 m2 g−1, which is 2.7 times higher than that of commercial Pd/C).

ES05.03.12
Creation of Controllable High-Density Defects in Silver Nanowires for Enhanced Catalytic Property
Chaoqi Wang; Xian Jiaotong University, Xi’an, China.

Noble metal nanocrystals with planar defects (e.g., twins, dislocations, stacking faults, and grain boundaries) symbolize a rising family in heterogeneous catalysts. It is of great importance to control surface terminations of planar defects of noble metal nanocrystals to play the significant role in their catalytic activity. However, there are still great challenges in preparation for noble metal nanocrystals with controllable high-density defects.

Here, we demonstrate a unique approach to the creation of Ag nanowires with high-density surface terminations of planar defects through controllable nanoparticles coalescence in one-dimensional pores of mesoporous silica. The density of defects can be easily adjusted by tuning the annealing temperature during synthetic process. The high-density defects promote the adsorption and activation of more reactants on the surface of Ag nanowires during catalytic reactions. As a result, the as-prepared Ag nanowires exhibit enhanced activities in catalyzing dehydrogenative coupling reaction of silane in terms of apparent activation energy and turnover frequency (TOF). We show further that the silane conversion rate can be enhanced by maximizing the defect density and thus the number of active sites on the Ag nanowires, reaching a remarkable TOF of 8288 h−1, which represents the highest TOF that has been achieved by far on Ag catalysts. The adsorption tests have further demonstrated the enhancement of the catalytic activity can be ascribed to the improved adsorption of reactants. This work not only proves the important role of surface terminations of planar defects in catalysis but also provides a new and general strategy for constructing high-density defects in metal catalysts.

ES05.03.13
Atomic-Resolution In Situ Observations of Metal-Support Interactions on Nanostructured Pt/CoO Catalysts
Joshua L. Vincent and Peter Greuter; Arizona State University, Tempe, Arizona, United States.

In reactions involving gas-solid interactions on nanostructured supports, the distinction between catalytically significant atomic structures and unreactive spectators is obscured by the variety of surface states that exist under reaction conditions. Studies of catalysts with well-defined support morphologies could assist in limiting the scope of structural configurations under consideration. Cerium dioxide (CeO2), a technologically important redox catalyst owing to its aliovalent behavior, can be synthesized into nanocrystalline cubes and rods; cubes surface-terminate with [100] planes, while rods surface-terminate with [110] and [100] planes [1]. Density functional theory (DFT) calculations indicate that CeO2 (100) surfaces are less stable than [110] surfaces, which suggests that cubes should be more reactive than rods [2]. However, for the CO oxidation reaction, rods are reported to be more active than cubes [1, 3], which is consistent with our results.

No atomic-resolution, in situ information exists for the surface structures or metal-support interfaces that occur on CeO2 rod/cube-supported catalysts, so we may only speculate upon the origin of the rods’ superior activity. This study employs ex situ and in situ environmental transmission electron microscopy (ETEM) to uncover the cooperative interactions that give CeO2 rod-supported catalysts enhanced catalytic activity. The CO oxidation reaction (CO + 1/2 O2 → CO2) will be employed as a probe for catalytic activity, due to its chemical simplicity and relevance to clean energy conversion. Nanostructured CeO2 cubes and rods will be synthesized through established hydrothermal methods [1], and Pt nanoparticles will be loaded onto them through conventional impregnation methods. A quartz tube reactor coupled to a gas chromatograph will be used to determine turn-over frequencies and activation energies for the catalyst, informing the reaction space to be explored during environmental transmission electron microscopy (ETEM) experiments. We expect that a Mars van Kevelten-of mechanism regulates activity in these catalysts, which would suggest that highly dynamic interfacial structures are likely to be catalytically significant. To this end, aberration-corrected ETEM (AC-ETEM) will be used to visualize the dynamic atomic structures that form in reaction conditions. The structures at the metal-support interface - and the dynamics that occur there - will be compared amongst the different types of interfaces that are observed (for example, Pt/CoO interfaces formed from Pt supported on CeO2 [100] vs. CeO2 [110] planes) [4].

[4] We gratefully acknowledge support of NSF grant CBET-1604971 and the use of facilities at Arizona State University’s John M. Cowley Center for High Resolution Electron Microscopy.
Tuning the Outcome of CO as the Intermediate

To address this challenge for science and the imagination often draw inspiration from the biological process of photosynthesis that powers our biosphere and supplied the fossil fuels global economies rely on. In this context, the active sites of enzymes have inspired researchers to develop molecular complexes that capture key environmental and functional principles of nature’s catalysts. However, not all aspects of biological energy transducing systems are or should be targets of chemical mimicry in designing an artificial photosynthesis, and some of the more favorable properties associated with solid-state heterogeneous catalysts have motivated molecular based surface-modification strategies. In this presentation, I will discuss efforts from our research group to develop heterogeneous–homogeneous architectures that combine the form factors of their underpinning solid-state supports with molecular coatings, enabling cooperative control and tunability of physical properties.1–6

8:45 AM *E0504.03 Tuning the Outcome of CO2 Reduction via Cooperative Interactions Between Bismuth Electrodes and Electolyte Cations Joel Rosenthal; University of Delaware, Newark, Delaware, United States.

Bismuth-based materials can promote the electrocatalytic reduction of CO2 to a variety of high energy density products depending on the conditions employed. For example, Bi cathodes promote the reduction of CO2 to CO with fast kinetics and high efficiencies in the presence of imidazolium ([Im]+) based cations. The Bi/[Im]+ systems can drive the electroreduction of CO2 to CO with Faradaic efficiencies and current densities of FE = 90 % and jF = 5–25 mA/cm2, respectively at applied overpotentials of ~300 mV. By contrast, when in the presence of [DBU–H+] based electrolytes, Bi cathodes promote the conversion of CO2 to formate (FE = 80 % at jF = ~45 mA/cm2) via an orthogonal 2e− reduction process. These studies reveal that variation of the electrolyte cation is a viable strategy to tune CO2RR with bismuth cathodes. We have undertaken a multipronged effort to understand how the cooperative interactions between polarized bismuth electrodes and electrolyte cations dictate the products of CO2 reduction. Through a combination of electroanalytical and computational methods along with advances analyses that include XANES, EXAFS and X-Ray reactivity experiments, we demonstrate that the Bi/[Im]+ and Bi/[DBU–H+] interfaces are not static. Under conditions at which CO2 electrolysis takes place, the bismuth materials undergo significant compositional and structural changes that are all believed to be important to the activity and selectivity of these systems for CO2RR. The mechanistic pathway(s) by which bismuth electrodes undergo potential-dependent chemical and structural transformations is dependent on cooperative effects between the electrode/electrolyte and manifest in the catalytic plasticity that is displayed by these Bi[cation] assemblies. Implications for future development of catalyst/electrolyte combinations that can efficiently promote CO2 conversion will also be discussed.

9:15 AM E0504.04 Electrochemical Reduction of Aqueous CO2 to Synthesis Gas Using β-PdH Wenchao Sheng; Tongji University, Shanghai, China.

Electrochemical reduction of CO2 (CO2RR) to value-added chemicals and liquid fuels using off-peak electricity or renewable energy is a green approach for energy storage and carbon cycling. The Faradaic efficiency and selectivity of CO2 reduction remain very low due to the very high energy barrier for CO2 activation. However, co-production of H2 and CO from the CO2RR aqueous electrolysis is appealing because H2 and CO with appropriate ratios as the synthesis gas can be used for methanol synthesis or Fischer-Tropsch reactions. Pd has been found to generate H2 and CO with a ratio between 1:1 and 2:1, which is in contradiction to the fact that Pd is prone for CO poisoning. In situ X-ray absorption spectroscopy and X-ray diffraction spectroscopy studies reveal that Pd has transformed into β-PdH under the electrochemical reduction conditions of CO2RR. Density functional theory calculations suggest that in situ formed β-PdH is not subjected to CO poisoning, and therefore the active species for the CO2RR.

9:30 AM E0504.05 Sequential Cascade Electrocataylsis Converts Carbon Dioxide to C-C Coupled Products Gourav Gourav1,2 and Joel W. Ager1,2; Joint Center for Artificial Photosynthesis, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 1School of Materials Science and Engineering, University of California, Berkeley, California, United States.

Inspired by nature’s use of multiple enzymes to produce multi-carbon products from CO2 and sunlight [1], it is attractive to consider analogous cascade catalysis schemes in electrochemical CO2 reduction to achieve higher selectivity than is possible now with conventional metal electrocatalysts [2]. Cascade catalytic processes perform multi-step chemical transformations without isolating the intermediates. Here, we demonstrate a sequential electrocatalytic cascade to convert CO2 to C2 hydrocarbons and oxygenates using CO as the intermediate [2]. CO2 to CO conversion is performed by using Ag and further conversion of CO to C-C coupled products is performed with Cu. Temporal separation between the two reaction steps is accomplished by situating the Ag electrode upstream of the Cu electrode in a laminar flow cell. Convection-diffusion simulations and evaluation of the electrodes individually were performed to identify optimal conditions for cell operation. With the upstream Ag electrode poised at -1 V vs RHE in a flow of CO2-saturated water in aqueous carbonate buffer, over 50% of the CO is further converted to C-C coupled products (ethylene, ethanol, propanol) on the downstream Cu electrode held at -1.2 V vs RHE. By independent control of the electrodes, control over hydrogenation and oxygenates selectivity is achieved, with increasing CO activity at the Cu electrode increasing the FE to C2 oxygenates. Additionally, by supplying CO as well as CO2 to downstream electrode, mass transfer of reactants is increased, which allows for higher CO2 reduction currents compared to single electrode controls.

Carbon dioxide utilization will play a critical role as the community aims to reduce the levels of atmospheric carbon dioxide. While 10% of current CO₂ emissions can be converted directly into fuels, the transformation of CO₂ into useful chemical feedstocks can account for another 7%. One central example of CO₂ utilization is the addition of CO₂ to cyclic epoxides, generating cyclic carbonates, a polymer precursor. This reaction is characterized by the attack of a Lewis acidic metal on the epoxide to activate it toward CO₂ insertion. This reactivity has been demonstrated by many metal organic framework scaffolds. The Morris group recently synthesized a new class of metal organic frameworks termed VPI-100-M. The MOFs incorporate a tetra-azaamacyclic and are competent catalysts for the aforementioned reaction. Herein, a detailed mechanistic study of the interactions between the VPI-100 analogs (Zr and Hf) and substrates of interest is presented. The implications of these results on the mechanism of catalytic action are discussed and placed in the context of the MOF catalytic field. The node appears to play a minor role during catalysis, as the dominant interacting center was determined to be the metalloccyclam via both quartz crystal microbalance studies and calculations. In contrast, the node appears to dominate the CO₂ sorption properties of the MOF. Therefore, there is a synergetic effect between the linker and the node imparting enhanced reactivity.

10:45 AM ES05.04.07
Nanoporous Au-Sn with Solute Strain for Simultaneously Enhanced Selectivity and Durability During Electrochemical CO₂ Reduction Lihua Qian and Xianglong Lv; Huazhong University of Science and Technology, Wuhan, China.

Electrochemical carbon dioxide (CO₂) reduction on metallic catalysts suffers from the restricted selectivity and the competition with hydrogen evolution, which sensitively depend on ambiguous contributions of strain state and alloying in bimetallic catalysts. Herein, nanoporous Au-Sn (NPAS) containing trace tin solute into Au lattices is delicately designed to convince real strain effect, while rule out the other disturbing factors, such as alloying, crystal facets and surface composition. In comparison with nanoporous Au, the NPAS with a solute strain of ~2.2% enables the efficient CO₂-to-CO conversion, being 92% at -0.85 V versus reversible hydrogen electrode and retains the activity for at least 8 hours. Simultaneous enhancements of selectivity and durability stem from the shifted d covalent band that might change adsorption energy of key intermediate *COOH, and sluggish Au surface diffusion onto the strained ligament against coarsening, respectively.

11:00 AM ES05.04.08
Strain As an Axis to Tune Selectivity in Electrochemical CO₂ Reduction Taewoo Kim and David Fenning; University of California, San Diego, San Diego, California, United States.

Electrochemical recycling of CO₂ to high-valued carbon-based products such as hydrocarbons and alcohols offers not only mitigation of greenhouse gas emissions but also the opportunity to use CO₂ as a medium to store energy. Copper is a promising electrocatalyst for CO₂ reduction, capable of producing such products with reasonable activity. However, poor product selectivity results in low energy efficiency – a critical challenge. In this study, we apply tensile strain to planar Cu catalysts and demonstrate the ability to direct the aqueous CO₂ reduction reaction toward particular products, indicating that we can manipulate the binding energy of key intermediates via strain. We observe that the magnitude of the tensile strain applied to the planar Cu catalysts strongly governs the CO₂ reduction selectivity. At overpotentials where higher reduction products are favored, the strongest tradeoff is between formation of CO and CH₄. This tradeoff indicates a change in CO binding energy, one of the key descriptors of CO₂ reduction to hydrocarbons and oxygenates. These findings provide evidence for strain engineering as a tunable approach to modifying the surface binding energy of CO₂ reduction intermediates and offer a practical experimental approach to identifying favorable strain states. We will describe our latest understanding of the changes in surface chemistry that strain introduces, offering insights to tailor the design of high surface-area electrocatalysts with enhanced selectivity for CO₂ reduction.

11:15 AM ES05.04.09
Functional Nanogluels for Robust Single-Atom Catalysts Xu Li¹,², Jia Xu¹, Jie Zeng² and Jingyue Liu¹; ¹Arizona State University, Tempe, Arizona, United States; ²University of Science and Technology of China, Hefei, China.

Recent advances in catalysis by supported single metal atoms have demonstrated that single-atom catalysts (SACs) can be highly active and selective for a variety of important catalytic reactions. The key challenge to practical applications of SACs is, however, the stabilization of high number density of single metal atoms dispersed onto high-surface-area supports during the desired catalytic reactions. Unless they are strongly anchored by defect sites supported metal atoms are thermodynamically unstable, especially at elevated temperatures and under reducing environment. The use of nanogluels, commonly practiced in industry to anchor metal nanoparticles, provides an alternative approach to confining the movement of supported single metal atoms during catalytic reactions. We recently demonstrated a novel strategy to anchor supported Pt single metal atoms by using CoO₂ clusters (1-2 nm) as nanogluels. The synthesis processes consist of dispersing CoO₂ clusters onto inexpensive and high-surface-area SiO₂ supports and then depositing Pt atoms onto the CoO₂ clusters. We used CO oxidation as a probe reaction to evaluate the stability of the Pt/CoO₂/SiO₂ SAC. The results demonstrate that not only the CoO₂ clusters stabilized the Pt single atoms during the CO oxidation but they also significantly enhanced the activity, presumably due to the redox capability of CoO₂ clusters that facilitate CO oxidation. Our strategy is general and can be extended to other types of functional nanogluels to develop robust SACs for a variety of catalytic transformation of important molecules.*

11:30 AM ES05.04.10
Robust and Synthesizable Photocatalysts for CO₂ Reduction—A Data-Driven Materials Discovery Arunima Singh¹, Joseph Montoya², John M. Gregoire¹ and Kristin A. Persson; ¹Physics, Arizona State University, Tempe, Arizona, United States; ²Lawrence Berkeley National Laboratory, Berkeley, California, United States; ³California Institute of Technology, Pasadena, California, United States.

The photocatalytic conversion of the greenhouse gas CO₂ to chemical fuels such as hydrocarbons and alcohols continues to be a promising technology for renewable generation of energy. Major advancements have been made in improving the efficiencies and product selectivity of currently known CO₂ reduction photocatalysts, nonetheless, materials discovery is needed to enable economically viable, industrial-scale CO₂ reduction. We report here the largest CO₂ photocathode search to date, starting with 68860 candidate materials, using a rational first-principles computation-based screening strategy to evaluate synthesizability, corrosion resistance, visible-light absorption, and compatibility of the electronic structure with fuel synthesis. The results confirm the observation of the literature that few materials meet the stringent CO₂ photocathode requirements, with only 52 materials meeting all requirements. The results are well validated with respect to the literature, with 9 of these materials having been studied for CO₂ reduction, and the remaining 43 materials are discoveries from our screening that merit further investigation.

1:30 PM ES05.05.01
Robust Single-Atom Catalysts for Energy and Environmental Applications Jingyue Liu, Jia Xu, Yang Lou, Yafeng Cai and Xu Li; Arizona State University, Tempe, Arizona,
The rapid advances in catalysis by supported single metal atoms are clearly manifested by the explosive growth of journal publications on this research frontier in the last few years. Single-atom catalysts (SACs), defined as those catalysts that consist of only isolated metal atoms dispersed onto an appropriate support, have demonstrated unparalleled selectivity and/or significantly enhanced activity for a variety of important catalytic reactions including gas- and liquid-phase, electrocatalytic, and photocatalytic reactions. From the materials science perspective, we can view the active sites of SACs as surface dopants or anchored impurities which modify the surface electronic structure of the support material. From the homogeneous catalysis perspective, we can view the active sites of SACs as metal centers coordinated by a rigid ligand of the solid support; the specific coordination environment depends on the anchoring site of the metal single atom. The catalytic performance as well as the stability of SACs strongly depend on the support material and the electronic atom-support interactions. Strong metal atom-support interactions usually involve charge transfer or formation of covalent bonds which can significantly modify the physiochemical properties of the metal atoms and consequently their adsorption properties for reactant molecules. Since we do not have much freedom to tune the properties of single atoms support (surface) engineering or functionalization becomes the central research theme in the field of catalysis by supported metal atoms. In this presentation, we will discuss the recent strategies in anchoring metal atoms to high-surface-area supports, key catalytic reactions that demonstrate the excellent selectivity/activity on SACs, challenges to commercial applications of SACs, and perspectives for developing robust SACs for energy and environmental applications.

This research was funded by the National Science Foundation under CHE-1465057. We gratefully acknowledge the use of facilities in the John M. Cowley Center for High Resolution Electron Microscopy at Arizona State University.

2:00 PM ES05.05.02
Does Polaronic Self-Trapping Occur at Anatase TiO₂ Surfaces? John J. Casey and Keith McKenna; University of York, York, United Kingdom.

The behavior of electron and hole charge carriers at surfaces of titanium dioxide (TiO₂) controls performance for important applications including photocatalysts and solar cells. While anatase TiO₂ exhibits high electron mobility in the bulk a commonly held belief is that strong coupling between electrons and phonons can lead to electron trapping at anatase surfaces. However, direct evidence is scarce and the nature of the trapping sites and electronic properties remains unclear. To address this question we investigate the trapping of electrons and holes at low and high index surfaces of anatase TiO₂ using an accurate hybrid density functional theory approach. We find that, as in the bulk, electrons do not trap on the low index planes (001, 100, 110, 112) of anatase crystals. For the higher index planes (103, 105, 107) that contain structural step defects, we find that electrons do trap at the low coordinated Ti cations present on the steps. The trapping of holes at the surfaces of anatase TiO₂ is a more complicated picture, as the distribution of hole traps is facet dependent. 001 and 100 surfaces, as well as 105 and 107 surfaces which have 001 type terraces, have the strongest affinity to trap holes. Hole trapping for the 101, 110, 112 and 103 surfaces is found to be favoured in the sub surface layers and not at the surface facet. These results provide crucial insights into the behavior of electrons and holes in TiO₂ relevant for applications in photocatalysis and challenge the common perception that electrons trap at low index surfaces of anatase TiO₂.

2:15 PM ES05.05.03

Composite catalytic aerogels provide a highly flexible design motif for solar-fuels photocatalysis. This multifunctional platform enabled us to physically connect surface plasmon resonant (SPR)-driven visible-light sensitization, electron and ion transport, and oxidation and reduction catalysis within Au–TiO₂ aerogels—a single, hierarchical composite catalyst nanarchitetture [1].

Although Au–TiO₂ aerogels exhibit attractive properties for photocatalytic H₂ generation [1] and photochemical water splitting [2], quantum efficiencies at the globular ~5-nm Au guests remain low. Here, we focus on the challenge of enhancing SPR-driven visible light water oxidation in our composite aerogels. We introduce iridium oxide (IrO₂)-based co-catalyst nanoparticles into the plasmonic aerogels to enhance SPR-generated electron–hole pairs. We also describe a new synthetic strategy to vary the size of SPR-active Au nanoparticles in the Au–TiO₂ aerogel architecture to increase the efficiency of the SPR sensitization process. Ultimately, we wish to retain the connectivity of the sensitization, charge separation, and catalytic steps we previously demonstrated in our composite plasmonic photocatalytic aerogels and add in the high (as high as 20–50%) SPR-sensitized charge separation efficiencies reported elsewhere [3] to create a robust composite aerogel-based solar fuels photocatalyst delivering state-of-the-art photocatalytic efficiency.

Mechanisms and Selectivity of the Electrochemical CO₂ Reduction Reaction on Multiple-Site vs Single-Site Catalysts Peter Strassner; Chemical Engineering, Technical University Berlin, Berlin, Germany.

Strategies for closing the anthropogenic carbon cycle using the chemical conversion of CO₂ into useful molecules have become a scientific and technological priority. Of all chemical ways to convert CO₂ into CO, oxygenates or hydrocarbons, the direct electrochemical coupling of water electrolysis and CO₂ reduction appears attractive, as it is a one-pot process step, occurs at ambient temperature and pressures, involves solely water and CO₂ as reactants, and may involve renewable electricity from wind, solar or hydro power plants.

The CO₂ electrode reaction is by and large carried out on the surface of metal catalysts. At industrially relevant current densities and electrode potentials, however, these catalysts typically suffer from low faradic C₃ product selectivities due to the competing, very fast reduction of water, i.e. the hydrogen evolution reaction. New catalyst concepts with tunable selectivity for hydrogen evolution versus CO₂ reduction are needed.

In this contribution, we share recent comparative experimental and computational mechanistic insight in the electroreduction of CO₂ on metallic multi-site versus molecularly inspired metal ion-N modified high surface area carbon single-site catalysts. We provide new insight into CO selectivity trends and put particular emphasis on the competing reaction pathways to methane and methanol. We show that carbon-based single site catalysts are an intriguing cost-effective alternative to their metallic rivals at industrial current densities.

CO Oxidation on Supported Ir Single Atoms—Consequences of Strong CO Adsorption on Kinetics and Resting State of the Catalyst Ayman M. Karim; Virginia Tech, Blacksburg, Virginia, United States.
Supported single-atom catalysts provide an ideal system to study reaction mechanisms on a molecular level and to bridge heterogeneous and homogeneous catalysis. Single atoms have shown remarkably different activity and selectivity for several reactions, however for low temperature CO oxidation the reaction mechanism is not well understood and there is debate whether single atoms have higher intrinsic activity than nanoparticles. In this talk, the mechanism of CO oxidation on atomically dispersed Ir/MgAl₂O₄ catalysts will be presented and compared to that on nanoparticles. Using in-situ and in-operando DRIFTS and HERFD-XANES complemented by DFT calculations, we identified the active Ir single-atom complex, and resting state of the catalyst for low temperature CO oxidation. We provide evidence that strong CO adsorption on single atoms leads to an Eley-Rideal mechanism where Ir(CO) is the active complex (i.e. a CO ligand is present during the catalytic cycle). The results show that due to the ability of single atoms to coordinate with more than one ligand, strong adsorption by CO does not necessarily lead to catalyst poisoning. Additionally, we demonstrate that the unusual kinetics on single atoms can be used as a facile surface sensitive characterization tool for quantifying the number of single atom sites in catalysts containing a mixture of single atoms and nanoparticles. The results provide a new perspective for understanding reaction mechanisms and interpreting spectroscopic and catalytic activity of supported metal single atoms.

4:30 PM ES05.06.03/ES06.05.03 Oxide Bilayers as High Efficiency Water Oxidation Catalysts Through Electronically Coupled Phase Boundaries Jennifer Redig, Sanjay Mathur and Thomas Fischer; University of Cologne, Cologne, Germany.

New semiconductor metal oxides capable of driving water-splitting reactions by solar irradiation alone are required for sustainable hydrogen production. Whereas most metal oxides only marginally deliver the photochemical energy to split water molecules, uranium oxides are efficient photoelectrocatalysts due to their absorption properties ($E_g \approx 2.0 - 2.6 \text{ eV}$) and easy valence switching among uranium centers that additionally augment the photocatalytic efficiency. Although considered a scarce resource, the abundance of uranium compounds in the environment is manifested in the huge quantities of stored UF₆ gas, produced as waste streams in the nuclear fuel enrichment process. Here we demonstrate that thin films of depleted uranium oxide (UO₂) and their bilayers with hematite (α-Fe₂O₃) are high activity water oxidation catalysts due to electronically coupled phase boundaries. The electronic structure of uranium oxides showed an optimal band edge alignment in U₃O₈ and UO₂ which can be tuned by electron doping and the reaction mechanism is confirmed by theory. The enhanced photocurrent density of the heterostructures with respect to well-known hematite offers unexplored potential of uranium oxide in artificial photosynthesis.

4:45 PM ES05.06.04/ES06.05.04 Design of Supported Transition Metal Catalysts for Methane Partial Oxidation Darinka Prince¹,², Julie Fornaciari¹,², Adam Weber² and Alexis T. Bell¹,²; ¹Department of Chemical and Biomolecular Engineering, University of California, Berkeley, Berkeley, California, United States; ²Lawrence Berkeley National Laboratory, Berkeley, California, United States.

The abundance of methane and its low cost makes it an optimal raw material for chemical precursors and energy-dense fuels. Conventional synthesis of methanol involve a multistep process, which requires high energy input and high cost [1]. Alternatively, electrochemical methane oxidation using a catalyst is a promising single-step approach to achieve a direct conversion of methane to methanol at lower temperatures and cost [2].

An efficient catalyst needs to be developed for this energetically challenging process. The catalyst should be active for C-H bond activation, thereby enabling oxidative hydroxylation of methane, and simultaneously inhibit further methanol oxidation. To date, a variety of the catalysts, including supported metals (Pd, Ru, Au, Ag) and metal oxides (V₂O₅, Fe₂O₃, CoO, Mn₃O₄, MoO₃, CrO₃) have been tested in electrochemical cells and shown promise for this approach [2]. However, further systematic studies are essential for understanding the mechanism for methane oxidation and thereby enabling the rational design of the catalysts. In this regard, porous metal oxides and supported single-atom catalysts (SAC) are particularly interesting [3]. These catalysts show potential for high methane conversion and are ideal model catalysts to identify active sites and facilitate understanding of the reaction process at a molecular level. In spite of great interest; however, it still remains challenging to achieve atomically dispersed metals in high loadings for efficient catalysis.

In this study, a design of first-row transition metal oxides and MOF-derived supported single-atom catalysts will be presented. The catalysts are synthesized with wet-chemistry, and subsequently, characterized for electrochemical methane-to-methanol oxidation. Structural and chemical analyses of catalysts using a combination of various microscopic and spectroscopy techniques are used to establish structure/property relationship. These insights provide valuable basis for a scientific-guided approach toward new metal oxide and supported single-atom catalysts for this challenging process.

ES05.07.01 Theory-Guided Sn/Cu Alloying for Efficient CO₂ Eletroreduction at Low Overpotentials Xuei Zheng and Yi Cui; Stanford University, Palo Alto, California, United States.

The electrochemical reduction of carbon dioxide (CO₂) to formate provides an avenue to the synthesis of value-added carbon-based fuels and feedstocks powered using renewable electricity. Unfortunately, high selectivity in formate electroreduction has thus far only been achieved at the expense of highly cathodic potentials, yielding impractically low power conversion efficiencies. In this work, we use density functional theory to investigate the effect of alloying Cu and Sn on the activity and selectivity towards formate. A theoretical thermodynamic analysis of the reaction energetics suggests that the incorporation of copper into tin could suppress hydrogen evolution and CO production, thus achieving high selectivity in formate electroreduction at lower potentials.

ES05.07.03 RuO₂-Loaded Black TiO₂ Nanotube Array Electrodes for Efficient Electrocatalytic Chlorine Evolution Reaction Deok Ki Cho and Jin Young Kim; Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

TiO₂ nanotube arrays (NTAs) substrate has highly ordered nanostructure, which is able to provide numerous surface area. Ruthenium oxide (RuO₂) is successfully deposited onto TiO₂ nanotube arrays via electrochemical deposition. We simply alter electrochemical properties of TiO₂ nanotube arrays through changing annealing condition. It is shown that air-annealed TiO₂ NTAs substrate is a good support for hydrogen evolution reaction (HER) but not for chlorine evolution reaction (CER). Also, non-annealed TiO₂ NTAs substrate shows dissolution in acidic condition under high cathodic current. Thus, Ar-annealed black TiO₂ NTAs substrate is appropriate to use both hydrogen evolution and chlorine evolution. It has been found that the conductivity of the electrode under the anodic polarization is essential for achieving good CER performance, and the black TiO₂ has been found to be the best scaffold for the RuO₂ catalysis.
Graphene, an atomically thin two dimensional carbon allotrope with hexagonal lattice structures, has been intensively studied in recent years owing to its outstanding electrical, mechanical, thermal and optical properties. In particular, graphene, as a highly conductive material not only because of its densely packed structure but also because of its outstanding optical transparency and mechanical flexibility. This is particularly important for flexible organic devices as the performance of organic materials considerably degrades in the presence of water or oxygen molecules from ambient air. Inorganic materials such as silicon oxides (SiOx) and aluminum oxides (Al2O3) have been predominantly employed as the gas barrier films. However, the complicated fabrication processes as well as the poor mechanical flexibility of these materials have hindered the practical application to flexible electronic devices. In this regard, the excellent gas impermeability, flexibility, and transmittance of graphene films are expected to be useful for more reliable and durable operation of organic devices. Nevertheless, the defects in CVD graphene are unavoidable due to imperfect synthesis, etching, and transfer processes, which considerably degrades the barrier performance of graphene films. Thus, the characteristics and catalytic activity of cWONFs and CsWONPs were studied. However, neither material modified GCE was used, and the LOD was 56.0 nM within a linear range of 0–280 μM. The LOD obtained when using WONFs in electrochemical sensing is lower than that of CsWONPs. Furthermore, WONFs have intrinsic peroxidase-like activity and electrocatalytic properties. For colorimetric detection, we investigate their peroxidase-like activity which is turning from colorless to blue by catalyzing the oxidation of a peroxidase substrate, such as 3,3′,5,5′-tetramethylbenzidine, in the presence of H2O2.

Chevrel-Phase MoS2—A Platform for Probing Ensemble Effects on Selective Conversion of CO2 and CO to Methanol Over Metal-Promoted Sulfides

**Joseph Perryman**1,

Jessica Ortiz-Rodriguez2, Ambarish Kulkarni3, Christopher Patridge4 and Jesus M. Velazquez4; 1University of California, Davis, Davis, California, United States; 2Chemistry, D’Youville College, Buffalo, New York, United States.

Presented herein is an investigation of a promising Chevrel-phase metal sulfide catalyst that is capable of electrochemically converting CO2 to liquid and gas fuels such as methanol and hydrogen. When promoted by copper, extended structures of Chevrel-phase MoS2 clusters are capable of reducing CO2 to CO in aqueous electrolyte with an overpotential of -0.4 V vs RHE. H2 gas is simultaneously evolved during this process, contributing to total current densities as high as 35 mA/cm2. Methanol and formate are the only CO2 reduction products formed from electrolysis, although utilizing CO as a feedstock has been shown to mitigate parasitic current density toward formate production. Also presented is the formulation of an interesting electronic structure-function correlation founded on the basis of ex-situ and operando X-ray absorption spectroscopic analyses and corroborated by results of electrocatalytic evaluation as well as theoretical calculation.

**ES05.07.06**

Fe-Doped Ni3P on Stainless Steel for Efficient Oxygen Evolution at High Current Densities

**Lejuan Cai**1 and Yang Chai; 1Department of Applied Physics, The Hong Kong Polytechnic University, Hong Kong, China.

Clean hydrogen energy produced from water-alkali electrolyzers has shown great potential to replace current fossil fuels due to its carbon-neutral and sustainable nature.[1] Although high hydrogen evolution (HER) electrocatalytic water splitting performance has been achieved, the overall water splitting performance is still hindered by oxygen evolution reaction (OER) due to the sluggish four-proton-coupled electron transfer process.[2] In addition, the OER process is also essential for CO2 reduction reactions and plays dominant role in rechargeable metal-air batteries.[3] Thus, it is of great significance to develop effective electrodes for large-scale oxygen evolution at the minimum cost of electricity. From the perspective of practical water-alkali electrolysis, commercial water splitting requires an overpotential below 300 mV to realize high current density above 500 mA/cm2, superior long-term stability and cost-effective OER electrolytes.[4] Therefore, designing highly efficient OER electrodes based on non-noble metals is highly desirable for practical water splitting.

In this manuscript, we successfully fabricate self-supported Fe-doped Ni3P electrocatalyst on 304-type stainless steel (SS) mesh and realize first-class OER performance. The as-prepared OER electrode exhibits an overpotential below 300 mV (about 255 mV) to achieve high current densities of 500 mA/cm2, which meets the commercial water electrolyzer requirements and outperforms most of other state-of-the-art OER electrodes. Besides, extremely low Tafel slope and superior long-term stability are also achieved due to the highly active catalytic sites, great conductivity and strong adhesion between electrocatalyst and current collector. DFT calculation was then introduced to verify the robust OER performance of Fe-doped Ni3P. According to the theoretical results, Fe-doping brings about reduced adsorption energy of O-containing intermediates and improve the charge transfer from catalytic surface to intermediates, which is beneficial for intermediates activation and O2 evolution. More importantly, Fe doping can greatly improve the Fe2+/Fe3+ adsorption on oxidized Ni-Fe-P surface, leading to activated O2 species for enhanced OER performance. The combination of experimental and theoretical results deepens our understanding to the synergistic effect of Ni- and Fe-sites during OER process and provides significative guidance to design OER electrodes for practical water electrolysis.

Hexagonal Tungsten Oxide Nanoflowers as Enzymatic Mimetics and Electrocatalysts

**Chan Yeong Park,** Hongil Jo, Juhyun Park, Kang Min Ok and Tae Jung Park; Chung-Ang University, Seoul, Korea (the Republic of).

Tungsten oxide (WOx) has been widely studied for versatile applications based on its photocatalytic, intrinsic catalytic, and electrocatalytic properties. Among the several nanostructures, we focused on the flower-like structures to increase the catalytic efficiency on the interface with both increased substrate interaction capacities due to their large surface area and efficient electron transportation. There are three keys to obtain the improved flower-shaped WOx (WONFs) with a large surface area. First is acidic environment (pH 1.6), seconds is the synthesis was conducted at a low temperature (to provide a low reaction rate), and last is high precursor concentration. Like hexagonal zinc oxide nanorods, hexagonal WOx crystals have been considered polar crystals with ± (0001) polar planes. These polar crystals are prone to grow along their polar directions (c-axis) at a low growth rate. The difference in crystal growth rate between the polar plane and nonpolar plane would produce anisotropic crystal growth. Another factor influencing the crystal morphology is the capping agent, which can selectively adsorb onto the preferred crystal planes and regulate the crystal growth rate. In this reaction system, NaCl can act as a capping reagent by adsorbing onto the crystal plane parallel to the c-axis of the WOx crystal nucleus. Moreover, Cs2WO4-based experiments were performed to investigate the influence of the NaCl on the overall crystal morphology and structure of the WOx nanoflowers, however, the resulting nanoparticles, Cs2WO4, were not flower-shaped and denoted as CsWONPs. The WONFs were compared with CsWONPs in terms of structural and catalytic properties. Therefore, improved WON, nanoflowers (WONFs) with large surface areas were developed through a simple hydrothermal method using sodium tungstate and hydrogen chloride solution at low temperature, without any additional surfactant, capping agent, or reducing agent. Structural determination and electrochemical analyses revealed that the WONFs have hexagonal Na0.33WOx, 0.17H2O structure. To verify the catalytic efficiency enhancement by the unique shape and structure of the WONFs, they were compared with calcined WONFs, cesium WOx nanoparticles, and other peroxide-like nanomaterials. The WONFs were characterized using a combination of experimental techniques, and it was found that WONFs have the largest surface area (51.936 m2/g) despite having a particle size larger than that of CsWONPs. Furthermore, WONFs have intrinsic peroxide-like activity and electrocatalytic properties. For color regeneration, a modified GCE was used, and the LOD was 56.0 μM within a linear range of 0–280 μM. The LOD obtained when using WONFs in electrochemical sensing is lower than that obtained when using WOFs in colorimetric detection. Additionally, the characteristics and catalytic activity of cWONFs and CsWONPs were studied. However, neither material exhibited both intrinsic peroxide-like activity and good electrocatalytic activity.
In heterogeneous catalysis, metal-support interactions can lead to enhanced catalytic performance. Cu and Pt nanoparticles supported on CeO$_2$, for example, are more active for CO oxidation than those supported on non-reducible metal oxides (such as SiO$_2$) [1]. The enhancement arises from CeO$_2$'s ability to locally donate oxygen at the metal-support interface, through a Mars van Krevelen-like mechanism. The ease with which oxygen may be removed from the CeO$_2$ lattice has been shown theoretically to depend on the atomic structure of the metal-support interface [2]. At present, though, there is little experimental data on the atomic structures that comprise the metal-support interface during catalysis. Correspondingly, many important questions remain as to what interface or proximal surface structures participate in or enhance interfacial oxygen transfer.

In the present study, we seek to elucidate the cooperative atomic-scale dynamics that occur at the metal-support interface during catalysis. The CO oxidation reaction (CO + $\frac{1}{2}$ O$_2$ > CO$_2$) will be employed as a probe for catalytic activity, due to its chemical simplicity and relevance to clean energy conversion. Nanostructured CeO$_2$ will be used as a model support, and Pt nanoparticles will be loaded onto them through conventional impregnation methods. A quartz tube reactor coupled to a gas chromatograph will be used to determine turn-over frequencies and activation energies for the catalyst, informing the reaction space to be explored during environmental transmission electron microscopy (ETEM) experiments. Abrerration-corrected ETEM (AC-ETEM) will be used to visualize the atomic structures that form in reaction conditions. Operando electron energy-loss spectroscopy will be implemented to track the gas composition during catalysis, allowing catalytic activity to be correlated directly with the observed surface and interfacial structures.

The results of these experiments will provide operando information on the interfacial and surface structures that correlate with activity for an important clean energy conversion reaction. These relationships are of fundamental interest to the heterogeneous catalysis community, and they may facilitate the engineering of highly active Pt/CeO$_2$ catalysts for the energy and environmental remediation applications where they are indispensably used [3].

ES05.07.10
Optimized Fabrication Process of Electrospun Nanofiber Film Using Circular Electrode for Multifunctional Filter Application

Dong Hee Kang, Na Kyong Kim, Liangjun Zheng and Hyun Wook Kang; Department of Mechanical Engineering, Chonnam National University, Gwangju, Korea (the Republic of).

Electrospinning technique is simple method to polymer based nanofiber film fabrication. Electrospun (ES) film is fabricated continuously stacked nanofiber that has porous structure. The porous characteristic of ES films permit their application in many fields such as textiles, filters, biomedical, drug delivery, energy, and sensors. Also, the electrospinning technique is readily adapted for the addition of micro and nanoparticles to provide specific functions in the mixing of the polymer solution. For further applications, the fiber diameter should be easily controlled by the electric field in the electrospinning, especially ES film based fiber application needs to have adequate fiber characteristics in uniformity, porosity and permeability. Traditional electrospinning using flat electrode for fiber collection has disadvantages to produce a ES film having a homogeneous thickness distribution. Also traditional electrospinning has difficulties in nanofiber film acquisition due to the deformation film layer in film detaching process. In this study, we investigate the electrospinning method using circular electrode for freestanding state nanofiber film fabrication. Freestanding ES film is possible to transfer layer by layer with film deformation through the repetition process. For the optimized freestanding ES film fabrication, numerical simulations are performed to analyze the electric field, equivalent polar, electric potential, and electrostatic pressure on the surfaces of the circle electrode collector in the electrospinning area. The electrostatic results explain the focusing phenomenon of freestanding films via ES fibers stacked on the surface of the 20 mm inner diameter circle electrode collector. Under the conditions with a 70 mm TCD and 12.5 kV, ES film is successfully fabricated on the top surface of the circular collector. After the optimization of ES film fabrication, PVDF/zeolite multilayer film fabricated by electrospinning with the circle electrode collector and repeated film transfer processes for the humidity removal test. Through the transferring process, the ES layers are laminated onto other film surfaces to fabricate a multifilayer. An ES multilayer film is composed with three-layer sandwich structure having a 2:5:2 volume ratio. The outer layers of filters I and II are ES layers of 15 wt% PVDF. The middle layers of filters I and II are 15 wt% PVDF and 18 wt% PVDF/zeolite (4:1) ES layers, respectively. The quantity of zeolite contained in the filter II multilayer is 17.2 μg. Filter I removes only 0.5% of the moisture with the film’s porous structure. In contrast, filter II absorbs 13.8% of the moisture from the humaid air. The zeolite particles embedded in the ES PVDF film capture moisture, which is absorbed to 15.1% of the weight of zeolite. As a result, freestanding ES film using circular electrode enables to functional multilayer for dust filtering, air ventilation and humidity removal.

ES05.07.11
Simulation of Realistic Dynamic NMR Spectra of Zeolites

Federico Brivio, Petr Nachtigall and Zdenek Tosner; Department of Physical and Macromolecular Chemistry, Charles University, Prague, Czechia.

Zeolites are crucial materials in fluid catalytic cracking. This process is of paramount importance in the production of fuel and other oil derivatives. Any improvement in their efficiency as catalytic compounds can hence lead to broad economic impact in this industrial sector, and general economy. The catalytic activity of zeolites is due to their crystalline micro-porous structure formed by interconnected alumino-silicate tetrahedra. This system of tetrahedra can be very complex and form several types of rigid frameworks where Si and Al can participate in different proportion. Frameworks can be further functionalized with the inclusion of other atomic species to tune their physical-chemical behavior.

Knowing the distributions of atoms in a given zeolite is hence crucial and can be investigated with means of nuclear magnetic resonance (NMR). Due to the critical role of Al atoms in catalytic process we focus on $^{27}$Al-NMR analysis. Experimental $^{27}$Al-NMR spectra are particularly difficult to interpret and obtain due to the quadrupolar moment of $^{27}$Al nucleus, but can return precious insight on the distribution of active catalytic sites usually associated with the Al atoms. Analysis of data can be supported by theoretical spectra obtained within ab-initio density functional theory (DFT) and the GIPAW formalism.

NMR signal is extremely sensitive to the atomic configuration and its chemical environment. Nonetheless, as far as we know, the large majority of theoretical investigations have compared experimental spectra to single specific structures assumed as representative of a whole system. This returns a partial, if not misleading, interpretation of the nature of the system, since different aspects, such as the dynamic of the system, or the measurement conditions, are overlooked.

To include such effects our study couples set of ab-initio Molecular Dynamics (AIMD) simulations with the calculation of NMR tensors of statistically significant (~100s) structures that occurs during the time evolution of the zeolites. This allows us to simulate realistic NMR spectra taking in account both dynamic effects and controlling the role on the NMR signal of different parameters such as temperature, pH, heterotomic substitution, hydration, …

The result of our study are then elaborated in collaboration with experimental group in order to compare our prediction with experimental spectra.

ES05.07.12
Photocatalytic Performance of Highly Transparent and Mesoporous Molybdenum-Doped Titania Films Fabricated by Templating Cellulose Nanocrystals

Yonghee Yoon, Soyoung Kim1, Cheolhwon Jeong1, Sunyong Lee1, Jaeyoung Kwon2 and Wonhee Lee1; 1Sejong University, Seoul, Korea (the Republic of); 2National Institute of Forest Science, Seoul, Korea (the Republic of).

In this paper, the synthesis of mesoporous Mo-doped titania films templated by cellulose nanocrystals (CNCs) and their photocatalytic performance are reported for the first time. The prepared titania composite precursors containing the CNCs and molybdanum chloride were spin-coated on indium tin oxide (ITO) glass substrate, followed by calcining at 400 °C for 1 h. X-ray diffraction (XRD), Brunauer–Emmett–Teller (BET), scanning electron microscopy (SEM), and UV–vis spectrometer were employed to characterize the phase composition, pore structure, morphology, and optical properties of the titania films in relation to CNCs templating and Mo doping. Photocatalytic performances of the titania films were also evaluated on the photodegradation of trichloroethylene under a fluorescent light source. The Mo-doped titania films with CNCs templating were highly transparent and mesoporous, exhibiting only anatase phase, high specific surface areas ranging in 135.4 ~ 149.0 m$^2$/g, and small crystallite sizes of 9.5 ~ 11.1 nm. The results indicate that Mo ions
High energy density electrode materials are highly desired in the area of energy storage to satisfy the demands of modern society's development. The porous nature of the hybrid carbon materials and its micro-scale porous distribution is attractive in energy storage fields. Conjugated microporous polymer (CMP) was synthesized through coupling polymerization with the catalysis of noble metal. The porous width of CMP can be adjusted by different precursors, while the noble metal catalyst will remain in the porous CMP after polymerization. After pyrolysis of the CMP, the noble metal nanoparticles will be encapsulated in the carbon matrix. The noble metal nanoparticles encapsulated in carbon materials will show its synergistic effects in energy storage area and potential applications in other fields.

Pd Encapsulated porous carbon materials (Pd-PCMs) were prepared from the coupling polymerization of ary1 halide and aryl terminal acetylene, whereas Pd(PPh3)4 serves as both the catalyst in polymerization and the precursor of Pd encapsulated in Pd-PCMs. With its porous microstructure and encapsulated Pd nanoparticles among porous carbon materials, Pd-PCMs provide strong physical confinement and surface chemical interaction to improve the affinity of polysulfides to the carbon matrix. The capacity of the battery is 920 mAh/g after 200 cycles at rate of 0.3C. The application of Pd-PCMs in Li-S batteries has broadened the applications of CMP and its derivatives in the field of energy storage, and with different particles encapsulated in adjustable porous carbon materials, CMP and its derivatives will also show its potential applications in other fields like catalysis and environmental applications.

### SESSION ES05.08: Advanced Characterization I

#### 8:00 AM *ES05.08.01*

**Easy and General Synthesis of Large Size Mesoporous Metal Oxides**

Bishnu Bastakoti; North Carolina A&T State University, Greensboro, North Carolina, United States.

The synthesis of mesoporous materials has attracted great interest due to their wide range of applications in drug delivery, catalysis, sensors, photovoltaic cells, and fuel cells. Low-molecular weight surfactants have normally been used to synthesize mesoporous materials. In this study, a new strategy has been proposed to synthesize large size mesoporous metal oxides. The use of asymmetric triblock copolymers with core-shell-corona nanoarchitecture as a template and structure directing agent gives rise a wide variety of mesoporous materials with large mesopores (10-50 nm). The catalytic activity of large size mesoporous metal oxides towards oxidation of CO will be discussed.

#### 8:15 AM *ES05.08.02*

**High Energy Rechargeable Zinc-Air Batteries**

Zhongwei Chen; University of Waterloo, Waterloo, Ontario, Canada.

Development of low cost, high energy, safe and long-life energy storage systems is critical for widespread commercialization of smart grid and electric vehicles. Rechargeable zinc-air batteries have been considered as most promising candidates as energy storage system for transportation, smart grids and stationary power. They can display a considerably high specific energy (1218 Wh/kg) and volumetric energy density (6136 Wh/L). Besides their high energy densities, zinc-air batteries also demonstrate other desirable characteristics, such as abundant raw materials, environmental friendliness, safety, and low cost. The current zinc-air battery is typically composed of four main components: an air electrode, an alkaline electrolyte, a separator, and a zinc electrode. For the electrically rechargeable zinc-air battery, each main structural component faces its own challenges. In this presentation, I will present our recent work on advanced energy materials development for rechargeable zinc-air batteries by focusing on the novel zinc electrode, nanostructured bifunctional oxygen electro-catalysts, 3D bifunctional air electrodes, and solid-state electrolytes. More specifically, we will discuss: 1) how the 3D zinc-sponge electrode solve problems of zinc dendrite, shape change and passivation, 2) how the nanoengineered materials can enhance the catalytic activity and durability of oxygen electro-catalysts, 3) how the 3D air electrode architectures can advance the practical performance of the zinc-air batteries, and 4) how the novel solid-state electrolytes can sustain cell operation substantially longer than common aqueous alkaline electrolytes do, as well as their extended applications include portable, flexible, and diversely shaped zinc-air batteries.

#### 8:45 AM *ES05.08.03*

**Approximate Density Functional Theory for Computational Heterogeneous Catalysis**

Stephan Irle; Computational Sciences and Engineering Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

The theoretical prediction of new catalysts requires precise knowledge of structural information on which to base accurate quantum chemical studies such as density functional theory (DFT) investigations of activation energies and reaction kinetics, often structural information is difficult to obtain, for instance when surfaces and nanoparticles undergo structural transformation under pretreatment and reaction conditions, exposing novel reactive sites responsible for the experimentally observed catalytic activity. A theoretical study based on ideal surfaces or particles created from bulk will entirely miss these important features, resulting in a theory-experiment disconnect.

The density-functional tight-binding (DFTB) method [1-5] is an approximation to DFT that reduces the computational effort by 2-3 orders of magnitude, and was used for the
prediction of the fullerene formation mechanism [6], the Haekelite formation mechanism on metal surfaces [7], the existence of a “sweet spot” for the catalyst oxygen content of carbon nanotube formation [8], and many other phenomena in materials sciences requiring highly complex quantum chemical modeling. The tremendous speed of the method originates from the careful parameterization of the Hamiltonian [9], eliminating all expensive integral evaluations. The method can deliver accuracy in structure and energetics comparable to DFT [4, 5, 10], and has recently been successfully employed in the pre-screening of reaction and activation energies for heterogeneous catalysis [11] and in the study of the topology of binary core-shell nanoparticles [12]. In this presentation we will highlight recent accomplishments in the parameterization effort related to the DFTB-based study of heterogeneous catalysis and illustrate the predictive capabilities in the context of graphene CVD synthesis on metal surfaces [13].

9:15 AM ES05.08.04 Nanoscale Probing of Adsorbates on Catalyst Surfaces with Allof Beam Vibrational Electron Energy-Loss Spectroscopy Karthik Venkatraman1, Barnabé D. Levin1, Katia March2, Peter Rez3 and Peter Crozier1; 1School of Engineering of Matter, Transport and Energy, Arizona State University, Tempe, Arizona, United States; 2EYing Materials Center, Arizona State University, Tempe, Arizona, United States; 3Department of Physics, Arizona State University, Tempe, Arizona, United States.

The ability to perform high-resolution mapping of adsorbate molecules or layers and correlate this with atomic structure would provide a transformative new tool for investigating the surface chemistry taking place on nanoparticles. Such a tool can be used to detect dissociative and non-dissociative sites on catalyst surfaces and study different bonding arrangements between the adsorbate and the catalyst. Electron energy-loss spectroscopy (EELS) in the scanning transmission electron microscope (STEM) has been used for studying vibrational modes in materials with high spatial resolution and sensitivity [1, 2]. Radiation damage may be substantial when a STEM electron probe is placed directly on the adsorbate layer of interest. We adopt the allof beam EELS technique that makes use of the long-range Coulomb interaction between electrons and adsorbate molecules to minimize damage when the probe is placed just outside the adsorbate layer. The delocalized vibrational signal in the allof beam mode has allowed for probing variations in the amine content of graphitic carbon nitride photocatalysts [3]. A theoretical treatment of surface-enhanced EELS has also been given which explains the electromagnetic coupling between the adsorbate and catalyst to demonstrate enhancement of the vibrational signal from the adsorbate [4]. Here, we explore three classes of adsorbate/catalyst systems because of their simplicity and overall scientific importance and their suitability for developing the allof beam vibrational EELS technique, viz. PVP ligand shell on Au nanoparticles, CO on Pt nanoparticles supported on CeO2 nanocubes, and CO2 on Mo5 nanocubes.

All our results were obtained using a NION UltraSTEM 100 aberration-corrected microscope operated at 60 kV and equipped with a monochromator. Allof beam EELS from the PVP ligand shell/Au nanoparticle system suffers from a low signal-to-noise ratio (SNR) and consists of two weak and broad vibrational signals centered at 160 meV and 205 meV. These signals correspond to peaks associated with the C-N stretch, CH stretch, and C=O stretch modes as observed in the Fourier-transform infrared (FTIR) spectrum from pure PVP, convolved with the experimental energy-resolution [5]. Preliminary allof beam EELS results from CO on Pt (111) particles demonstrate that the “on-top” vibrational mode of CO at 260 meV can be detected from a monolayer of adsorbate, although the signal suffers from poor SNR. This is in qualitative agreement with the diffuse reflectance infrared Fourier-transform spectrum (DRIFTS) from the CO on Pt/CeO2 system. Allof-beam EELS from the CO2 on Mo5 system showed that the Mo5 surface was hydrated before chemisorption of CO2, which led to the formation of a bicarbonate species on the surface. Further vibrational EELS results to investigate the bonding arrangements at different crystallographic surfaces in all three systems will be presented.

9:30 AM ES05.08.05 Pocket-Like Active Sites of Rh/MoS2for 100% Selective Hydrogenation of Crotonaldehyde Yang Liao1, Yongping Zheng2, Xu Liu2, Kyongjae Cho2 and Jingyue Liu1; 1Arizona State University, Tempe, Arizona, United States; 2University of Texas at Dallas University, Dallas, Texas, United States.

Selective hydrogenation of unsaturated aldehydes to saturated alcohols is extremely valuable for synthesis of fine chemicals but is a major challenge. We here report that single Rh atoms anchored on the edges of 2D MoS2(Rh/MoS2) can efficiently unsaturated crotonaldehyde to crotyl alcohol with 100% selectivity via steric confinement effect. The Rh/MoS2single-atom catalyst (SAC) is not only 100% selective but also active at moderate reactions conditions with a turnover frequency (TOF) of crotonaldehyde of 26.4/h at 80 °C (H-pressure is 5 bar). To our knowledge, the TOF of Rh/MoS2SAC is more than 50 times higher than that of the other reported heterogeneous catalysts that provides 100% selectivity for hydrogenation of crotonaldehyde to crotyl alcohol. Atomic resolution electron microscopy and CO-DRIFTS (diffuse reflectance infrared Fourier transform spectroscopy) results suggest that the Rh atoms strongly anchored to the edges of the Mo5sheets creates, resulting in unique electronic properties. The DFT calculations suggest that the edge anchored Rh can facilely dissociate H molecules to H atoms which spill over to form OH groups on the oxidized Mo edge sites of the Mo5sheets. The OH group and the associated Mo atom on each side of anchored Rh atom form a pocket-like active site with the configuration of HO-Mo-Rh-Mo-OH, in close resemblance of pocket-like sites of enzymes. Such specifically configured active sites impose severe steric hindrance that limits the possible adsorption configurations of the crotonaldehyde molecules and thus guide the chemical reaction to 100% selectivity. The strategy we used to construct pocket-like active site configurations is general and can be broadened to develop highly selective catalysts for a variety of important catalytic transformation of molecules [1].

Cowley Center for High Resolution Electron Microscopy at Arizona State University. This research was funded in part by the International Energy Joint R & D Program (No. 20168510011350) of the Korea Institute of Energy Technology Evaluation and Planning (KETEP) grant funded by the Ministry of Knowledge Economy, Korean government.

9:45 AM ES05.08.06 Synergistically Enhanced Hydrogen Evolution Activity by Ni3S2 Nanocluster Decoration on Vertically Aligned MoS2 Thin Films for Efficient Solar Water Splitting Seokhoon Choi, Changyeon Kim, Ki Chang Kwon, Kootak Hong, Jun Min Suh and Ho Won Jang; Seoul National University, Seoul, Korea (the Republic of).

Hydrogen emerges as a next-generation clean energy source to replace fossil fuels. One of the most promising ways to produce hydrogen is photoelectrocatalytic (PEC) water splitting in which sunlight-illuminated photoelectrodes generate electrical current to transform water into useful hydrogen. However, the existing photoelectrodes such as Si with noble catalysts still suffer from low efficiency and poor stability. Moreover, the extremely high cost of the noble metal catalysts limits the wide use of water splitting photoelectrodes. Recently 2-dimensional transition metal disulfides (2D TMDs) have been attracted much attention as promising candidates to replace Pt, because 2D TMDs such as molybdenum disulfide (MoS2) and tungsten disulfide (WS2) have inherently large surface-to-volume ratios and possess high densities of catalytically active sites for hydrogen evolution reaction (HER). Herein, we demonstrate that large-area (12 cm x 12 cm) and transferable MoS2 thin-film catalysts with vertically aligned layers, which maximally
expose the edges on the thin film surface. The vertically aligned domains in the transferable MoS
thin films not only facilitate the charge transport toward reaction interfaces, but also maximize the exposure of active edge sites of MoS
. Furthermore, the Fe-doped NiS
(Fe: NiS
) nanoparticles (NPs) grown on the vertically aligned MoS
(v-MoS
) thin films are obtained by in situ growth during the synthesis of v-MoS
. The synthesized Fe: NiS
/v-MoS
 thin films exhibits only 105 mV at 10 mA/cm
2 for HER with exceptionally low Tafel slope of 66.6 mV/dec among the thin film type catalysts. Moreover, the Fe:NiS
/v-MoS
/p-Si heterostructure photocathode can provide the high photocurrent density of 25 mA/cm
2 in the measurements in reversible hydrogen electrolyte. Density functional theory (DFT) calculations further reveal that the constructed coupling interface between v-MoS
 and Fe:NiS
 facilitates the absorption of protons (H
+ ), consequently enhancing the catalytic activity of the Fe:NiS
/v-MoS
 thin film catalyst. Such outstanding performances indicate that the unique structure suggests a novel approach for designing advanced 2D materials-based electrocatalysts.

10:30 AM *ES05.08.07
Atomic Resolution In Situ and Operando Characterization of Cooperative Catalysts
Peter Crozier; School for the Engineering of Matter, Transport and Energy, Arizona State University, Tempe, Arizona, United States.

The functionalities associated with many thermochemical and photochemical catalysts rely on a variety of different materials properties which regulate and control electron, ion and hole transfer across surfaces, interfaces and three-phase boundaries. Developing a fundamental understanding of these processes requires an atomic level picture of the structure and bonding during reactions. The interactions between different components of the catalytic system can be explored with aberration corrected imaging and spectroscopy in a transmission electron microscope (TEM). The critical surface motifs that convert reactants into products may form only under reaction conditions and must be investigated with in situ or operando approaches (1, 2). Here we show how advanced imaging and spectroscopy can be employed to elucidate the functionally important features for a variety of catalysts. One strategy for addressing the problems associated with storage of solar energy is to generate solar fuels. Photocatalytic splitting of water to generate hydrogen is extremely challenging systems must be able to harvest light and transfer electrons/holes to suitable reaction sites at the surface. Carbon nitrides have bandgaps in the visible and are promising materials for hydrogen evolution (3). The domain size and location of the Pt co-catalyst nanoparticles on the surface plays a critical role in interfacial charge transfer and the overall H
2 production efficiency. Interfacial sites may also play an important role in light harvesting. For example, TiO
2 which usually only harvests UV light, can be functionalize to absorb in the visible by depositing thin layers of CeO
2. Moreover, the Fe:Ni co-catalyst nanoparticles on the surface plays a critical role in interfacial charge transfer and the overall H
2 production efficiency. Interfacial sites may also play an important role in light harvesting. For example, TiO
2 which usually only harvests UV light, can be functionalize to absorb in the visible by depositing thin layers of CeO
2.

MoS
2 Supported Gold Nanoparticle Catalysis of CO to CO
2: William C. Coley and Amirali S. Akhavi; UCR, Morgan Hill, California, United States.

Transition metal dichalcogenides (TMDs) such as MoS
2 have technological application from chemical catalysis to emerging microelectronic integration. At the same time gold nanoparticles have demonstrated catalytic properties that differ from bulk gold depending on the substrate and particle size. We have indication that there may be catalytic states on gold nanoparticles supported by MoS
2 that allow for the room temperature binding of CO. We have shown with XPS the retention of CO and subsequent its removal with O
2. This may open up the potential to convert CO to CO
2 and methanol to higher order hydrocarbons such as ethanol. The MoS
2 is grown on a SiO
2 layer on a silicon wafer. We then deposit the gold nanoparticles by using e-beam deposition onto our MoS
2.

11:15 AM ES05.08.09
Spectroscopy of Ultrathin Bilayer Silicate Films on Pd(100) and Pd(111)
: Samuel A. Tenney, Veronica Lee, Jeffry A. Kelber and Dario Stacchiola; 1University of North Texas, Denton, Texas, United States; 2Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States.

In this talk we present the first reported photothermal infrared (PTIR) spectra of ultrathin bilayer silicate films with a spatial resolution better than 10nm and compare this with traditional infrared reflection absorption spectroscopy (IRRAS) of the same surface. The growth of ultrathin bilayer silicates on Pd(100) and Pd(111) is demonstrated under a variety of conditions and was observed in real-time with an in-situ low energy electron microscope (LEEM) and micro-low energy electron diffraction (μ-LEED). The bare Pd(100) and Pd(111) surfaces are fluid-like at the crystallization temperature of the silicate film as evidenced by the movement of the steps and terraces on the Pd surfaces. After crystallization of the silicate film was observed with LEEM and μ-LEED the samples were further characterized with X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES), IRRAS and PTIR. The resolution of the infrared peaks from the nanoIR instrument are substantially better than those obtained from the traditional IRRAS setup owing to the significantly smaller sampling area. The PTIR spectra are overlaid with the topographic information obtained from the AFM tip and some hyperspectral images will be presented. The chemical activity and selectivity of these model silicate/Pd catalysts will be discussed.

11:30 AM ES05.08.10
Controlling the Concentration of Oxygen Vacancies in CeO
2-ZrO
2 Nanoparticles via Spatial Tailoring of the Active Site
Behnam Safavinia, Yumang Wang, Smiti Sahu, Jared Larrihueeri, Kerry M. Dooley and James A. Dorman; Louisiana State University, Baton Rouge, Louisiana, United States.

According to Environmental Protection Agency, over 55% of NO
x emissions in the US is caused by automobile exhaust and also resulting in the formation of CO
2 and hydrocarbon residues. Transition metal doped CeO
2-ZrO
2 (CZO) nanoparticles (NPs) are extensively employed in three-way catalysis due to their ability to adsorb and release oxygen helping to prevent coking. These CZO NPs have shown a 5.3 mW/mg catalytic activity comparable to state of the art catalysts utilized in dry reforming of methane. However, the activity of these structures under reaction conditions, which is function of the position of the active site (Ni), has been shown to reduce the oxygen storage capacity and increase coking over time. To address this, the current work aims to understand the structural and electronic properties of the active site of CZO NPs, allowing for an in-depth study of the formation of oxygen vacancies in the lattice due to the position of the active site.

In this work, a two-step process, co-precipitation/molen salt synthesis (MSS), has been explored for a CZO-Ni catalyst, comparing its catalytic activity to oxygen vacancy concentration to a standard prepared by sol-gel technique. Transmission electron microscopy and X-ray diffraction identify that the as-synthesized NPs are monodisperse spheres, with 10 nm mean diameter, exhibiting floccular phase. The concentration of oxygen vacancies in these NPs was studied using Raman spectroscopy, which shows a higher intensity defect-induced (D) band at 600 cm
-1 for the as-synthesized catalyst than the reported standard. Furthermore, the information regarding the site occupancy of the active site (Ni) in these catalysts was obtained by calculating the change in FWHM of the F
2 band. To further correlate the concentration of oxygen vacancies to the position of the active site (Ni) in the lattice, surface sensitive electronic characterizations such as X-ray photoelectron (XPS) and soft X-ray absorption spectroscopy (XAS) were performed. The oxidation state of Ni was identified as 2+, indicating that the metallic Ni clusters are not present. Furthermore, the local bond structure and geometry of the active site was accurately probed from Ni L2,3 edge XAS measurements in addition to the site occupancy measurements from Raman spectroscopy. These preliminary results on CZO-Ni catalysts demonstrate that controlling the oxygen vacancies in the lattice by varying the position of the active site (Ni) is the first step to understand the diffusion of the active site during a reaction and deactivation pattern of the catalyst.
Quantum-Espresso is an open-source software widely used for predicting the properties of materials from first principles [P. Giannozzi et al., Journal of Physics: Condensed Matter 21, 395502 (2009)].

In this tutorial, we will train the participants on how to use the Quantum-Espresso software for different applications. The focus is on the simulation of molecular species, metal electrodes, and semiconductor photoelectrodes under electrochemical conditions using the self-consistent continuum solvation (SCCS) model [O. Andreussi, I. Dabo, N. Marzari, Journal of Chemical Physics 136, 064102 (2012)].

URL: www.quantum-espresso.org; www.quantum-environment.org

The tutorial will follow the format adopted in previous Quantum-Espresso workshops. It will contain brief overviews of the theory being the codes, followed by tutorials and hands-on activities. The morning session will cover: Fundamentals of Density-Functional Theory and the afternoon session will cover: Quantum Chemistry in Continuum Environments.

8:30 AM
Overview of Density-Functional Theory Ismaila Dabo; The Pennsylvania State University

The first lecture will cover the basic concepts behind DFT simulations using a plane-waves basis set and pseudo-potentials to treat core electrons. The main flavors of DFT, their advantages and their limitations for the study of molecular species, bulk metals and semiconductors, interfaces and heterogenous systems will be reviewed.

9:45 AM BREAK

10:15 AM
Hands-ON: Equilibrium Structure Calculations Ismaila Dabo; The Pennsylvania State University

The core functionalities of the PWscf code of the open-source Quantum-ESPRESSO package will be explored: self-consistent electronic structure calculations, geometry and cell optimizations, simple ab-initio molecular dynamics simulations will be performed. An overview of input and output files and post-processing of the simulation results will be provided.

1:30 PM
Overview of Implicit Solvation Oliviero Andreussi; University of North Texas

Continuum embedding models in condensed-matter simulations will be reviewed, focusing on the recently developed self-consistent continuum solvation (SCCS) and to the soft-sphere continuum solvation (SSCS) models. Models to treat metal and semiconductor electrified interfaces will be reviewed.

2:45 PM BREAK

3:15 PM
Hands-On: Quantum-Continuum Solvation Oliviero Andreussi; University of North Texas

The core features of the Environ plugin to the PWscf code will be explored, including SCCS and SSCS simulations with default and non-default parameters. A comprehensive overview of input and output files, as well as post-processing and visualization of the simulation results, will be presented. Simulations of electrified interfaces and advanced continuum interfaces will also be included.
Interfaces play an essential role in nearly all aspects of life and are critical for electrochemistry. Electrochemical systems ranging from high-temperature solid oxide fuel cells (SOFC) to batteries and capacitors have a wide range of important interfaces between solids, liquids, and gases which play a pivotal role in how energy is stored, transferred, and/or converted. This talk will focus on our use of ambient pressure XPS (APXPS) to directly probe the solid/gas and solid/liquid electrochemical interface. In particular, I will discuss our progress to probe the solid/liquid interface across a range of metal/aqueous systems and the role halide ions play on the stability of the interfacial properties. Additionally, I will highlight some of our recent investigations into CO₂ adsorption phenomena on various metals as we move closer to developing the capabilities for studying CO₂ reduction under electrochemical conditions. Information gained from these studies will aid in the guided design and control of future electrochemical interfaces.

11:00 AM ES06.01.02
Stimulated Raman Spectroscopy of Amorphous Oxide Catalyst During Oxygen Evolution Reaction
Chuhyon J. Eom and Jin Sunivich; Materials Science and Engineering, Cornell University, Ithaca, New York, United States.

Understanding of the in-reaction structure and the functionality of a catalyst are closely connected. Detailed structural information can be revealed through vibrational techniques; however, a number of challenges need to be overcome. For instance, low scattering rates for Raman spectroscopy have made in-situ Raman of catalysis difficult. In this contribution, we demonstrate stimulated Raman spectroscopy (SRS) as an in-situ probe to address the challenge of low scattering rates in Raman. As a nonlinear spectroscopic technique, SRS holds several advantages including efficiency. Leveraging the improved efficiency, we apply SRS to measure the vibrational structure of an amorphous cobalt oxide catalyst during the oxygen evolution reaction (OER). Additional experiments using isotope labelling are used to identify the nature of the vibration structure. These results present the potential of SRS as a useful tool to investigate the much sought-after catalyst surface in-situ. The spectroscopic techniques, methods of analysis, and the experimental results will be presented.

11:15 AM ES06.01.03
Introducing Geometric Distortions in Disordered Nickel (Oxy)hydroxide Electrocatalysts by Incorporation of Fe(III)  Rodney Smith and Holger Dau; 1University of Waterloo, Waterloo, Ontario, Canada; 2FB Physik, Freie Universität Berlin, Berlin, Germany.

The dramatic change in electrochemical behavior of nickel (oxy)hydroxide films upon incorporation of Fe ions provides an opportunity to establish effective electrocatalyst design principles. It is well established that the addition of miniscule amounts of Fe(III) ions to nickel (oxy)hydroxide results in significant improvements in kinetics for the electrocatalytic water oxidation, but the chemical understanding of these gains remains a matter of debate. This presentation will introduce and discuss an asymmetric geometric distortion that was revealed by structure-property analysis of a series of disordered Fe–Ni (oxy)hydroxides. [1] These distortions were revealed by first identifying prominent structural motifs in the composition series by X-ray absorption spectroscopy, then correlating their structural descriptors to electrochemical and structural data acquired by in-situ UV-visible spectroelectrochemical data. Structural analysis indicated the presence of di-µ-hydroxo Ni-Ni and di-µ-hydroxo Ni-Fe motifs, with relatively important resonances on Fe-content. Both motifs exhibit trigonal distortions away from ideal octahedral coordination environments, imparting a local D₃₄ symmetry that is known in crystalline β-Ni(OH)₂. The distortion of Ni-Ni motifs in both the oxidized and reduced phases of the disordered materials is comparable to that observed in β-Ni(OH)₂, with O-Ni-O bond angles of 82°. The Ni-Fe motif contrasts with this, exhibiting a relaxed distortion in the reduced phase (84°-degree bond angle) and an increased distortion (<80-degree bond angle) in the oxidized phase. Spectroelectrochemical experiments reveal a previously unreported change in optical absorbance at ca. 1.5 V vs. RHE in Fe-containing samples, which is assigned as the oxidation of Ni(II) ions in the distorted di-µ-hydroxo Ni-Fe motif. A mechanism is proposed wherein the pre-catalytic redox process is assigned to oxidation of Ni-Ni motifs, while the catalytic process is decoupled from this process and assigned to the electrochemical oxidation of Ni sites in the Ni-Fe motif. The asymmetric distortion is attributed to the redox-inactivity of the Fe(III) ions in the material and the favored Fe(II)-O bond length being located between that of Ni(II)-O and Ni(IV)-O.

systems. In specific, we have developed an on-chip electrical transport spectroscopy (ETS) approach for directly probing the electrochemical surfaces of metallic nanocatalysts under in operando conditions, using ultrathin PdNWs as model electrocatalysts. Our results show a high degree of consistency with generally accepted conclusions in platinum electrochemistry, and provide important new insights into various technologically important electrocatalytic (such as fuel cell) reactions. This study defines a novel nano-electronic on-chip characterization strategy, as an alternative to the traditional spectroscopic characterization techniques, for in situ electrochemical surface studies with high surface sensitivity and surface specificity. The on-chip nano-electronic investigations have been further applied to investigate the anisotropic surface adsorptions on platinum surface, in simulating their competitive adsorption behavior with oxygenated species and correlating them to the electrokinetics of the oxygen reduction reaction (ORR). The ETS enables highly sensitive characterization of anionic adsorption and opens an efficient pathway to address the practical poisoning issue (at trace level contaminations) from a fundamental perspective. Additionally, ETS has also been applied to reveal the charge transport mechanism and the electrochemical behavior in electronic microbes (including Shewanella and Geobacter, two widely used microbes in microbial fuel cells), which has been a subject of on-going debate. Our results elucidate the complex basis of electrical conductivity of both individual microbial cells and biofilms, and have led to a new model revealing the electrochemical origin of microbial conductivities.

1:30 PM *ES06.02.01
Catalyst Development for Water Electrolysis and Fuel Cell Reactions Involving H2, O2, H2O, and H2O2 Thomas Jaramillo1, 2; 1Chemical Engineering Dept., Stanford University, Stanford, California, United States; 2SUNCAT Center for Interface Science and Catalysis, Stanford University, Stanford, California, United States; 3Photon Sciences, SLAC National Accelerator Laboratory, Menlo Park, California, United States.

Water electrolyzers and fuel cells are promising technologies that can play a role in a sustainable future. Catalyst development is needed to advance these systems, to improve performance and to lower costs such that the systems can be cost-competitive with respect to conventional technology. This talk aims to describe catalyst development challenges and opportunities within this area. The focus will be on catalyzing interconversions involving H2, O2, H2O, and H2O2, with an emphasis on low- or zero-precious metal content catalyst materials. Examples will be given for catalyst design from first principles, the development of materials based on those principles, and their integration into functional devices.

Molecular Understanding of the Oxide Electrocatalyst Surface Kelsey A. Stoerzinger1; 1Physical and Computational Sciences Directorate, Pacific Northwest National Laboratory, Richland, Washington, United States; 2School of Chemical, Biological and Environmental Engineering, Oregon State University, Corvallis, Oregon, United States.

Oxide catalysts are an important class of electrocatalysts for the oxygen reduction and evolution reactions in fuel cells and electrolyzers. Electrochemical studies of well-defined surfaces grown by pulsed laser deposition or molecular beam epitaxy establish the intrinsic activity of oxide catalysts in a way that cannot be realized with polydisperse nanoparticle systems, and can also reveal how different terminations1 and structures2 affect the energetics and kinetics. Furthermore, the surface speciation of epitaxial films in an aqueous environment can be quantitatively assessed in situ using ambient pressure X-ray photoelectron spectroscopy. Understanding oxide electronic structure in an aqueous environment is also critical for promoting charge transfer reactions. To this end, we investigate changes in the electronic structure as a function of the oxygen and water chemical potential, enabling comparison with the metal redox potential and catalytic activity.3 The resultant molecular-level understanding of interfacial interactions developed from epitaxial surfaces can guide the rational design of high-surface-area oxide catalysts for technical applications.

Combining Electrochemistry, Surface Science and Density Functional Theory to Identify Electrocatalytic Structure-Property Relationships in OER Catalysts Douglas R. Kaufman1, Xingyi Deng1, 1National Energy Technology Lab, Pittsburgh, Pennsylvania, United States; 2AECOM, South Park, Pennsylvania, United States.

We present an approach that couples electrochemistry, surface science, and density functional theory (DFT) calculations to precisely identify structure-property relationships in electrocatalytic oxygen evolution reaction (OER) catalysts. The OER is an essential component in electrochemical CO2 conversion systems, and mixtures of nickel, cobalt, and iron have shown remarkable alkaline OER activity that exceeds state-of-the-art IrOx. However, atomic-level understanding of how OER activity evolves with the catalyst shape, size, composition, and support are still lacking in the literature. Our approach grows well-defined transition metal electrocatalysts with precisely controlled morphology, composition, and loading. Scanning tunneling microscopy (STM) and X-ray photoelectron spectroscopy quantify the catalyst loading (mol/cm2), number density (particles/cm2), and morphology with unrivaled spatial resolution. Electrochemical testing then correlates mass activity, turnover frequency, and specific current density with the catalyst structure and composition. We find clear experimental and computational evidence for edge-enhanced OER at pure FeOx structures, and this insight was translated into the synthesis of a nanoparticulate analog for demonstration in alkaline electrolyzer devices. On the other hand, mixed metal NiFe systems showed a more complex evolution of structure-dependent activity that did not directly depend on the relative density of under-coordinated edge sites. Our approach provides atomic-level structure-property relationships for emerging OER catalysts that can be used to guide scalable synthetic strategies and expedite the deployment of more energy efficient electrocatalyst systems.

2:45 PM ES06.02.04
Measurements of Oxygen Electroadsorption Kinetics on RuO2(110) and IrO2(110) Ding-Yuan Kuo, Hanjong Paik, Jocienne Nelson, Kyle Shen, Darrell Schlom and Jin Suntivich; Cornell University, Ithaca, New York, United States.

RuO2 and IrO2 are among the best catalysts for the oxygen evolution reaction (OER), an electrochemical reaction that limits the efficiency of water splitting. The high activity of these rutile oxides has been attributed to their ability to stabilize the OER intermediates via electroadsorption which involves related elementary proton and electron transfer steps related to the oxygen electroadsorption are still unclear. In this presentation, we present our measurements of these kinetics on well-defined RuO2 and IrO2 surfaces. We use rate-dependent cyclic voltamnograms to extract the rates of the oxygen electroadsorption on RuO2 and IrO2. Well-defined surfaces are used to minimize convolution from different facets. We further identify the pathway and related fundamental rate laws by investigating the influence of different electrolytes on kinetics. Our results provide insights into the kinetics of oxygen electroadsorption on oxides and the fundamental origin of the sluggishness in the OER kinetics.

Identify Atomic-to-Nano Structures and Structure Evolution of Pt and PGM-Free Electrocatalysts for Oxygen Reduction Reaction Vivyan Shao; Pacific Northwest
Oxygen reduction reaction (ORR) catalysts account for the largest efficiency loss and one of the largest cost portions of PEM fuel cells. There has been intensive research effort on ORR electrocatalysts from precious metals to nonprecious metals (also called platinum group metal (PGM)-free catalysists). Developing highly efficient precious metal electrocatalysts and highly active PGM-free catalysts remains a grand challenge, and finding catalysts that are stable and durable in the harsh PEM fuel cell environment is even more challenging. In this talk, we will discuss our research to understand the instability of the catalysts from materials innovation to advanced characterization. We will introduce our environmental TEM study of PGM catalysts, PGM-free catalysts instability and the proposed solutions.

Modification of Fuel Cell ORR Catalyst Surface with Organic Ligands for Enhanced Activity and Durability—The Effect of Ligand Structures Yuta Ikehara, Tomoyuki Nagari and Hironori Hiai; 1Fuel Cell System & Component Design Department, Toyota Motor Corporation, Toyota, Japan; 2Materials Research Department, Toyota Research Institute of North America, Ann Arbor, Michigan, United States.

Recent advances of polymer electrolyte membrane fuel cell (PEMFC) technology has been substantial and successfully led to the commercialization of fuel cell electric vehicles (FCEVs) such as Toyota Mirai. However, the continuation of FCEV development is facing several hurdles, of which one major issue is related to the high cost of fuel cell system as compared to conventional engines. Economic analysis has shown that catalysts is by far the most expensive material component for high production volume. [1] Current state-of-art PEMFCs use platinum-based catalysts to speed up hydrogen oxidation reaction (HOR) and oxygen reduction reaction (ORR) on the anode and the cathode, respectively. While the HOR proceeds very fast on Pt surface, the ORR has a sluggish kinetics, as it involves sequential steps of proton coupled electron transfer processes and a “scaling” issue makes it difficult to optimize every elemental reaction step simultaneously. [2]

Many previous works have focused mainly on ORR catalyst material properties, for example, alloy, core-shell, shape control and so on. Engineering catalyst-electrolyte interface properties may offer another way to overcome the problem. One recent effort involves the modification of Pt catalyst surface with organic ligands and has demonstrated some successes in enhancing catalyst activity. [3-5] The improvement was mostly attributed to either the change of surface structural material of the catalyst, or the protection of Pt active sites from poisoning by strong anion adsorption. [6-8] In this study, we systematically examined a series of organic ligands with different structures. Combining material characterization with electrochemical analyses allowed us to assess not only the catalyst activity and durability, but also the ligand stability. Such a comparative study is expected to provide additional insights on ligand structural design for further improvement of catalyst performance.

Optimization of Pt Loading Ratio in Low Pt-Cathode Catalysts for PEFC Application Kenta Inaba 1, Toshihiko Manda 1, Tatsuya Takeguchi 1, Yasuo Kaneda 2 and Koichi Urui 1; 1Faculty of Science and Engineering, Iwate University, Morioka, Japan; 2JUKES Inc., Kui, Japan.

Polymer electrolyte fuel cells (PEFCs) have attracted much attention as one of the highly efficient power sources for fuel cell vehicles. A large amount of platinum (Pt) is used in general as electrode catalysts to improve reaction kinetics – an oxygen reduction reaction (ORR) and hydrogen oxidation reaction (HOR) on the cathode and anode sides, respectively. Pt loading ratio on the electrode is critical. In PEFC, the Pt loading ratio on the electrodes is considered as a practical use of large-scale PEFCs. In this study, we studied the effect of the Pt loading ratio and carbon supports (C) on ORR activity of the Pt/C cathode catalysts. Well-dispersed Pt nanoparticles were successfully loaded on the two carbon supports having different surface area and pore distributions. The ORR activity of the resulting Pt/C catalysts was evaluated with respect to the mass activity, electrochemically active surface area (ECSA), and cell voltage under PEFC operation.

Two Ketjen black (ECP300J and ECP600JD, LION) were used as a carbon support. The Pt/C catalysts with different Pt loading ratio, Pt/C = 20 - 40 %, were prepared by the ethanol reduction method. The specific surface area and pore size distribution of the carbon support with and without Pt loading were determined by Brunauer-Emmett Teller (BET) measurements. The mass activity and ECSA of a series of Pt/C catalysts were evaluated by the Koutecky-Levich plot at 0.7 V vs. RHE and CO stripping, respectively, by using the rotating disk electrodes. The fuel cell tests were carried out by using the membrane electrode assembly (MEA) consisting of the prepared Pt/C cathode catalysts, commercial Pt/C anode catalysts, and typical polymer electrolyte membrane (Nafion). The Pt loading in the cathode and anode was fixed at 0.1 and 0.5 mg-cm⁻², respectively. The I-V polarization curves were measured at 70 °C with the steady flow of fully humidified O₂ and H₂ gases into the cathode and anode, respectively. In the prepared Pt/C catalysts, the Pt particles were well dispersed on the carbon supports with the average diameter of 1.8 nm, almost irrespective of the Pt loading ratio. The mass activity and ECSA however indicate the presence of superior number of active sites for the catalysts using ECP600JD as a support. The BET analysis on the Pt/C catalysts also supports the larger specific surface area of the Pt/C catalyst with ECP600JD than that with ECP300J. Intrinsically large surface area of the ECP600JDs a likely reason. The ORR activities of the MEAs clearly reflects the mass activity and ECSA of the Pt/C cathode catalysts. The MEAs with Pt/C catalysts with ECP600JD indeed showed higher cell voltage than those with ECP300J at the same current density. On the other hand, the ORR activity of the Pt/C catalysts was not proportional to the Pt loading ratio, but local maxima were observed at around 35%. As the Pt loading ratio was fixed, the thickness of the catalyst layer decreases thicker with increasing the Pt loading ratio, while mass activity decreases. A balance between the thickness of the catalyst layer and the number of active sites would predominant the ORR activity of the Pt/C cathodes under PEFC operation.

4:30 PM ES06.02.08
Catalytic Activity of Oxygen Reduction Reaction on Mono-Layer Molecule Electrode using the Transition-Metal Oxide Nanosheet Takahiro Saida, Miyu Mashiyma and Takahiro Maruyama; Meijo Univ., Nagoya, Japan.

Polymer Electrolyte Fuel cell (PEFC) is attracted attention as one of the next generation power sources because it exhausts theoretically only water. However, its high cost and short service life are inhibiting the wide-spread commercialization. It is thought as one reason that this is attributing to using the platinum-based electrocatalyst. To reduce cost and lengthen service life radically, the non-platinum-based catalyst such as oxide, carbon-allowing and the enzyme has been developing. The oxide-based catalyst has the high possibility as the alternative the platinum-based catalyst due to possessing the high stability under PEFC operation conditions. Several researchers had reported that a part of oxide, such as group 4- and 5-metal oxide and precious metal oxide, showed the high activity of oxygen reduction reaction (ORR). However, these ORR activity does not achieve that of the conventional platinum catalyst. One reason for this situation is the active site on oxide surface is not fully understanding as the common recognition. Thus, it is hard to advance the new concept to increase the active site density. The situation inside the catalyst layer during the ORR progress is too much complex since it needs to take consideration with the diffusion of oxygen, proton, electron, and water in catalyst layer other than the ORR mechanism on the oxide surface.

Therefore, we focused on the mono-layer molecule electrode forming by the metal oxide nanosheet in order to exclude a variety of the diffusion resistance on an electrode. This study focused on the role of the oxygen vacancy site on titanium oxide nanosheet (TiO₂ns) and titanium-niobium oxide nanosheet (TiNbO₂ns) and the redox site on nuthenium oxide nanosheet (RuO₂ns) for the ORR.

A mono-layer molecule electrode was prepared by Layer by Layer method combining with the poly-cation copolymer and each transition-metal oxide nanosheet. Various types of transition-metal oxide nanosheets were synthesized along previous literature. The deposition condition of transition-metal oxide nanosheet on the substrate was observed by AFM. The electrochemical measurement was conducted by the rotating disc electrode as the reference and a carbon rod as the counter electrode. At that time, 0.1 M HClO₄ at room temperature was employed as the electrolyte. ORR activity was evaluated by the potential at -0.05 mA cm⁻² of difference current between oxygen flow conditions and nitrogen flow conditions.

The ORR activity of RuO₂ns mono-layer electrode showed about 0.6 V which was almost agreed with that of evaluation used powder sample. Addition, the redox peaks of RuO₂ns were clearly observed also in a mono-layer electrode. Thus, it is thought that a mono-layer electrode, which was prepared by Layer by Layer method, was also possible to evaluate accurately the electrochemical behavior including of ORR activity. In the case of TiNbO₂ns without oxygen vacancy or Nb doping, the ORR activity was lower than that of RuO₂ns.
Thus, it is thought that ORR activity depends on the kind of transition metal.

4:45 PM ES06.02.09
Maximization of Quadruple Phase Boundary for Alkaline Membrane Fuel Cell Using Non- Stoichiometric α-MoO3 as Cathode Catalyst Xuan Shi1, AM Kamann1 and Haotao Zheng2; 1Arizona State University, Mesa, Arizona, United States; 2MSM, Council for Scientific and Industrial Research, Pretoria, South Africa.

Oxygen can only be reduced at the quadruple phase boundary (catalyst, carbon support, ionomer and oxygen) of the cathode catalyst layer with the non-conducting electrocatalyst. To maximize the quadruple phase boundary sites is crucial to increase the peak power density of each membrane electrode assembly. The quadruple phase boundary is depending on the ratio of catalyst, carbon support and ionomer. The loading of the catalyst layer is also crucial to the fuel cell performance. In this study, the non-stoichiometric α-MoO3 manganese dioxide nanorod material has been synthesized and the ratios of carbon, ionomer, and catalyst loadings were optimized in alkaline membrane fuel cell. In total, ten membrane electrode assemblies have been manufactured and tested. Taguchi design method has been applied in order to understand the effect of each parameter. The conclusion finds out the ionomer has more influence (68% factor effect) on the alkaline fuel cell peak power performance than carbon and loading.

SESSION ES06.03: High-Temperature Electrochemical Analysis
Session Chairs: Kelsey Stoezinger and Jim Suntivich

In Situ/Operando XRD Study of a Reversible PtOx Formation at the Pt/YSZ Interface Sergey A. Volkov1, Alexander Hutterer2, Pirmin Lakner1, Florian Bertram1 and Vedran Vonk1; 1DESY, Hamburg, Germany; 2Technische Universität Wien, Vienna, Austria.

Complexity of the fuel cell technology drives researchers to study different model systems in order to get insight into the processes during Solid Oxide Fuel Cell (SOFC) operation. One of such model systems is a Pt/YSZ where platinum plays role of a cathode on yttria-stabilized zirconia (YSZ) electrolyte. Different phenomena may lead to undesirable electrode deactivation. Along with irreversible morphological changes (e.g. film dewetting, blistering), another process, observed as an additional resistivity during anodic polarization, hinders oxygen transport in our model-electrode system. This process is assigned to the formation of Pt “phase” oxide at the Pt/YSZ interface and triple-phase boundaries. PtOx is predicted to be responsible for passivation of the working electrode in Pt/YSZ model systems. Indirect but convincing evidences of electrochemically driven Pt oxidation on well-defined Pt electrodes are present in several studies. Although there is still a debate on the exact mechanism of PtOx formation and its structure (PtO, PtO2 or Pt2O3), there is no doubt it influences oxygen exchange kinetics, which decreases electrocatalytic activity of an electrode in Pt/YSZ model system. Employing X-ray diffraction (XRD) combined with electrochemistry measurements at beamline P08, Petra III Synchrotron, DESY, Hamburg, we provide first direct evidence of the existence of PtOx phase at the Pt(111)/YSZ(111) interface after anodic polarization, which decomposes once the potential is reversed. In situ/operando surface XRD on electrode/electrolyte interface reveals its structure and evolution on atomic scale. Our results show feasibility of applying synchrotron based surface XRD to study fuel cell related electrode/electrolyte model interfaces operando and contribute to better understanding of a complex multistep oxygen reduction and evolution reactions in electrochemical devices, such as SOFCs and oxygen lambda sensors.

Thermochemical and Electrochemical Trends in the Ceria-Zirconia System Sossina M. Haile1 Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States.

Introduction of zirconia into ceria is known to enhance the reducibility of the latter, despite the fixed tetravalent state of zirconium. Here we use a host of techniques to explore the origin of this behavior, its relevance to surface oxidation state, and its impact on kinetic properties. We find, for example, from in situ XANES (X-ray Absorption Near Edge Spectroscopy) that while the surface of ceria is reduced relative to the bulk whether or not zirconium is present, the extent to which the surface and bulk regions differ depends strongly on the Zr concentration. Specifically, with increasing Zr, the differential between the two regions diminishes. In parallel, using electrical conductivity relaxation methods, it is observed that the bulk chemical diffusion of oxygen in Ce0.8Zr0.2O2−δ is lower than that in undoped ceria. The connections between these and related observations is discussed.

9:30 AM ES06.03.04
Nanoscale Design of Grain Boundary Composition for Improved Ionic Conductivity in CeO2 Ceramics Tara M. Boland1, Peter Rez2 and Peter Crozier2; 1Materials Science and Engineering, Arizona State University, Tempe, Arizona, United States; 2Physics, Arizona State University, Tempe, Arizona, United States.

Ceramic oxides are used for a wide variety of technologically relevant applications from electrochemical devices, novel resistive switching devices and oxygen sensors. Applications such as these typically rely upon the ability of oxides to conduct ions efficiently through the lattice. For oxides, such as CeO2 (ceria), it is common to dope with alternative elements to increase the number of available charge carriers. While the methods developed for bulk-doping have been successful, they have provided little insight when optimizing the grain boundary (GB) ionic conductivity in polycrystalline ceramic oxides. Recent nanoscale compositional characterization has shown different nominal concentrations could result in orders of magnitude increase in GB ionic conductivity relative to the undoped samples [1]. This effect has been attributed to increases in local dopant/solute concentrations at the GB. This study aims to predict the optimal dopants that, when present in high concentrations, increase the ionic conductivity across the GB.

To show how the various dopants modulate the ionic conductivity across the GB, computational modeling is employed using molecular statics to optimize the GB interfacial structure for three symmetric tilt and one twist GB in CeO2. The GB structures are then doped using a high concentration profile obtained from ref 1. Molecular dynamics simulations are performed to correlate migration energetics with changes in conductivity for the various dopants. The energetic and structural properties of various oxygen migration pathways are compared for each dopant species to ascertain how nanoscale composition and local atomic structure can modulate ionic conductivity across GBs. The trends obtained using molecular dynamics are validated using density functional theory calculations. This study further develops our understanding of high solute GB composition and structure, enabling the development of methods such as selective doping to improve macroscopic ionic conductivity for both the grain and GB.

9:45 AM ES06.03.06
Determining the Atomic Structures at Fluorite-Perovskite Interfaces Bonan Zhu1, Georg Schusterlighthouse1, Ping Lu1, Judith L. MacManus-Driscoll2 and Chris J. Pickard1; 1Department of Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom; 2Advanced Institute for Materials Research, Tohoku University, Sendai, Japan; 3Sandia National Laboratories, Albuquerque, New Mexico, United States.

Interfaces play important roles in many functional thin film devices. However, the atomic configurations at interfaces between two phases with different crystal structures are not easily determined experimentally, yet they are the key for understanding the properties induced. Vertically aligned nanocomposites (VAN) typically have pillar-matrix nanostructures combining two distinct phases. Up to two orders of magnitude increase in out-of-plane ionic conductivity was observed using Sm-doped CeO2 (SDC)/SrTiO3 (STO) VAN films grown on STO substrates. To investigate the roles of vertical interfaces, we used random structure searching to explore the atomic configurations at the vertical interfaces. The structures were found to contain any features that promoted interfacial oxygen diffusion. Instead, they suggested that vacancy movement may be suppressed near the interface due to the existence of trapping sites. In addition, motivated by the controversies claims of enhanced ionic conductivity at yttria stabilized zirconia (YSZ)/STO planar interfaces,
we performed fully first-principles random structure searching at a model CeO$_2$/STO (001) interface. We found previously unknown stable interfaces structures that differ from the bulk phases. Vacancy formation energies and diffusion pathways were studied and their effects on ionic conductivity will be discussed.

Strategic Design of Catalysts and Electrolytes for the Electrochemical Reduction of CO$_2$: Alexis Bell, University of California, Berkeley, Berkeley, California, United States.

Recent experimental studies have shown that the electrochemical reduction of CO$_2$ depends on many factors, including the composition and structure of the electrocatalyst, the composition of the electrolyte, and the effects of mass transfer between the bulk electrolyte and the catalyst. The choice of electrocatalyst affects the principal products produced. For example Ag would be the catalyst of choice to reduce CO$_2$ to CO, whereas Cu would be the preferred catalyst for the production of C$_2$H$_4$ hydrocarbons and alcohols. The choice of alkali metal cation used for the electrolyte also influences catalyst activity and product selectivity. For both Ag and Cu, the action and the selectivity towards forming carbon-containing products versus hydrogen is strongly enhanced by using Cs$^+$ rather than Li$^+$. Mass transfer of from the electrolyte to the catalyst and of OH$^-$ anions from the catalyst to the bulk electrolyte also affect the product distribution. It will be shown that manner in which mass transfer affects the distribution of product formed during the electrochemical reduction of CO$_2$ is best understood from simulations of a complete electrochemical cell. This point will be illustrated based upon simulations of CO$_2$ reduction occurring in an aqueous electrolyte containing planar electrodes.

11:00 AM ES06.03.07
CO Site Preference on Copper Surfaces in Electrochemical Environments—Deciphering Voltage and Electrolyte Composition Effects: Stephen E. Weitzner, Sneha A. Akhade, Joel B. Varley, Brandon C. Wood, Sarah E. Baker and Eric B. Duoss; Lawrence Livermore National Laboratory, Livermore, California, United States.

The development of effective electrocatalysts to convert carbon dioxide into value-added products such as methane and ethylene requires a detailed atomistic understanding of the reaction pathway. While it is well known that copper (100) surfaces exhibit a higher selectivity towards ethylene production, both electrochemical and non-electrochemical pathways have been proposed to describe this process. In both cases, the presence of adsorbed CO plays a crucial role and the pathways are observed to be active under different conditions. In this work, we study the role of the electrochemical environment in stabilizing CO across different copper surface sites and evaluate the energy barriers of key steps in the carbon dioxide electroreduction pathway. Using the recently developed Effective Screening Medium—Reference Interaction Site Method (ESM-RISM), we provide a detailed assessment of the roles of both applied voltages and electrolyte composition effects. Our results demonstrate that these two factors are synergistic, leading to behavior that qualitatively deviates from conventional models.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

11:15 AM ES06.03.08
Hierarchical Quasi-1D CuO$_x$-Derived Nanostructured Copper Catalysts for CO$_2$ Reduction: Giorgio Giuffredi$^{1,2}$ and Fabio Di Fonzo$^1$; Istituto Italiano di Tecnologia, Milano, Italy; $^2$Department of Energy, Politecnico di Milano, Milano, Italy.

Electrochemical reduction of emitted CO$_2$ to fuels and complex hydrocarbons represents a promising solution to efficiently store intermittent, renewable energies-generated electricity in the form of chemical energy of carbon-based fuels. Copper is one of the most interesting CO$_2$ reduction electrocatalysts, thanks to its ability to reduce carbon dioxide to complex hydrocarbons with good efficiency, however when in bulk polycrystalline form it has low activity and requires a high overpotential for the reduction reaction. Oxide-derived Cu catalysts are one of the most efficient way to increase the intrinsic activity of Cu: this class of materials have higher selectivity for complex hydrocarbons and longer stability. Moreover, their CO$_2$ reduction activity and selectivity are strongly affected by the morphology, which controls the mass transport of the reactants to the active sites and influences the local pH. In this contribution, the CO$_2$ reduction activity and selectivity of Cu catalysts derived from the reduction of Copper Oxide (CuO$_x$) hierarchical nanostructures with different structural features are investigated.

We propose an approach that couples two aspects: the first one is employing an amorphous CuO$_x$ material, which presents a higher availability of undercoordinated surface sites which, coupled with the high surface area, increases the activity. The second aspect is controlling the morphology of the CuO$_x$ nanostructures down to the nanoscale by exploiting Pulsed Laser Deposition (PLD) as synthesis method: this technique, in fact, allows for a fine control over the deposit morphology by finely tuning the deposition parameters. In this way, the chemical composition and thickness of the hierarchical quasi-1D nanostructures are kept constant and it is possible to modify their aspect ratios, their nanostructuring and their micro- and nanoparticles diameters. With this approach, it is possible to evaluate the effect of the nanoscale morphological features on the overall catalytic activity – that is, on a smaller length scale than what is usually performed for Oxide-derived Copper catalysts.

Characterization of the PLD-synthesized nanostructures shows an amorphous matrix with embedded crystalline seeds of CuO and Cu$_2$O, differently from other reported oxide-derived Cu catalysts. CO$_2$ reduction performance of the oxide-derived Cu nanostructures is assessed through chromatographic measurements in aqueous electrolyte, showing good current densities up to -60 mA cm$^{-2}$ and a good stability for at least one hour of prolonged operation. Liquid products analysis, performed via $^1$H NMR spectroscopy, shows a high productivity of ethanol at limited potentials applied (V=-0.4 V RHE).

This contribution shows how coupling an amorphous, oxide-derived Cu catalyst with a fine control over morphology can be an efficient way to increase the activity of CO$_2$ reduction catalysts.

11:30 AM *ES06.03.09
Isolated Transition Metal Single Atom Catalysts for Selective CO2 Reduction: Haotian Wang; Chemical and Biomolecular Engineering, Rice University, Houston, Texas, United States.

The development of highly selective and earth-abundant electrocatalysts for CO$_2$ reduction is becoming increasingly important for renewable energy applications. The challenge here is the strong competition from water reduction, as well as the low selectivity towards a desired product. In this talk I will introduce the rational tuning of electronic properties of catalytic materials for their significantly improved CO$_2$ reduction performance. By dispersing transition metals into isolated single atoms with electronic structures significantly different from their bulk counterparts, we can dramatically suppress the competing hydrogen evolution and deliver an ultra-high CO$_2$ reduction selectivity of more than 95% under ambient conditions in water.

1:30 PM *ES06.04.01
Enhanced Electrocatalytic Activities of Ruddlesden-Popper Catalysts for the Oxidation of Urea and Small Alcohols By Active Site Variation: Keith Stevenson$^2$ and Robin Forslund$^1$; $^1$University of Texas at Austin, Austin, Texas, United States; $^2$Center for Electrochemical Energy Storage, Skolkovo Institute of Science and Technology, Moscow, Russian Federation.

The electrooxidation of urea continues to attract considerable interest as an alternative to the oxygen evolution reaction (OER) as the anodic reaction in the electrochemical generation of hydrogen due to the lower potential required to drive the reaction and the abundance of urea available in waste streams. Herein we investigate the effect of Sr
substitution in a series of LaxSr1-xNiO4+δ Ruddlesden-Popper catalysts on the electrooxidations of urea, methanol, and ethanol and conclude that activities toward the urea oxidation reaction increase with increasing Ni oxidation state. The 75% Sr-substituted LaxSr1-xNiO4+δ catalyst exhibits an exceptionally high mass activity of 588 mA and 7.85 A for the electrooxidation of urea in 1 M KOH containing 0.33 M urea, demonstrating the potential applications of Ni-based Ruddlesden-Popper materials for direct urea fuel cells and low-cost hydrogen production. Additionally, we find the same correlations between Ni oxidation state and activities for the electrooxidations of methanol and ethanol, as well as identify processes that result in catalyst deactivation for all three oxidations. Most importantly, this is the first demonstration of how systematically increasing Ni – O bond covalency by pushing the formal oxidation state of Ni above +3 serves to increase catalyst activity for these reactions and will act as a governing principle for the rational design of catalysts for the electrooxidation of urea and other small molecules going forward.

2:00 PM *ES06.04.02
Active Sites and Activity of Sub-/Multi-Atomic Layer Electrocatalysts on Tetrahexahedral Nanocrystals Shi-Gang Sun; Xiamen University, Xiamen, China.

Tetrahexahedral nanocrystals (THI NCs) of face-centered-cubic (fcc) metals such as Pt, Pd, Rh are enclosed with high-index facets and present a high density of step sites on their surfaces, and exhibit therefore a high electrocatalytic activity for oxidation of small organic molecules that serves as anode reaction in direct fuel cells. To further identify the active sites on THI NCs and investigate the activity of sub- and multi-atomic layer electrocatalysts on the THI NCs are significant in rational design and preparation of electrocatalysts with low-precious metal and superb property. The current study focuses on the identification of surface active sites on the THI Pt NCs through applying cyclic voltammetry (CV) and in situ FTIR spectroscopy and using CO adsorption and oxidation as probe reactions in order to understand their role in practical electrocatalysis, and demonstrates that the surface structure of nanocrystals with high-index facets can be tuned precisely and continuously by carefully adjusting the electrochemical conditions upon their synthesis. The finely-tuned nanocrystals could play as model electrocatalyst at nanoscale to gain the structure-catalytic functionality relationship under realistic application conditions. Furthermore, the electrocatalytic properties of small organic fuel molecule oxidation of sub-monolayer of adatoms as Bi, Ru and Au on THI Pt NCs and multi Pt atomic layer on THI Pt NCs were studied to reveal the structure effect and interaction of atoms/layers with nanocrystals of high-index facets in electrocatalysis.

Mechanisms and Selectivity of the Electrochemical CO2 Reduction Reaction on Multiple-Site vs Single-Site Catalysts Peter Strasser; Chemical Engineering, Technical University Berlin, Berlin, Germany.

Strategies for closing the anthropogenic carbon cycle using the chemical conversion of CO2 into useful molecules have become a scientific and technological priority. All chemical ways to convert CO2 into CO, oxygenates or hydrocarbons, the direct electrochemical coupling of water electrolysis and CO2 reduction appears attractive, as it is a one-pot process step, occurs at ambient temperature and pressures, involves solely water and CO2 as reactants, and may involve renewable electricity from wind, solar or hydro power plants.

The CO2 electroreduction is by and large carried out on the surface of metal catalysts. At industrially relevant current densities and electrode potentials, however, these catalysts typically suffer from low faradic CΟ2 product selectivities due to the competing, very fast reduction of water, i.e. the hydrogen evolution reaction. New catalyst concepts with tunable selectivity for hydrogen evolution versus CO2 reduction are needed.

In this contribution, we share recent comparative experimental and computational mechanistic insight in the electroreduction of CO2 on metallic multi-site versus molecularly inspired metal ion-N modified high surface area carbon single-site catalysts. We provide new insight into CO selectivity trends and put particular emphasis on the competing reaction pathways to methane and methanol. We show that carbon-based single site catalysts are an intriguing cost-effective alternative to their metallic rivals at industrial current densities.

4:00 PM *ES06.05.02/ES05.05.02
CO Oxidation on Supported Ir Single Atoms—Consequences of Strong CO Adsorption on Kinetics and Resting State of the Catalyst Ayman M. Karim; Virginia Tech, Blacksburg, Virginia, United States.

Supported single-atom catalysts provide an ideal system to study reaction mechanisms on a molecular level and to bridge heterogeneous and homogeneous catalysis. Single atoms have shown remarkably different activity and selectivity for several reactions, however for low temperature CO oxidation the reaction mechanism is not well understood and there is debate whether single atoms have higher intrinsic activity than nanoparticles. In this talk, the mechanism of CO oxidation on atomically dispersed Ir/MgAl2O4 catalysts will be presented and compared to that on nanoparticles. Using in-situ and in-operando DRIFTS and HERFD-XANES complemented by DFT calculations, we identified the active Ir single-atom complex, and resting state of the catalyst for low temperature CO oxidation. We provide evidence that strong CO adsorption on single atoms leads to an Eley-Rideal mechanism where Ir(CO) is the active complex (i.e. a CO ligand is present during the catalytic cycle). The results show that due to the ability of single atoms to coordinate with more than one ligand, strong adsorption by CO does not necessarily lead to catalyst poisoning. Additionally, we demonstrate that the unusual kinetics on single atoms can be used as a facile surface sensitive characterization tool for quantifying the number of single atom sites in catalysts containing a mixture of single atoms and nanoparticles. The results provide a new perspective for understanding reaction mechanisms and interpreting spectroscopic and catalytic activity of supported metal single atoms.

4:30 PM ES06.05.03/ES05.05.03
Oxide Bilayers as High Efficiency Water Oxidation Catalysts Through Electronically Coupled Phase Boundaries Jennifer Leduc; Sanjay Mathur and Thomas Fischer; University of Cologne, Cologne, Germany.
New semiconductor metal oxides capable of driving water-splitting reactions by solar irradiation alone are required for sustainable hydrogen production. Whereas most metal oxides only marginally deliver the photochemical energy to split water molecules, uranium oxides are efficient photoelectrocatalysts due to their absorption properties ($E_g = 2.0 - 2.6$ eV) and easy valence switching among uranium centers that additionally augment the photocatalytic efficiency. Although considered a scarce resource, the abundance of uranium compounds in the environment is manifested in the huge quantities of stored $Uf$ gas, produced as waste streams in the nuclear fuel enrichment process. Here we demonstrate that thin films of depleted uranium oxide ($UO_x$) and their bilayers with hematite ($a-Fe_2O_3$) are high activity water oxidation catalysts due to electronically coupled phase boundaries. The electronic structure of uranium oxides showed an optimal band edge alignment in $UO_x/Fe_2O_3$ bilayers (DFT calculations) resulting in improved charge transfer at the heterojunction as supported by TAS and XAS measurements. The enhanced photocurrent density of the heterostructures with respect to well-known hematite offers unexplored potential of uranium oxide in artificial photosynthesis.

Design of Supported Transition Metal Catalysts for Methane Partial Oxidation
Darinka Princic1,2, Julie Fornaciari1,2, Adam Weber2 and Alexis T. Bell1,2; 1Department of Chemical and Biomolecular Engineering, University of California, Berkeley, Berkeley, California, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

The abundance of methane and its low cost makes it an optimal raw material for chemical precursors and energy-dense fuels. Conventional synthesis of methanol involves a multistep process, which requires high energy input and high cost [1]. Alternatively, electrochemical methane oxidation using a catalyst is a promising single-step approach to achieve a direct conversion of methane to methanol at lower temperatures and cost [2].

An efficient catalyst needs to be developed for this energetically challenging process. The catalyst should be active for C-H bond activation, thereby enabling oxidative hydroxylation of methane, and simultaneously inhibit further methanol oxidation. To date, a variety of the catalysts, including supported metals (Pd, Ru, Au, Ag) and metal oxides ($V_2O_5$, $Fe_2O_3$, $CoO$, $MnO_2$, $MoO_3$, $CrO_3$), have been tested in electrochemical cells and shown promise for this approach [2]. However, further systematic studies are essential for understanding the mechanism for methane oxidation and thereby enabling the rational design of the catalysts. In this regard, porous metal oxides and supported single-atom catalysts (SAC) are particularly interesting [3]. These catalysts show potential for high methane conversion and are ideal model catalysts to identify active sites and facilitate understanding of the reaction process at a molecular level. In spite of great interest; however, it still remains challenging to achieve atomically dispersed metals in high loadings for efficient catalysis.

In this study, a design of first-row transition metal oxides and MOF-derived supported single-atom catalysts will be presented. The catalysts are synthesized with wet-chemistry, and subsequently, characterized for electrochemical methane-to-methanol oxidation. Structural and chemical analyses of catalysts using a combination of various microscopic and spectroscopy techniques are used to establish structure/property relationship. These insights provide valuable basis for a scientific-guided approach toward new metal oxide and supported single-atom catalysts for this challenging process.

Three-Dimensional Honeycomb-Like Cu$_{65}$Co$_{10}$O$_{42}$ Nanoparticles on Nickel Foam as a High Efficient Oxygen Evolution Electrode for Anion Exchange Membrane Electrolyzer
Kyu Hwan Lee1,2, Myeong Je Jang1,2, Woo-Sung Choi1, Yoo Sei Park1, and Sung Mook Choi1; 1Korea Institute of Materials Science, Gyeong Nam, Korea (the Republic of); 2Advanced Materials Engineering, Korea University of Science and Technology (UST), Changwon, Korea (the Republic of).

Anion exchange membrane (AEM) electrolyzer is based on PEM electrolyzer combined with an anion exchange membrane (AEM) in the middle of cell. AEM electrolysis provides benefits of both PEM membrane (acidic) and traditional liquid alkaline (KOH) electrolysis with efficiency likely in between these two existing technologies. Although the most important benefit of AEM is possibility of adapting non-PGM catalysts, low activity of those catalysts remain still big challenges.

In this presentation, we prepared three-dimensional honeycomb-like Cu$_{65}$Co$_{10}$O$_{42}$ nanoparticles arrays supported by Ni foam via electrochemical co-deposition of Co and Cu hydroxides on Ni foam followed by thermal oxidation. The co-deposition with Cu changes the morphology of the Co hydroxide deposit to form honeycomb-like nanostructures, significantly decreasing the onset potential for oxygen evolution. The Cu$_{65}$Co$_{10}$O$_{42}$ anode displays an exceptionally low overpotential of 290 mV at a current density of 10 mA cm$^{-2}$ in 1 M KOH, and an anion exchange membrane water electrolysis cell employing the above anode achieves a current density of 100 mA cm$^{-2}$ at 1.68 V in 0.1 M KOH.
When in amorphous form (a-TMD), these materials have even higher activity, thanks to their disordered structure with a high density of under-coordinated sites. However, the structure-performance relationship is unknown and traditional synthesis methods do not grant precise control over the deposited morphology, usually resulting in unsatisfactory HER performances for self-supported a-TMD.

In this contribution, we explore a HER performance/structure correlation for self-supported amorphous TMD catalysts, focusing on amorphous Molybdenum Sulphide (a-MoS₂), Molybdenum Selenide (a-MoSe₂) and Tungsten Selenide (a-WSe₂). We couple the intrinsic high activity of amorphous materials with a precise control over the morphology of the synthesized catalysts, obtained by utilizing Pulsed Laser Deposition (PLD) as synthesis method. In this way it is possible to control down to the nanoscale the structure and the morphological features of the materials, obtaining structures that range from compact films to hierarchical nanostructured morphologies.

We firstly analyse the shared electrochemical activation process, occurring at the beginning of catalysis, where the pristine a-TMD are transformed into the actual HER catalysts. Pre/post characterization is employed to evaluate how the activation modifies the composition and the catalytic performance. We find that the effect of the activation process on the electrochemical performance is related to the different transition metal (i.e. Mo or W) in the a-TMD.

By tuning the morphology of the a-TMD, we maximize the Tafel slope value and the -10 mA cm⁻² overpotential ($\eta_{10}$). The optimized morphologies reach HER performances among the state-of-art for TMD materials, regardless of their support or crystalline structure. For a-MoS₂, a Tafel slope of 35 mV dec⁻¹ – close to the Pt benchmark of 30 mV dec⁻¹ – and a -10 mA cm⁻² overpotential ($\eta_{10}$) of 126 mV are obtained, while for a-WSe₂, a $\eta_{10}$ of 196 mV is registered.

In conclusion, by controlling during the synthesis process the a-TMD nanostructures’ morphology we show the correlation between structure and HER performance, that is reflected by the relation between morphological features and intrinsic HER catalytic parameters, such as charge transport efficiency and onset potential; moreover, we exploit this correlation on materials with intrinsic high activity, obtaining catalysts that with their performances provides a promising alternative to precious catalysts.

9:00 AM *ES06.06.04
Tracking and Identifying the Active Origin in Chalcogenide Catalysts for Electrochemical Hydrogen Evolution Jiangtian Li and Deryn Chu; U.S. Army Research Laboratory, Adelphi, Maryland, United States.

Water electrolysis has been emerging as a strategic approach to produce hydrogen, especially with the clean and renewable energy sources like solar and wind. To this end, the design, development, and fabrication of facile, active, stable earth abundant electrocatalysts for highly efficient hydrogen evolution reaction are essential. In this presentation, we will show a bunch of electrochemical catalysts we recently developed for the hydrogen generation. We experimentally demonstrate the facet-dependent HER activity and the interfacial dipole enhanced HER activity in chalcogenide based catalysts. With the assistance of synchrotron radiation characterization techniques, we were able to track and identify the changes in the local atomic environments, and reveal and establish structure/function relationship in a catalyst. This could be coordinated with the HER performance and provide fundamental understanding on the reaction mechanism.

9:30 AM *ES06.06.05
An Efficient Acid-Stable N₂-Plasma Treated Hafnium Oxyhydroxide Electrocatalyst for Hydrogen Evolution and Oxidation Reactions Xiaofang Yang and Bruce E. Koel; Princeton University, Princeton, New Jersey, United States.

Lack of a highly active, stable, earth-abundant electrocatalyst for carrying out hydrogen evolution and oxidation reactions (HER and HOR) in strongly acidic conditions is a major technical challenge for developing economical polymer electrolyte membrane (PEM)-based electrolyzers and fuel cells. We have found that processing Hf oxide with an atmospheric N₂ plasma forms an acid-insoluble hafnium oxynitride material. We propose that under electrochemical environments this material is transformed into an active oxynitride hydrate that demonstrates unprecedented high catalytic activity and stability for both HER and HOR in strong acidic media for earth-abundant materials. The zero overpotential and high current densities demonstrate that this material is a promising alternative to Pt. This material demonstrates excellent HER and HOR activities in acids using non-platinum group metal (PGM) catalysts, opening new opportunities to develop technologically and economically viable regenerative fuel cell (URFC) systems and cost-effective PEM electrolyzers. Furthermore, these results have broad implications for using nitrogen incorporation (e.g. by N₂ plasma treatment) to activate other non-conductive compounds and films to form new active electrocatalysts.

Nonprecious Electrocatalysts for Hydrogen Evolution via Water Electrolysis Shuo Chen; University of Houston, Houston, Texas, United States.

Water electrolysis produces hydrogen gas with high purity and no greenhouse gas emission. Large-scale applications of water electrolyzers require low cost, efficient, and stable electrocatalysts. In this presentation, I will introduce our recent efforts on nonprecious electrocatalysts for both cathodic hydrogen evolution reaction (HER) and anodic oxygen evolution reaction (OER) of water electrolysis. Our best electrolyzer can reach current densities of 500 and 1000 mA cm⁻² at 1.586 and 1.657 V, respectively. To understand and better design the electrocatalysts, we employed density functional theory calculations to reveal active sites and their roles in water activation and hydrogen adsorption.

11:00 AM ES06.07.02
Atomic-Level Insights into Platinum Group Metal-Free Electrocatalysts Derived from Metal Organic Frameworks David Cullen 1, Karren More3, Gang Wu2, Deborah Myers1, K.C. Neyerlin4, Hoon T. Chung1 and Piotr Zelenay2; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2University at Buffalo, The State University of New York, Buffalo, New York, United States; 3Argonne National Laboratory, Lemont, Illinois, United States; 4National Renewable Energy Laboratory, Golden, Colorado, United States; 5Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

The search for low-cost electrocatalysts to drive the oxygen reduction reaction (ORR) in polymer electrolyte membrane fuel cells has intensified with the recent deployment of commercial fuel cell electric vehicles. Platinum group metal-free (PGM-free) catalysts may offer a solution to using standard Pt-based catalysts if their activity and durability can be significantly improved. Breakthroughs in atomically-dispersed transition metal (Fe, Co, Mn) catalysts derived from metal organic frameworks (MOFs) have demonstrated improved performance and durability in fuel cell tests. It is expected that an increased understanding of the atomic-level structure–property relationships in PGM-free catalyst systems will enable further enhancement of these recent gains.

To this end, we have utilized in situ low-voltage, aberration-corrected scanning transmission electron microscopy (ac-STEM) coupled with quantitative analytical techniques such as electron energy loss spectroscopy (EELS) and energy dispersive X-ray spectroscopy (EDS) to study the structural evolution of MOF-derived catalysts at various stages of synthesis and fuel cell testing. The high spatial resolution (sub-Å) of ac-STEM allows for direction visualization of the catalytically active sites, which take the form of metal-nitrogen moieties within or at the edges of the meso-graphitic carbon support particles. We will present a quantitative analysis of the evolution in composition and support graphitization during high temperature pyrolysis (up to 1100°C) for catalysts containing Fe, Co, and Mn. The effects of metal loading and the negative impact of metal clustering on performance will be demonstrated. The critical role of support graphitization in the formation of the highly activity metal-nitrogen sites and electrode durability will also be explored. High-resolution microscopy results will be correlated with other advanced characterization methods, including synchrotron-based scattering techniques, and discussed within the context of fuel cell performance and durability to provide a more complete view of the materials-based mechanisms that control the electrochemical performance of
Titanium dioxide, or titania, is an important material being researched for energy and environmental applications, chiefly photocatalysis. Titania’s photocatalytic properties allow it to be used in water-splitting, detoxification, and photovoltaics. Titania exists in multiple polymorphic structures, of which the most common are rutile and anatase. We focused on anatase for the purposes of this research, due to its promising results for hydrolysis.

Anatase is a non-stoichiometric oxide (TiO$_2$) which enables it to perform redox reactions by absorbing and releasing oxygen into its environment. When this happens, oxygen vacancies form within the anatase lattice. In situ electron microscopy can provide a window into these structural changes taking place in anatase during photocatalysis. However, to correctly interpret vacancy induced structures and evolution from TEM imaging, it is necessary to compare the experimental images with simulated structural models.

Here we model the oxygen vacancy structures in anatase, using a combination of molecular dynamics and density functional theory. Using a forcefield designed for the simulation of titania-water interactions, different vacancy structures were relaxed and analyzed. To compare the theoretical models with experimental data, TEM image simulation was performed. We investigate a series of different vacancy configuration and generated TEM fingerprints for comparison with the experiment. This comparison yielded results which demonstrate a proof of concept for a technique suggesting that it should be possible to identify oxygen vacancy structures directly from the TEM image contrast.

The effect of surfaces on vacancy structure, and the interaction of water with the surface of anatase will also be examined. This research aims to satisfy an unfilled niche in our atomic-level understanding of oxides, by providing the methodology for analysis of vacancy formation from very subtle phenomena in TEM images.

Continuum Models to Handle Electrolyte Solutions Effects in First-Principles Simulations of Materials

Oliviero Andreussi; University of North Texas, Denton, Texas, United States.

Continuum models of solvation have played a crucial role in quantum chemistry simulations and are now starting to be popular for the computational characterization of solvated, possibly electrified, interfaces. Some recent advances in the field have opened the possibility of modeling heterogeneous catalysis and electrochemistry in a first-principles-based framework, where the multiscale nature of the developed approaches provides a significant reduction of the computational burden while retaining a good accuracy. Nonetheless, extending continuum approaches to condensed-matter simulations present some non-trivial issues, related to the complexity of the electrostatic problem in charged two-dimensional interfaces and to the open structure of many crystalline substrates. Here we will present some of our recently proposed approaches to overcome these limitations, in particular focusing on a hierarchy of approaches and algorithms to describe the electrochemical diffuse layer. Moreover, handling environment (solvent and electrolyte) effects through the continuum embedding allows us to exploit a more rigorous grand canonical approach to study the thermodynamic properties of electrochemical interfaces, thus overcoming some possible limitations of the computational-hydrogen electrode (CHE) technique. Applications to noble metal (electro-)catalysis and beyond will be presented.

2:00 PM *ES06.08.02
First-Principles Discovery and Understanding of Materials for Renewable Hydrogen Production

Brandon Wood1, Yuanyue Liu2, Tadashi Ogitsu2 and Tuan Anh Pham2; 1 Lawrence Livermore National Laboratory, Livermore, California, United States; 2 The University of Texas at Austin, Austin, Texas, United States.

Despite significant promise as a clean and sustainable energy carrier solution, today’s low-cost hydrogen is conventionally produced from fossil fuels. A far more attractive alternative involves the use of abundant renewable solar and wind energy, which provide avenues for producing hydrogen from water, either indirectly through electricity generation and electrolysis, or else directly through solar photochemical and photoelectrochemical processes. However, these new avenues introduce significant materials...
challenges, prompting the use of computational methods for aiding discovery, understanding, and optimization. To this end, I will review some of our recent simulation activities within the U.S. Department of Energy HydroGEN Advanced Water Splitting Materials Consortium, which aims to accelerate the development of materials for renewable hydrogen production from water. Focusing on the use of first-principles computational methods, I will provide examples of how atomic-level understanding of chemical bonding in 2D materials has been applied towards the discovery of new hydrogen evolution electrocatalysts. I will also show how simulations have been combined with in situ experiments to understand atomistic mechanisms of water splitting at photoelectrochemical interfaces, leading to novel approaches for improving device lifetime and performance. These successes demonstrate the power of computational methodologies for translating atomic-level understanding into practical solutions for renewable hydrogen production.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

2:30 PM *ES06.08.03
First-Principles Studies of Activity and Selectivity in the Electrocatalysis of CO2 Reduction into Methanol  
Jianguo Yu, Yipeng Gao, Dong Ding, Hanping Ding, Lucun Wang and Wei Wu; Idaho National Laboratory, Idaho Falls, Idaho, United States.

Despite an extensive interest in developing advanced direct electrochemical reduction of CO$_2$ into value-added fuels and specialty chemicals using renewable energy as an input, its application is still constrained partly due to the fundamental challenges related to activity and selectivity towards the particular product of interest. Detailed first principles calculations are invaluable in complementing the experimental investigations to unravelling important aspects of the electrochemical reduction reaction mechanisms for various type of catalysts. Here, we present advances in the understanding of reactivity and selectivity in the electrocatalysis of converting CO$_2$ into methanol using density functional theory and thermodynamics. We will also discuss the role of protons and electrons transfer, and possible processes through different surface-bound reaction intermediates in order to steer catalyst selectivity among the vast number of possible carbon-based products.

2:45 PM *ES06.08.04
MXene Electrode Materials for Electrochemical Energy Storage—First-Principles and Grand Canonical Monte Carlo Simulations  
Yasauki Okada, 1 Nathaniel Keilbart, 2 James Goff, 2 Shin ‘ichi Higai, 1 Kosuke Shiratsuyu 1 and Ismaila Dabo 2; 1Murata Manufacturing Co., Ltd., Nagaokakyo-shi, Japan; 2Department of Materials Science and Engineering, Materials Research Institute, and Penn State Institutes of Energy and the Environment, The Pennsylvania State University, University Park, Pennsylvania, United States.

MXene compounds are drawing attention due to their advantageous characteristics, including the large surface area of their two-dimensional structure, which may enable high energy density for electrochemical storage. These compounds have the generic formula M$_{1-x}$Ti$_x$(X, T)$_y$, where M, X, T$_x$ represent the transition-metal cation, the carbon or nitrogen atom, and the surface termination of MXene layers, respectively. Since the discovery of MXene in the laboratories of Barsoum and Gogotsi, a number of studies have shown applications of their catalytic, electronic, mechanical, and optical properties [1,2]. In parallel, first-principles simulations have delivered quantitative information about their electrochemical response [3,4,5]; however, there is still debate over the charge-transfer mechanisms at the origins of electrochemical storage in MXene-based pseudocapacitors. In particular, it is still not fully understood how charge transfer is affected by transition-metal chemistry, stoichiometry, and surface termination. In the present study, we performed first-principles calculations on MXene compounds with 12 different transition metals (Sc–Cr, Y–Mo, La, and Hf–W), three different composition ratios (M$_x$X$_{1-x}$T$_y$, and M$_x$X$_{1-y}$T$_z$), and two different terminal groups (oxygen and fluorine). It was found that the electronic structures, formation energies and the amount of charge transferred from the cations to the MXene electrode is dependent on composition and that their charge is stored in the bond between the MXene and adsorbing cations. Importantly, the Bader atomic charge analysis revealed that the changes in valence number of the M-elements and X-elements are rather small, while the terminal groups play an important role in the pseudocapacitive charge storage of MXene compounds. Additionally, we carried out grand canonical simulations using a dataset of first-principles free energies, taking into account solvation effects using implicit solvent models based on the self-consistent continuum solvation (SCCS) formalism and including configurational entropy contributions via finite-temperature Monte Carlo sampling in an effort to clarify the charge storage mechanisms underlying the operation of the pseudocapacitive electrode [6]. We provide a detailed description of the sequence of desorption steps at the MXene surface as the applied voltage increases. Moreover, changes in the valence state and projected density of states were observed during the cation desorption reaction. These results provide design principles to improve the performance of MXene as an electrode material for electrochemical energy storage and to assess the electrochemical stability of MXene-based electrocatalyst under applied voltage and controlled pH.

Metal Phosphide Catalysts for Low Temperature Fuel Cells and Beyond  
Scott Grever; Wake Forest University, Winston Salem, North Carolina, United States.

We have demonstrated the use of metal phosphide nanoparticulates (MPNs) as catalysts for key processes (oxygen reduction, formic acid oxidation, methanol oxidation) in low temperature fuel cells and in the related applications of CO$_2$ reduction and hydrogen peroxide production via oxygen reduction. At a basic level, we show that MPNs analogs of well-known metallic fuel cell catalysts such as Pd show significant improvements in stability and activity per mg of catalyst. Further, the P atoms can act to tune the metal atom charge density as demonstrated for AgP$_2$ catalyzed CO$_2$ reduction, where experiment and density functional theory both show a large decrease in overpotential for CO production compared to Ag, again with improved stability.

However, the strongest improvements are observed for systems in which the dilution of the metal atom on the surface completely alters the coordination of the adsorbed species. This is demonstrated in our recent work developing CoP$_2$, CoP$_3$, and CoP$_4$ as HER and ORR catalysts, where increased P content decreases the overpotential for HER to near the level of the Pt benchmark. DFT shows that sites with low absolute free energies of H adsorption are associated with single coordinating binding or highly strained bridge sites. Of interest is the extent to which MPNs can act as analogs to single atom catalysts, with initial results suggesting oxygen reduction by PnP$_2$ NPs generates hydrogen peroxide, similar to single atom Pt catalysts and unlike traditional Pt NPs.

4:00 PM *ES06.09.02
Synthesis and Electroanalytical Characterization of Binary and Ternary Sulfides for the Conversion of CO2 and CO to Methanol  
Jesus M. Velazquez, 1 Joseph Perryman, 2 Jessica Ortiz 1, Sarah Jones 2, Forrest Hyler 1, Joshua Jude 1, Aparva Melta 2, Ryan C. Davis 3, Anbarish Kulkarni 2 and Christopher Patridge 2; 1University of California, Davis, Davis, California, United States; 2Pomona College, Claremont, California, United States; 3SLAC National Accelerator Laboratory, Stanford, California, United States; 4D’Youville College, Buffalo, New York, United States.

Development of materials that can feasibly solve the growing dichotomy of simultaneously increasing energy demands and carbon emissions is an imperative that has become
uniquely important for current research efforts. An emerging avenue in this regard is the conversion of vastly abundant renewable energy sources that can be harnessed and directed towards synthesis of traditionally fossil fuel-based products from atmospheric feedstocks like CO₂. In order to translate such an energy conversion process into a viable technology, it is critical that design principles of selective electrocatalyst materials be elucidated in order to mitigate operating costs and improve overall process efficiency.

Results that will be presented herein, focuses on structure—function correlations across three versatile classes of transition metal chalcogenide materials, including metal dichalcogenides (MX₂; M = Mo, W; X = S, Se) Chevrel-phase sulfides (CPs) (MₓMoₓSₓ; M = transition or alkali metal; x = 0–4), and thiospinels (AB₂X₄; A = Cu, Mg; B = Ti, V, Cr; X = S, Se). These chalcogenides were found in our preliminary work to display exceptional promise as CO₂R catalysts. As such, the compositional, structural, and dimensional tunability of these classes of compounds will allow for development of structure—function correlations and design rules. Furthermore, we have identified CPs as selective towards the electrochemical reduction of CO₂ and CO to methanol (major liquid product) under an applied potential of -0.4 V vs RHE. Moreover, CPs such as Cu₂Mo₆S₈ exhibit an interesting electronic structure-function correlation founded on the basis of X-ray absorption spectroscopy. We correlate the selective electrochemical reduction of CO₂ and CO to methanol due to the potentially increased reactivity of the chalcogen species to the filling of 3p orbitals by metal promoters such as Cu, Ni, and Cr. It is suspected that CO₂ hydrogenation will be the rate-limiting step in the CO₂R to liquid fuels, hence being able to surmount the energy barrier associated with this step will rely strongly on the ability of the catalyst to facilitate hydrogenation. These reactive chalcogenides neighbor susceptible active sites (Mo) for CO binding, and so the overall reduction of CO₂ and CO to methanol through a CO hydrogenation mechanism is likely enhanced by the presence of an electron-donating species like a transition or alkali metal.

4:30 PM ES06.09.03

Electrochemical Conversion of CO₂ into C₂ Products at Anion Vacancy of Transition-Metal Dichalcogenides—A Computational Mechanism Study and Material Screening

Sungwoo Kang¹, Youngho Kang² and Seungwu Han³; ¹Department of Materials Science and Engineering and Research Institute of Advanced Materials, Seoul National University, Seoul, Korea (the Republic of); ²Materials Data Center, Korea Institute of Materials Science, Changwon-si, Korea (the Republic of).

The electrochemical carbon dioxide reduction (CO₂R) has been received large attention in converting CO₂ into valuable chemical species. For practical application of CO₂R, a catalyst with low overpotential and selectivity for the desired product is required. In general, C₁ species such as CO and HCOOH are mainly produced on the catalyst at the cathode. Production of multi-carbon (Cₙ) species such as ethanol and n-propanol can achieve higher economic value when produced with optimized current density, Faradaic efficiency (FE), and overpotential. Recently, Francis et al. demonstrated that MoS₂ converts CO₂ into 1-propanol as a major product for CO₂R at onset potential of ~0.5 V vs RHE.[1] It is also reported that the current density decreases when increasing the portion of edge sites, which implicates that the active site places on the basal plane rather than the edges. Despite the fact that MoS₂ produces 1-propanol, which is a highly valuable product, practical utilization of MoS₂ is limited because FE of CO₂R is only about 5% because of the poor selectivity compared to hydrogen evolution reaction (HER).

In this work, we first study the mechanism of CO₂R at sulfur vacancy (Vₖ) of MoS₂ by calculating free energies through the density functional theory calculations and computational hydrogen electrode model. We find several pathways leading to C₂ products such as HCOOH, HCHO, CH₃OH and CH₄. C₃ and C₄ pathways are discovered considering C-C coupling among C₁ intermediates. We want to note that HCHO is found to be a key intermediate for C₂ and C₃ pathways by coupling of sp² carbons. The computationally predicted reaction products and corresponding onset potentials are in good agreement with the experiment, which leads to the conclusion that Vₖ is the main active site of CO₂R on MoS₂. To discover a material producing C₂ products with better selectivity than MoS₂, computational screening of the catalytic performances of CO₂R is performed for anion vacancies of various transition-metal dichalcogenides (TMDs). As a result, TaS₂ and SnSe₂ are suggested as good candidates that can convert CO₂ into CO and HCHO, respectively, with much higher selectivity compared to MoS₂. Especially, we expect that production of HCHO at 5e-vacancy of SnSe₂ possibly leads to the production of C₃ products.

PBI-Type Polymers and Acidic Proton Conducting Ionic Liquids—Conductivity and Molecular Interactions

Jingjing Lin, Jürgen Griffin, Klaus Wippermann and Carsten Korte; Institut für Energie- und Klimaforschung (IEK-3), Forschungszentrum Jülich, Juelich, Germany.

The operation of polymer electrolyte fuel cells (PEFC) at elevated temperatures above 100°C would allow a much simpler system setup: i) no feed gas humidification, ii) a more efficient cooling system (easier water and heat management), iii) the possibility of recovering high-grade waste heat, and iv) a higher tolerance against feed gas impurities. Currently, (high temperature) HT-PEFC, based on phosphoric acid doped polybenzimidazole (PBI) membranes, cannot compete with the performance characteristics of NAFION-based low temperature-PEFCs. The presence of H₃PO₄ causes a slow cathodic oxygen reduction reaction kinetics (ORR). Thus, there is a necessity for new non-aqueous proton conducting electrolytes operational for the temperature range between 100–120°C.

Proton conducting ionic liquids (PILs) with acidic cations are promising candidates for the use as non-aqueous electrolytes at operation temperatures above 100 °C. In this contribution, an experimental study on the interaction of PBI based proton exchange membrane (PEM) with highly acidic betaine-type PILs is presented. 2-Sulfoethylmethylammonium triflate exhibits a ~3 times higher ORR current densities on Pt compared to H₃PO₄.[1] There is a (slow) uptake of the electrolyte by PBI due to a swelling process, up a weight increase of 135%. The doping process was monitored by Raman spectroscopy, proving the protonation of the imidazole groups in the polymer chains. The thermal stability is measured by TGA.

NMR analysis and inelastic neutron scattering has been applied to elucidate the proton dynamics and the molecular interactions between PIL, PIL, and residual water, which is present during fuel cell operation. The total conductivity in the neat PILs depends highly on the H₂O concentration. The high acidic PILs are able to protonate H₂O. The self-diffusion coefficients are measured by DOSY NMR, revealing that the proton diffusion is faster than the diffusion of the PIL cation. The above results indicate a cooperative mechanism involving fast proton exchange between PIL cations, H₂O and H₃O⁺.

Compared to the neat PIL, the proton conduction in the doped PBI membrane is restricted due to the constraining network of the polymer chains. To optimise the conductivity but also the uptake of the PIL into the polymer, the use of solution casting methods have been studied for these materials.

Sustainable Noble Metal-Free Electrocatalysts for Fuel Cells and Electrolyzers Sanjeev Mukerjee and Qingying Jin; Northeastern University, Boston, Massachusetts, United States.

Enabling concerted charge transfer at the inner Helmholtz plane of an electrochemical interface is a prelude to higher selectivity and activity for electrochemical processes hitherto not possible with conventional highly dispersed metal and metal alloy electrocatalysts. This presentation will focus on recent shifts away from conventional supported metal and metal oxide based catalysts to organo-metallic and composite metal oxides based structures, which promise orders of magnitude higher turnover frequency and selectivity. Taking oxygen reduction and hydrogen evolution reactions (ORR/H2R) as a theme, this presentation will provide a clear comparison of electrochemical response between supported metal catalysts (alloys and oxides), especially carbon supported noble metals in acidic pH and catalyst based on transition metal nitrogen coordinated systems and multi-phase composite oxides. Electrochemical data will be discussed in the context of spectroscopy, especially in situ synchrotron x-ray absorption spectroscopy (XAS). Here the conventional bulk averaged XANES and EXAFS spectroscopy will be further embellished by the unique use of the subtractive method referred to as ‘Δμ technique’. This specially designed subtractive technique using the near edge part of the spectra (x-ray absorption near edge spectra, XANES) has been previously validated and has unprecedented ability to elucidate nature of adsorbed species on transition metals. The unique element specificity and the in situ and operando capability of the XAS spectra in close conjunction with electrochemical data will be used to provide insight on steady-state electrocatalytic pathways as a function of various operating conditions and associated applications. Unique structural features of the active sites determined in situ using the extended part of the spectra (i.e., extended x-ray absorption spectra, EXAFS) will be invoked to explain activity difference based on pH and water activity.

Searching for the Active Site in Carbon-Based Noble Metal-Free Oxygen Reduction Electrocatalysts Piotr Zelenay1, Siddharth Komini Babu2, Hoon T. Chung1, Ulises Martinez1, Xi Yin1, Edward F. Holby2 and Geraldine M. Purdy1; 1Materials Physics and Applications Division, Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 2Sigma Division, Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

The focus of this presentation will be on carbon-based noble metal-free or, as they are often called, platinum group metal-free (PGM-free), electrocatalysts for oxygen reduction reaction (ORR) as an alternative to the state-of-the-art low-PGM catalysts in the polymer electrolyte fuel cell (PEFC) cathode. In the past decade, PGM-free catalysts, especially those obtained by heat-treating precursors of transition metals, nitrogen and carbon, have gradually narrowed the performance gap to precious metal-based materials already used in fuel cell cars. We start by reviewing PGM-free catalyst development at Los Alamos National Laboratory (LANL), part of the DOE-EERE’s Electrocatalysis Consortium (ElectroCat), emphasizing approaches aimed at improving the ORR active-site density and electrode porosity via the use of pore-forming agents and sacrificial templates.

In the second part of this presentation, we will specifically concentrate on the sources of catalytic activity in Fe-based PGM-free catalysts and ORR active sites as a prerequisite for successful development of future noble metal-free catalysts. While of key importance to further progress in PGM-free electrocatalysis, the identification of the ORR active sites in the catalysts is highly challenging due to their embedded nature within the carbon phase and highly heterogeneous catalyst morphology resulting from the high-temperature synthesis process. They make identification and improvement of activity and durability of such sites difficult and often ambiguous. The results from both theoretical modeling and experiment will be presented. Of a number of both in situ and ex situ techniques used for gaining a better insight into the origins of ORR activity in PGM-free catalysts, we will concentrate on the microscopic and X-ray absorption spectroscopic methods, as well as on the implementation of molecular dioxygen analogues as probes for the ORR active sites on the catalyst surface, which makes otherwise bulk techniques surface-specific. This part of the presentation will include research performed in close collaboration with LANL’s ElectroCat partners.

Time permitted, we will report on the activity and durability of catalysts derived from transition metals other than Fe, specifically, Co, Mn and Ni, studied by using once again both modeling and experimental methods. Finally, we will present a few highlights from a continuing comparative study of the degradation of active sites in noble-metal-free catalysts during fuel cell testing.

Carbon-Based Materials for Electrochemical Transformation in Energy Conversion and Storage—Defects or Not? Yuyan Shao, Xiaohong Xie, Huilin Pan and Jun Liu; Pacific Northwest National Laboratory, Richland, Washington, United States.

In this talk, we will present our recent research on carbon-based electrode materials for oxygen electrocatalysis (related to fuel cells) and sulfur transformation (related to metal-S batteries). We investigate elemental doping (including metals, N, O, ... ) on carbon properties. Broadly speaking, all dopings produce structural or chemical defects in carbon. However, from practical application point of view, not all defects benefit electrochemical transformation reactions. Our research reveals that, while defects (with right composition and configuration) in general are positively related to oxygen electrocatalysis, defects (or functional groups) seem to be unfavorable for sulfur transformation in a battery under conditions relevant to real applications. We will discuss our understanding on defects vs. electrochemical transformation.

2:00 PM *ES07.02.02 High-Throughput Synthesis and Characterization of PGM-Free Oxygen Reduction Electro catalysts for Polymer Electrolyte Fuel Cells Deborah Myers, Magali Ferrandon, Jaehyung Park, Nancy Kariuki, A. Jeremy Kropf and Evan Wegener; Argonne National Laboratory, Lemont, Illinois, United States.

Incredible progress has been made over the past decade in increasing both the oxygen reduction reaction (ORR) activity and durability of platinum group metal-free (PGM-free) polymer electrolyte fuel cell (PEFC) cathode catalysts. For example, electrocatalytic activities approaching those of platinum have been obtained with heated-treated iron-doped zelite imidazolate frameworks (ZIFs). With further improvements in these materials and electrodes based on these materials, especially in hydrogen-air performance and long-term performance durability, these materials will become viable for numerous applications, including automotive propulsion power. For the pyrolyzed iron-carbon-nitrogen class of PGM-free materials, it has been determined that variables such as the metal, polymer, and carbon content, as well as the temperature and atmosphere in which the composites are pyrolyzed are important in determining the activity and activity stability of the resulting catalysts. Changing these variables and testing their effect on the resulting catalyst properties is a very time-consuming process and only a limited portion of the composite composition and temperature space have been explored for this broad class of materials. This presentation will describe the development and application of high-throughput methodology to explore the effects of these parameters on the activity and fuel cell performance of iron- zelite imidazolate framework-derived ORR electro catalysts with a variety of transition metal dopants. A multi-channel flow double electrode (m-CFDE) cell was designed and constructed for the simultaneous screening the ORR activity of multiple materials using an aqueous hydrodynamic technique. The high-throughput structural characterization of the materials using techniques such as X-ray diffraction and X-ray absorption spectroscopy and correlation of the phase and atomic structure with ORR activity will be described as will the high-throughput testing and optimization of the electrode composition using a 25-electrode array fuel cell. In addition, the use of in situ multiple X-ray absorption spectroscopy to determine the atomic structure of the materials during pyrolysis of the precursors will be presented.

2:30 PM ES07.02.03 Conversion of Solar Power to Chemical Energy Based on Carbon Nanoparticle Modified Solar-Thermoelectric Generator and Electrochemical Water Splitting System Xiaofei Zhang1, 2, Zhijian Sun1 and Hong Liu1; Shandong University, Jinan, China; 1Georgia Institute of Technology, Atlanta, Georgia, United States.

Nanogenerator has caused extensive attraction to convert/collect dispersive energy as electric energy. Solar thermoelectric generator (STEG), based on Seebeck effect of semiconductors, is one of the most promising approaches for solar energy conversion because of its simple structure, high stability and long lifetime. The light absorbers are of paramount importance for high-efficient STEG. In this work, high performance carbon nanoparticles for light harvesting have been synthesized via a facile and efficient method. By the in-situ coating of the nanoparticles on a commercial thermoelectric generator, a high-efficient STEG was constructed. The performance of the designed STEG device can be further improved with the integration of heat preservation and heat sink components. There is 34 times higher efficiency than that of the bare commercial thermoelectric generator, which enables an electrochemical process to generate hydrogen gas by water splitting. Be a kind of nanogenerator, this designed STEG devices provide a cheap and facile strategy for the portable power supply.

2:45 PM ES07.02.04 Self-Assembly of Large-Area 2D Polycrystalline Transition Metal Carbides for Hydrogen Electrocatalysis Xingming Zhang1, Wenshu Chen2, Jiayuan Gu2, J. Nathan Holman3 and Liwei Lin4; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Shanghai Jiao Tong University, Shanghai, China; 3Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 4University of California, Berkeley, Berkeley, California, United States.

Low-dimensional (0/1/2 dimension) transition metal carbides (TMCs) possess intriguing electrical, mechanical, and electrochemical properties, and they serve as convenient supports for transition metal catalysts. Large-area single-crystalline 2D TMC sheets are generally prepared by exfoliating MXene sheets from MAX phases. Here, a versatile bottom-up method is reported for preparing ultrathin single-crystal TMC sheets (=10 nm in thickness and >100 μm in lateral size) with metal nanoparticle decoration. A gelatin hydrogel is used as the scaffold to coordinate metal ions (Mo4+, W6+, Co2+), resulting in ultrathin-film morphologies of diverse TMC sheets. Carbonization of the scaffold at 600 °C presents a facile route to the corresponding MoC2, WC and CoC2, and to metal-rich hybrids (Mo4- xW6x and Mo4C–Co). Among these materials, the Mo4C–Co hybrid provides excellent hydrogen evolution reaction (HER) efficiency (Tafel slope of 39 mV dec-1 and 48 mV dec-1 in 1 M H2SO4 and 0.5 M H2SO4). Such performance makes Mo4C–Co a viable noble-metal-free catalyst for the HER, and it is competitive with the standard platinum on carbon support. This template-assisted, self-assembling, scalable, and low-cost manufacturing process produces a new tactic to construct low-dimensional TMCs with applications in various clean energy-related fields.

3:00 PM BREAK

3:30 PM *ES07.02.05 Pyrolyzed Metal-Nitrogen-Carbon Catalysts for Oxygen Reduction in Polymer-Electrolyte Fuel Cells Frederic Jaouen; UMR 5253, CNRS, Montpellier, France.

The oxygen electro-reduction reaction (ORR) is the cathode reaction in fuel cells, an electrochemical energy conversion device envisioned to replace combustion engines for transportation, and with stationary applications as well. While novel platinum nanostructures have allowed decreasing the amount of precious metal required to catalyze the ORR in proton-exchange membrane fuel cells, strong advances in the class of Earth-abundant metal-nitrogen-carbon (Me-N-C) catalysts has attracted a lot of attention. Synthesized above 700 °C, recent Me-N-C catalysts are the object of intense research regarding the nature/structure of their active site, ORR mechanism and stability in a variety of conditions. The electrolyte pH, electrochemical potential cycling, temperature, and presence of peroxide are recognized key factors that can influence the stability. This presentation will focus on novel understanding acquired on a recent set of Fe-N-C and Co-N-C catalysts comprising, in parallel with atomically-dispersed metal cations covalently attached to the N-doped carbon matrix, a controlled amount of metal-based crystalline structures, down to their complete absence. The synthesis of model Me-N-C catalysts and the coupling of electrochemical studies with spectroscopic techniques revealed important aspects of Me-N-C catalysts regarding the origin of their ORR activity and, perhaps even more importantly, on the fate of the metal-based active sites when subjected to a broad variety of stressing conditions. It will be shown how structure-stability relationship could be established in some cases, but also how unmodified metal coordination is a necessary but non-sufficient criterion for catalyst durability. Due to the intimate integration of the metal in the nitrogen-doped carbon matrix, changes in the physico-chemical properties of the carbon surface will be shown to impact the catalytic properties (activity and selectivity) of the metal-based sites. This will highlight the importance of the properties of the hosting carbon material on metal-based sites, in strong relation with the symposium topic.

4:00 PM *ES07.02.06 Graphite Electrodes for Potassium-Ion Batteries Shinichiro Komaba1, 2, Kei Kubota1, 2 and Hiroo Onuma1; 1Tokyo University of Science, Tokyo, Japan; 2ESICB, Kyoto University, Kyoto, Japan.

We have been studying electrode and electrolyte materials and their interface designs for Li-ion, Na-ion, and K-ion batteries [1]. Yearly paper numbers of Na and K batteries have increased drastically in recent years. Indeed, research and development of high-performance positive/negative electrode materials for Na- and K-ion are conducted actively over the world. Because of larger ionic size of potassium than lithium, much wider variety and unique feature of materials chemistry attract researchers' interests as post Li-ion battery. New carbons are of great importance for higher energy Na-ion and K-ion batteries. In this talk, we will present our recent studies on phase transition and electrochemical properties
of graphite electrode for K-ion batteries compared to some carbons for Li-ion and Na-ion batteries. [1] K. Kubota, S. Komaba et al., “Towards K-ion and Na-ion batteries as “beyond Li-ion,” Chem. Rec., 18, 459 – 479 (2018).

4:30 PM ES07.02.07
Impact of Surface Modification of Carbon Felt-Supported Pd Nanoparticles on Electrochemical Hydrogenation of Oxygenates
Abhi Karkamkar; Pacific Northwest National Laboratory, Richland, Washington, United States.

Electrochemical reduction of biomass-derived feedstocks is a critical need to improve conversion efficiencies without the need for generating molecular hydrogen. During an electrochemical hydrogenation (ECH) process, it is formed on the surface of the catalyst via reduction of protons supplied by the electrolyte, hydrogenating organic substrates. The feedstock derived from biomass is uniquely complex in composition and functionality. Solvents such as water and other organic solvents add an unprecedented level of complexity to the catalyst design and synthesis. Majority of the electrocatalytic reduction studies are mostly carried on simple but versatile electrocatalyst (Pt/K or Pt/C) that have shown superior activity in PEM fuel cells. There is a critical need to understand the impact of electrocatalyst structure and composition on enhancing conversion of biogenic substrates to fuels or intermediates. Here we present our recent progress in modification of carbon felt based electrocatalysts. We have developed synthetic protocols and methods to modify these carbon felt based materials by incorporating heteroatoms such N or O containing polymeric materials. We further engineer the nanostructure by utilizing inorganic structure modifiers to enhance surface area and porosity. We have demonstrated the ability to change the surface area from 2 m²/g to 110 m²/g. The effect of these modifications on incorporation of metal nanoparticles will also be presented with XPS techniques. The impact of these structural and chemical modification of the carbon felt based catalysts on electrocatalytic reduction of carboxyl compounds will be discussed.

4:45 PM ES07.02.08
Jacob D. Beley1, Deepan Kishore Kunjilar2, Bo-Rei Pas1, Hung-Kuei Chang3 and Nai-Chang Yeh1, 3Department of Chemistry, California Institute of Technology, Pasadena, California, United States; 1Institute of Materials Science and Engineering, National Central University, Taoyuan, Taiwan; 2Department of Materials Science and Engineering, National Chiao Tung University, Hsinchu, Taiwan; 3Department of Physics, California Institute of Technology, Pasadena, California, United States; 4Kavli Nanoscience Institute, California Institute of Technology, Pasadena, California, United States; 5Department of Electrical Engineering, California Institute of Technology, Pasadena, California, United States.

Despite the advantageous properties, graphene has found limited use in practical applications due to the difficulty of producing appropriate graphene materials in high yield. In particular, a scalable synthesis of graphene materials would benefit electrochemical energy storage applications, i.e., batteries and supercapacitors, by virtue of graphene’s high electron mobility, allowing fast charging and discharging, and graphene’s high surface area, providing a high density of electrochemical active sites for better storage capacities. To overcome this barrier, we have developed a scalable synthesis of high quality vertical graphene nanostripes (GNSPs) via plasma enhanced chemical vapor deposition (PECVD). GNSPs are a class of vertical graphene nanostructures (VGNSs), wherein multilayer graphene sheets grow vertically with respect to the growth substrate. This vertical growth allows the graphene materials to be synthesized in high density affording the possibility of scalability, as compared to horizontal sheet graphene. However, typical VGN syntheses require several hours and temperatures in excess of 700 K. In contrast, our GNSPs synthesis is fast and room temperature. In addition, typical VGN syntheses produce short graphene sheets, whereas our GNSPs synthesis produces long aspect ratio graphene materials with dimensions such as 500 nm x 70 μm; long aspect ratios are particularly desired for electrochemical energy storage due to the superior electrochemical activity of graphene edges and the percolation effect of the high aspect ratio graphene that affords greater charge transport. To achieve fast and high quality growth of GNSPs we place a copper foil in a microwave-induced hydrogen/methane plasma under medium vacuum with trace contents of substituted benzene precursors (e.g., 1,2-dichlorobenzene, tolue, etc). The substituted benzene precursor both acts as a seed that initiates growth of the sp²-hybridized graphene lattice and further propagates growth of the vertical graphene materials. In addition, methane radicals and hydrogen radicals act to enhance growth and etch/remove defects, respectively, resulting in high quality graphene materials. Various characterizations have validated the high quality of our GNSPs. The Raman spectrum contains narrow peak widths and peak height ratios that suggest high quality graphene. X-ray photoelectron spectroscopy demonstrates a chemically pure material, ultraviolet photoelectron spectroscopy reveals a work function similar to pristine graphene, and four-point probe measures reveal high electron mobility. Furthermore, the defect content, dimensions and surface area of GNSPs can be tuned by adjusting the PECVD parameters such as the microwave power, flow rate, pressure, and gas composition. Practical application of graphene, particularly in the field of energy storage, may be achievable by this scalable growth of high quality GNSPs.

SESSION ES07.03: Poster Session I: Carbon-Based Materials in Energy Applications
Tuesday Afternoon, April 23, 2019
PCC North, 300 Level, Exhibit Hall C-E

ES07.03.02
Copper-Promoted Nitrogen-Doped Carbon Derived from Zeolitic Imidazole Frameworks for Oxygen Reduction Reaction
Yunchao Xie1, Chi Zhang1, Xiaoming He1, Jheng-Wun Su1, Thomas Parker1, Tommi White1, Mark Gries1 and Jian Lin1; University of Missouri-Columbia, Columbia, Missouri, United States; “Weapons and Materials Research Laboratory, U.S. Army Research Laboratory, Aberdeen Proving Ground, Maryland, United States.

Rational design of oxygen reduction reaction (ORR) electrocatalysts based on earth-abundant elements is critical important towards sustainable energy applications. Among various reported ORR electrocatalysts, transition metal-nitrogen doped carbon (TM-N/C) materials such as Fe-N/C and Co-N/C exhibit excellent catalytic activity. Nevertheless, comprehensive understanding of these TM-N/C electrocatalytic systems is still lacking, which demands extension of investigation to other TM-N/C systems (Cu, and Mn, etc). Herein, we developed a Cu promoted nitrogen-doped carbon (Cu-N/C) via high temperature pyrolysis of Cu-adsorbed zeolite imidazole frameworks (Cu@ZIF-8). The Cu-N/C electrocatalyst exhibited satisfactory ORR activity with half-wave potential of 0.813 V in 0.1 M KOH electrolyte. Moreover, it also showed excellent methanol tolerance and long-term stability. The enhanced ORR electrocatalytic performance is attributed to the strong synergistic effect between Cu(II)-N ligands and Cu catalysts, sufficient active sites, and fast mass transfer.

ES07.03.03
Rapid Synthesis of Zeolitic Imidazolate Frameworks in Laser Induced Graphene Microreactors
Yunchao Xie, Chi Zhang, Jheng-Wun Su, Heng Deng, Cheng Zhang and Jian Lin; University of Missouri-Columbia, Columbia, Missouri, United States.

To date, various approaches to synthesize zeolitic imidazolate frameworks (ZIFs) have been developed, such as solvothermal, sonochemical, microfluidic, and mechanochemistry reactions. However, most of them are time-consuming and involve complex processing steps, thus they cannot rapidly screen potential candidates to obtain ZIFs on demand. Such a challenge calls for efficient synthetic approaches. Herein, we overcome this challenge by employing two nonconventional heating strategies, i.e., microwave- and Joule-heating, which are induced by laser-induced graphene (LIG) microreactors, for rapidly synthesizing ZIFs. In the first reaction, the LIG acts as a susceptor that absorbs electromagnetic energy, which is converted to heat. In the later one, LIG acts an electrical conductor that converts electrical energy to heat. Both two can rapidly heat up the reactor, accelerating the crystal growth for synthesizing ZIFs with well controlled morphology and crystallinity. To demonstrate a conceptual application, a ZIF-67/LIG composite was converted to a CoCoN/C/LIG by a CO₂ laser induction process. It shows great oxygen reduction reaction (ORR) performance with a half-wave potential (E₁/₂) of 0.798 V, and superior methanol tolerance and long-term stability. These rapid and facile synthesis methodologies will enable to quickly optimize reaction conditions and fast screen compound libraries for searching new materials, paving a way to high-throughput and autonomous nanomanufacturing.

ES07.03.04
Nitrogen Doped Coal—A High Efficient Electrocatalyst for Oxygen Reduction Reaction
Chi Zhang and Jian Lin; University of Missouri Columbia, Columbia, Missouri.
United States.

It is of a great challenge to develop high efficient nonprecious electrocatalysts to replace Pt-based catalysts for oxygen reduction reaction (ORR). This study introduces a cost-effective and environmentally friendly ORR electrocatalyst based on nitrogen doped coal (NOC) via a pre-oxidation of raw coal followed by a urea assisted annealing process. The obtained materials show great electrocatalytic activity with the onset potential, half-wave potential, and diffusion-limited current density comparable to those of a commercial Pt/C catalyst. In addition, it follows a four-electron pathway and has relatively low peroxide yield. Finally, it exhibits a good stability and strong tolerance to methanol poisoning. A systematic characterizations illustrate that these great performance could arise from high graphitic N and pyridinic N contents, existence of trace metal elements, and porous structures in the synthesized NOC. The demonstrated high performance makes NOC a promising catalyst for applications in metal air batteries and alkaline fuel cells.

**ES07.03.06**

**Texture Controllable Hierarchical Porous Carbon as Flexible Electrode for High Rate Performance Supercapacitor**

Jiang Hedong and Chunyang Jia; University of Electronic Science and Technology of China, Chengdu, China.

Hierarchical porous carbon (HPC) as flexible electrode attracts enormous attention due to its favorable properties, which is advantageous for the improvement of supercapacitors capacitance and rate capability. In this research, texture controllable HPC flexible electrode with high capacitive performance is successfully prepared by polymerization induced phase separation method. Solvents with various viscosities and hydroiodic acid with various amounts are used to regulate the texture. Scanning electron microscopy (SEM), high resolution transmission electron microscopy (HRTEM), nitrogen adsorption and desorption isotherms, density functional theory (DFT) method are used to characterize or modelling the morphology, micro-pore, specific surface area and pore size distribution, respectively. The desired hierarchical porous structure endows the carbon material with a high specific surface area and ideal transportation paths. The optimized HPC flexible electrode reaches a high specific capacitance of 142.9 F g\(^{-1}\) at 1 A g\(^{-1}\) in a two-electrode configuration in 6 M KOH, which is 79.1\% of the capacitance measured at 0.2 A g\(^{-1}\). Furthermore, energy density of the supercapacitor device ranges from 6.27 Wh kg\(^{-1}\) to 4.23 Wh kg\(^{-1}\) with the power density ranges from 100 W kg\(^{-1}\) to 46195 W kg\(^{-1}\).

**ES07.03.07**

**Soft-Templated Tellurium-Doped Mesoporous Carbons as a Pt-Free Electrocatalyst for High-Performance Dye-Sensitized Solar Cells**

Chang Ki Kim and Hwan Kyu Kim; Korea University, Sejong City, Korea (the Republic of).

In recent years, research into sustainable and renewable energy resources has attracted much attention due to the increase in concerns about the energy crisis, decreasing availability of fossil fuels and environmental issues. From these points of view, photovoltaic technologies are a highly desirable solution because clean solar energy is supplied indefinitely by the sun. Among various photovoltaic devices, dye-sensitized solar cells (DSSCs) are some of the most promising energy conversion devices because of their low fabrication cost, environmentally friendly nature and high conversion efficiency. Generally, DSSCs consist of four important components: an n-type semiconductor photoanode, a sensitizer (dye), an electrolyte with an iodine or cobalt redox couple, and a counter electrode (CE). For the high performance of a DSSC device, optimization of all components is necessary. In particular, the CE is a very important component in the DSSC device, as it behaves as a catalyst for regeneration of oxidized electrolyte, as well as an electron collector from the external circuit. The use of rare metals such as Pt counter electrodes (CEs) is one major drawback of DSSC devices for broad real-life applications. In this regard, alternative materials to Pt CEs have been long sought for DSSC employing both cobalt and iodine redox couples. Therefore, in this study, soft-templated tellurium-doped graphene films were prepared by the simple pyrolysis of PAN-ht-PBA block copolymer in the presence of a tellurium precursor for replacing the Pt CE. To confirm the chemical composition and porosity, the as-prepared Te-SMC materials were evaluated by elemental analysis (XPS, EDS), and nitrogen sorption isotherm measurements. As-prepared Te-SMC materials contained mainly mesopores and retained three-dimensionally hierarchical graphite-like structure with many defect sites. They displayed doping levels with nitrogen of 9.15 atom % and tellurium of 0.15 atom % and had specific surface area of 540 m\(^2\) g\(^{-1}\). Therefore, these characteristics enabled the development of a high-performance CE in DSSCs with cobalt and iodine redox couples. As a result of its catalytic performance, Te-SMC exhibited outstanding electrocatalytic activity as well as a much better electrochemical stability than the Pt CE for both redox couples even after 1000 potential cycles. The results show that a maximum conversion efficiency of 11.6\% and 9.67 \% could be achieved under one sun illumination (AM 1.5 G) for SGT-021(Co(bpy))\(^{2+/-}\) and N719(I \(^{-}\)-based devices with Te-SMC CEs, respectively and these values are superior to the corresponding device with Pt-CEs.

**ES07.03.08**

**Multifunctional Metal Incorporated Graphene Aerogels for Energy Management Applications**

Sahibah Peranaathan,1 Krishna Murulidharan1,² Srinivasa Raghavan1,³ Douglas A. Loy4, and B.G. Potter1,5; 1Department of Material Sciences and Engineering, University of Arizona, Tucson, Arizona, United States; 2Department of Planetary Sciences, University of Arizona, Tucson, Arizona, United States; 3Department of Chemical and Environmental Engineering, University of Arizona, Tucson, Arizona, United States; 4Department of Chemistry and Biochemistry, University of Arizona, Tucson, Arizona, United States; 5Department of Optical Sciences, University of Arizona, Tucson, Arizona, United States.

Lightweight carbon based aerogels are widely recognized as promising platforms for electronic, biomedical, energy storage and sensor applications. In this context, the ability to fabricate multifunctional graphene based aerogels with tunable properties is demonstrated in this work. In particular, using a unique coagulation technique, ultra-lightweight, chemically modified, mechanically robust, and electrically conductive reduced graphene oxide (rGO) aerogels were fabricated. The salient aspects of the fabrication process are (i) the incorporation of crosslinking metal cations, and (ii) self-assembly of rGO platelets in solution, giving rise to porous, mechanically robust 3D structures. Further, the controllable incorporation of metal ions within the rGO matrix provides distinct routes towards tuning the ensuing electrical, electrochemical, thermal, and mechanical properties. To illustrate the versatility of the fabricated aerogels, their applications as binder-free supercapacitor electrodes, thermal interface materials with exceptional thermal transport properties, and high electrical conductivity coatings will be discussed.

**SESSION ES07.04: Syntheses and Characterization of New Carbon-Based Materials**

**8:15 AM ES07.04.01**

**Iodine-Doped Graphene Films for High-Performance Electrochemical Capacitive Energy Storage**

Zhu Yucan and Chunyang Jia; School of Electronic Science and Engineering, University of Electronic Science and Technology of China, Chengdu, China.

Recently, the fabrication of high-performance graphene films as electrode materials has become a research tendency for flexible energy-storage devices. Here, we successfully prepared iodine-doped reduced graphene oxide (r-GO) films with excellent capacitive performance by a simple and versatile technique of iodine steam doping. The iodine as an effective n-type dopant can enhance the electrical conductivity of graphene films by charge transfer process, further improving capacitive performance of the devices. The electrochemical properties of as-prepared r-GO films with different mass loadings were systematically and comprehensively studied. With the change of mass loading (1.5–6.7 mg cm\(^{-2}\)), the gravimetric specific capacitance of r-GO films remained almost variable at the studied range of current density, and finally can reach ~150 F g\(^{-1}\) at 0.2 A g\(^{-1}\) with 6 M KOH electrolyte, exhibiting the high utilization of electrode materials. With the increasing mass loading, supercapacitors based on the r-GO films show almost linear growth of areal specific capacitance at any current densities from 1 to 30 mA cm\(^{-2}\) (eventually reach ~524 mF cm\(^{-2}\) at 1 mA cm\(^{-2}\)) and nearly no decline of the rate performance. Additionally, we fabricated flexible all-solid-state supercapacitors, which also display excellent areal specific capacitance (~450 mF cm\(^{-2}\)), great cycling stability and favorable electrochemical stability. These results indicate that the fabricated r-GO films have a great advantage as electrode materials for flexible energy-storage devices.

**Single Walled B@I\(_3\) and Gd@I\(_3\) Nanotubes Encapsulated within CNT**

Leonard D. Francis; Department of Advanced Electron Microscopy, Imaging and Spectroscopy,
The hollow interior of CNTs provides a unique environment for the fabrication of novel morphologies by stabilizing novel phases within its cavity (1). Inorganic nanotubes are morphological counterparts of carbon nanotubes. The synthesis and structural elucidation of single walled nanotubes of inorganic compounds is still a challenge (2). In this work, we employ AC electron microscopy imaging and spectroscopy to study a novel morphology of BiI$_2$ and GdI$_2$ - SWNTs encapsulated within CNTs. Thus the single walled nanotubes of BiI$_2$ and GdI$_2$ phases in this study, are obtained by employing CNT as a nanotemplate. This method involves the capillary filling of BiI$_2$/GdI$_2$ within CNT, by annealing the BiI$_2$/GdI$_2$-CNT mixture above the melting point of BiI$_2$ (GdI$_2$). Aberration corrected electron microscopy and spectroscopy in combination with image simulations are employed to reveal the morphology, structure and composition of these nanotubes. A critical host internal diameter was estimated, for the formation of such single walled nanotubes, based on the electron microscopy images. First-principles density functional theoretical calculations were carried out to determine the stability and electronic properties of these BiI$_2$/GdI$_2$ nanotubes. The ultrahigh one dimensional morphology of BiI$_2$/ GdI$_2$ presented here could lead to novel physical properties and applications (3-5).

8:45 AM ES07.04.03 Functional Nanoporous Graphene@Metal-Organic Frameworks—Design, Synthesis, Properties and Applications Jayaramlu Kollebovina$^{1,2}$, Stepan Kmert$^1$, Roland Fischer$^2$ and Radek Zboril$^1$; $^1$Regional Centre of Advanced Technologies and Materials, Olomouc, Czechia; $^2$Inorganic and Metal-Organic Chemistry, Technical University of Munich, Munich, Germany.

Among the porous materials, the hybrid porous materials metal-organic frameworks (MOF’s) have attracted attention, due to their potential applications in various fields owing to their inherent qualities like high surface area, large pore volume, active metal sites with ordered and tunable pores. But MOFs have important challenges for practical or industrial applications like moisture stability, conductivity and micro pores. However, non-porous graphene sheets are becoming an inexpensive material, have been proven an outstanding matrix to support various materials, leading to advanced materials for electro catalysis and other energy-related application. Further, hybrids of MOF and Functional Graphene materials or GOMFs have collaborative properties like conductivity, large internal surface area with hierarchical pores and significant stabilities, which can exploit for the various energy and environmental applications. Herein, we would like to discuss, our recent research interest focused on the synthesis of various novel hybrid Graphene-MOF porous materials by different approaches. The structure and coordination environment thoroughly characterized by various microscopy and spectroscopy measurements. Depends on functional properties of these G/MOFs exploited for environmental oil spills separation from water, hydrocarbon separation and photo/electrochemical water splitting applications.$^{1-5}$

9:00 AM ES07.04.04 Self-Assembly Synthesis of Carbon Electrode Architectures for Energy-Related Applications Sheng Dai$^1$; $^2$Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; $^3$Department of Chemistry, The University of Tennessee, Knoxville, Knoxville, Tennessee, United States.

Enhancement in electrochemical energy storage resides in tailored nanotextures resulting from making electrode materials hierarchically nanoporous. The complex interplay of solvent and solute structure and dynamics at the charged interface, the transport of electrolyte ions into and out of the pores, the solvation/desolvation processes occurring in pores approaching bare-ion dimensions, and formation of interfaces via chemical reactions are all important parameters. Herein, several self-assembly synthesis methods for carbon composites as electrode materials for energy storage will be discussed. The objective of this talk is to demonstrate that mesoporous carbons derived from soft-template synthesis not only entail a high storage capacity but also, most importantly, can be made through self-assembly synthesis to have a significantly enhanced electronic conductivity and storage capacity. This enhanced electronic conductivity in 3D architectures is the key to providing high rate capability for the corresponding energy storage systems.

9:30 AM ES07.04.05 Science of Nitrogen and Boron Doped Electrically Conductive Ultrananocrystalline Diamond Thin Films and Applications to Energy Generation/Storage Devices Pablo Tirado$^1$, Jesus Alcántara$^2$, Elida I. de Obaldia$^3$, Rafael Garcia$^4$ and Orlando Aucillo$^5$; $^1$MSE, The University of Texas at Dallas, Dallas, Texas, United States; $^2$Facultad de Ciencias y Tecnologia, Universidad Tecnologica de Panama, Panama, Panama; $^3$Departamento de Investigacion en Fisica, Universidad de Sonora, Hermosillo, Mexico.

Ultrananocrystalline Diamond (UNCD) films are being investigated due to their unique combination of properties such as high wear resistance, highest hardness relative to any other film, lowest friction coefficient compared with metal and ceramic coatings, corrosion resistance, negative electron affinity, low work function, and high electrical conductivity for Boron (B) doped and nitrogen-grain boundaries incorporated UNCD films. The combination of these properties make doped UNCD films suitable for many applications like Li-ion batteries electrodes, corrosion resistant coatings for metal electrodes for electrolysis-based water purification, thermionic and field emission devices, and future high power electronic devices. B-UNC films are currently marketed by Advanced Diamond Technologies, but the drawback is that B doping is produced during film growth by hot filament chemical vapor deposition (HFCVD) involving B contamination of the chamber where the film is grown, which can be used only for growing B-doped UNCD or other diamond films. This presentation will describe the results from research and development of a novel process for B doping large area UNCD films by thermal diffusion after growth, thus eliminating the problem of B contamination of the diamond film growth chamber. The research focused on understanding the chemical, structural and electrical properties of the UNCD films before and after doping with B by thermal diffusion. The UNCD films were grown by Microwave Plasma Chemical Vapor Deposition (MPCVD) and HFCVD techniques on Si(100) Si substrate. Subsequently, 200-nm thick Spin on Dopant (SOD) coating containing B atoms was grown on the UNCD films. followed by annealing in an atmospheric oven to evaporate any excess solvent from the SOD film. Successive chamber evacuations and purges flowing N$_2$ were performed to minimize O$_2$ content in order to avoid the C-based UNCD film being etched by oxygen at the high temperatures needed for Boron diffusion. UNCD films were ultra-sonically cleaned with solvents to remove remaining SOD coating. -doped and as deposited UNCD films were characterized by Raman, XRD, SIMS, UPS, XPS and Hall effect measurements. Raman and XRD analysis confirm that there was no induced graphitization or damage in the UNCD films during the B diffusion process, while SIMS, UPS, XPS and Hall effect analysis confirmed B doping and correlation with changes in electrical properties. The B-doped UNCD films exhibit 10$^4$ Ohm.cm resistivity. We also explored the synthesis of UNCD films with nitrogen (N) atoms incorporation into grain boundaries, during HFCVD growth with Ar/CH$_4$/N$_2$/H$_2$ gas mixture flow, and observed that N-UNC films also exhibit 10$^4$ Ohm.cm resistivity. Analysis of the N-UNCD films revealed that N atoms are inserted in the grain boundaries and satisfy dangling C atoms bonds, providing electrons for electronic conductions. We will discuss the conductivity mechanisms in both B-UNCD and N-UNC films and their potential applications to a new generation of energy related and high power electronic devices.

Lithium dicyanamide (Li[N(CN)]$_2$) reacts with phosphorus cyanide (P(CN)$_3$) in ethereal solution to form a resin, which separates into a second liquid phase, which is then redissolved in acetonitrile or other solvents. The resin can also be prepared in a single solvent in which it remains soluble for several days (pyridine), or indefinitely (propylene carbonate). The resin solution is used to coat metal coupons or disks which are then cured at temperatures of up to 300 °C, forming adherent, ion conducting films. Samples were also prepared in button cells. We characterized the ionic conductivity and chain motions of these films by dielectric relaxation spectroscopy, and the transference number by electrochemical measurements. Furthermore, bulk thermostet material was analyzed by elemental analysis. We evaluated how the composition and conductivities of these materials depend on conditions of preparation.

**Encapsulating Various Sulfur Allotropes within Graphene Nanocages for Long-Lasting Lithium Storage**  
Jun Lu  
Chemical Sciences and Engineering Division, Argonne National Laboratory, Argonne, Illinois, United States.

The encapsulation of sulfur within carbon matrices is widely utilized in the cathode of a rechargeable lithium-sulfur battery, whose energy density largely depends on the design of the carbon structure. Here we report an advanced graphene nanocage structure with the capability of hosting both cyclo-S$_2$S and smaller sulfur molecules (S$_2$). The cage inner cavity is partially filled with S$_2$ to form a yolk-shell structure that enables free volumetric variation of S$_2$ during (de)lithiation. In the graphene shell of the cage, S$_2$ is downsized to S$_{2x}$ to activate extra sulfur loading sites within graphene layers. Importantly, the graphene shell exhibits inward volumetric variation upon (de)lithiation of the loaded S$_{2x}$, and the overall electrode strain is thus minimized. This prototyped design promises an ultimate solution to maximize sulfur loading in carbon matrices as well as to circumvent the polysulfide dissolution problem and boost the commercialization of lithium-sulfur batteries in the future.

**Electrochemical Quartz Crystal Microbalance for Study of Iodide Affinity to Carbon Surface**  
Anetta Platek, Krzysztof Fic and Elżbieta Frackowiak; Poznan University of Technology, Poznan, Poland.

Nowadays iodides have been extensively used in electrochemical capacitors in order to boost their energy output. Due to the presence of relatively fast reaction of 2I$^-$/I$_2$, redox couple specific capacitance recorded on the positive electrode is extremely high. However, kinetics conditions of this process limit high rate ability of the system, what is its main drawback. Furthermore, other ambiguous issues could be listed as: low energetic efficiency of charging/discharging process at higher voltage range, iodide confinement only in the positive electrode responsible for electric double layer (EDL) creation, their exact movement and interactions with water molecules. For detailed studies, a rubidium iodide aqueous solution has been selected using EQCM. It has been revealed that iodide anions do not participate in EDL creation. During negative polarization movement of cations with solvation shell (Rb$^+$) have been described simultaneously with fluxes of H$^+$ and OH$^–$. Notwithstanding, for positive polarization mass change recorded is significantly smaller than it was expected for bare I$_2$. Therefore, recorded mass have been recalculated to exact species responsible for this phenomenon. It disclosures that OH$^–$ ions are equilibrating the charge in EDL during positive polarization. In order to clarify and confirm this phenomenon rubidium hydrioxide have been analysed. EQCM is capable to detect mass change resulting from OH$^–$ movement with satisfactory quality. Moreover, it has been revealed that cations and anions affect their solvation shell. For rubidium hydrioxide Rb$^+$ ion is hydrated with 2 molecules of water (Rb$^+$)$^{2+}$(H$_2$O)$_2$. Furthermore, sodium and potassium iodides have been analysed in order to verify versatility of iodide affinity to carbon surface. In all iodide solutions, a confinement of I$_2$ into porosity has been validated, as during positive polarization only OH$^–$ ions were responsible for charge balance. Solution number of alkali metals (Na$^+$, K$^+$, Rb$^+$) have been experimentally determined by this in-situ technique. Moreover, this work proves that ions adsorption/desorption in aqueous solution reveals very complex mechanism and description of ongoing processes cannot be simplified as long as solvent interaction with ions are considered. Iodide affinity to carbon surface have been clearly demonstrated by electrochemical quartz crystal microbalance.

**The Electronic Structure Underlying Carbon for Energy Applications**  
Yuan Yue Liu; The University of Texas at Austin, Austin, Texas, United States.

The electronic structure theory (e.g. density functional theory) and calculations are powerful tools to offer mechanistic insights. Here I will discuss how the electronic structure of carbon controls atoms adsorption, and use this understanding to explain a number of puzzles related with energy applications, including: (1) why structurally similar C forms have distinct binding energies with Li$^+$ [1], (2) why graphite has a low Na capacity while a high capacity for other alkaline metals [2]. Finally, I will discuss the effects of varying charge and fixed potential in electrocatalysis of graphene [3], which are often neglected in modeling but are important for 2D materials due to their peculiar electronic structure, calling for re-evaluation of their electrocatalytic mechanisms by incorporating these effects into simulations.

**Effect of Ionic Liquid Confinement in Carbon Nanopores on Electrical Double-Layer Charging**  
Vladimir Pavlenko, Emmanuel Pamete Yambou, Barbara Gorska and Francois Beguin; Poznan University of Technology, Poznan, Poland.

Room temperature ionic liquids (ILs) represent a perspective class of electrolytes for energy storage devices, particularly electrochemical capacitors (ECs). However, the relatively high melting point of ILs limits their applicability at low temperature, which is a requirement for commercial ECs. Accordingly, lowering the melting point of ILs down to -50°C, and even beyond, is a great challenge. The first strategy to expand the liquid state of IL electrolytes to sub-zero temperatures is the formulation of binary mixtures. Besides, since ECs are primarily constructed from porous carbon electrodes, and it was already proven that the IL melting temperature maybe depressed under confinement in porous silica, it is interesting to investigate if this effect also occur with carbons. Three aprotic ILs consisting of the same imidazolium-based cation (EMIm) and FSI, TFSi, BF$_4$ anions were selected for this study.

The thermal behavior and physico-chemical properties of EMImFSi, EMImTFSi, EMImBF$_4$, and their binary mixtures with various molar ratios were investigated. Some binary mixtures did not show any first order transition unlike the neat ILs, and remained in the liquid state down to -90°C, where only a glass transition was observed. The temperature dependence of dynamic viscosity and ionic conductivity for pure ILs and their mixtures followed the Vogel-Tammann-Fulcher equation, whilst the density showed a linear decrease. The corresponding Walden plot for pure ILs and their mixtures revealed a high degree of ionicity classifying them as “good ionic liquids”. Hence, by implementing BP2000 carbon (Cabot), carbon/carbon capacitors using binary mixtures (1:1 molar ratio) as electrolytes operated down to -40°C with good performance, contrary to the cells with the parent neat ionic liquids.

In a second part of the research, the effect of confinement in porous carbons – microporous carbon Maxsorb (Kensai) and mesoporous carbon Maxsorb (Cabot) with average pore sizes of 0.9 nm, 3.7 nm and 9.2 nm, respectively - on the phase transitions of neat ILs has been studied by differential scanning calorimetry. The SC2A (Cabot) with average pore sizes 0.9 nm, 3.7 nm and 9.2 nm, respectively - on the phase transitions of neat ILs has been studied by differential scanning calorimetry.

During (de)lithiation of the loaded S$_{2x}$, the intensity of the peaks corresponding to crystallization and subsequent melting decreased and the melting temperature downshifted to a value depending on the type of IL. For instance, as compared to the neat IL, the melting temperature of EMImTFSi confined in Maxsorb MSP-20X (for V$_{t}$/V$_{m}$=0.9) is downshifted by 6.5°C. Finally, for V$_{t}$/V$_{m}$> 1, we did not observe any freezing/melting peak, suggesting that freezing is prevented when ILs are such dispersed within the nanopores that they cannot form an ordered crystal structure. For V$_{t}$/V$_{m}$>1, it is also worth noting that the IL glass transition disappeared, whilst it still exists for the two mesoporous carbon matrices.
Raman spectroscopy is one of the most used characterization techniques in carbon science and technology. The measurement of the Raman spectrum of graphene triggered a huge effort to understand phonons, electron–phonon, magnetophonon and electron–electron interactions, as well as the influence of the number and orientation of layers, electric or magnetic fields, strain, doping, disorder, quality and types of edges, and functional groups. I will review the state of the art, future directions and open questions in Raman spectroscopy of graphene and carbon materials, focussing on the effect of disorder, doping, stress.

2:00 PM *ES07.05.02
Directional Flow-Aided Sonoechemistry Yields Graphene with Tunable Defects to Provide Fundamental Insight on Sodium Metal Plating Behavior

David Mitlin\(^1\)\(^2\) and Wei Liu\(^1\); 1Clarkson University, Potsdam, New York, United States; 2SCU, Chengdu, China.

We report a directional flow-aided sonoechemistry (FAS) exfoliation technique that allows for unparalleled control of graphene structural order and chemical uniformity. Depending on the orientation of the shockwave relative to the flow aligned graphite flakes, the resultant bilayer and trilayer graphene is nearly defect free (at-sonication graphene [AES-G]) or is highly defective (in-plane sonication graphene [IPS-G]). AES-G has a Raman G/D band intensity ratio of 14.3 and an APS derived O content of 1.3 at.%, while IPS-G has kossel of 1.6 and 6.2 at.%. AES-G and IPS-G are then employed to understand the role of carbon support structure and chemistry in Na metal plating/striping for sodium metal (SMB) anodes. The presence graphene defects and oxygen groups are highly deleterious: In a standard carbonate solution (1M NaClO\(_4\), 1:1 EC:DEC, 5vol.%/FEC), AES-G gives stable cycling at 2 mA/cm\(^2\) with 100% CE (within instrument accuracy), and an area capacity of 1 mA/cm\(^2\). Meanwhile IPS-G performs on-par with the baseline Cu support in terms of poor CE, severe mossy metal dendrites, and periodic electrical shorts. We argue that SEI stability is the key for stable cycling, with defects IPS-G being catalytical towards SEI formation. For IPS-G, the SEI layer also shows F-rich "hot spots" due to accelerated decomposition of FEC additive in localized regions.

3:30 PM *ES07.05.03
Advanced Carbon Materials for Lithium-Sulfur Batteries—From Basic Research to Pouch Cells

Stefan Kaskel\(^1\); 2Fraunhofer IWS, Dresden, Germany; 3Chemistry, TU Dresden, Dresden, Germany.

Lithium sulfur batteries are considered as the next generation batteries due to their high gravimetric energy density up to 350-400 Wh/kg. Highly porous carbon materials with surface areas up to 3000 m\(^2\)/g play a key role for the performance of such systems. A key requirement is to achieve high sulfur loadings up to 75 wt. % in the cathode and high degree of sulfur utilization. In particular challenging is to identify new electrolytes to achieve high cycling stability. Electrolyte minimization is an often overlooked requirement to achieve high energy densities in prototype cells. The development of porous carbon materials for lithium sulfur batteries requires pore size and polymer tailoring [1-8] Mesoporous carbon materials are ideally suited as sulfur host for the lithium sulfur batteries. Microporous carbons (d < 2 nm) show high sulfur utilization but the overall sulfur loading is limited to a maximum of about 50 wt % sulfur posing limitations to achieve a high gravimetric energy density. Hard carbons are highly promising anode materials to achieve up to 4000 cycles in a lithium sulfur battery with only minor degradation.[3] Moreover, sodium sulfur batteries can operate with this concept at room temperature.[5] The presentation will give examples for pouch cell production, laser cutting, silicon anode integration [9] and fundamental advances for cathode evaluation [10].

4:00 PM ES07.05.04
Structure of Bulk and Confined Ionic Liquids from Ab Initio Molecular Dynamics Simulations and X-Ray Scattering

Tuan Anh Pham\(^1\), Riley Coulthurd\(^2\), Mirjam Zobel\(^3\), Steven Buchsbaum\(^1\), Destree Plata\(^1\), Brandon C. Wood\(^1\), Francesco Fornasiero\(^4\) and Eric R. Meshol\(^1\); 1Lawrence Livermore National Laboratory, Livermore, California, United States; 2Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3University Bayreuth, Bayreuth, Germany; 4Yale University, New Haven, Connecticut, United States.

Room temperature ionic liquids (ILs) have recently emerged as highly promising electrolytes for a wide range of emerging energy technologies, including next-generation supercapacitors and ion-batteries, due to their high thermal stability, ionic conductivity and wide electrochemical windows. In this presentation, we combine first-principles simulations and synchrotron X-ray characterization experiments to unravel the key structural properties of several imidazolium-based ILs. In particular, we use extensive ab initio molecular dynamics simulations to probe the local density distribution and medium-range order of bulk ILs, which can be directly compared and validated by X-ray scattering measurements. Having established this cross-validation, we then compare and contrast via simulation the structural, chemical and electronic properties of the ILs in the bulk and under confinement in sub-2 nm carbon slit nanopores, which serve as model systems for understanding confinement effects in porous carbon and eventually new carbon chemistry. Our integrated theoretical and experimental approach relates these structural and chemical signatures with the intrinsic cation-anion interactions, by considering bulk and under confinement in sub-2 nm carbon slit nanopores, which serve as model systems for understanding confinement effects in porous carbon and eventually new carbon chemistry. Our integrated theoretical and experimental approach relates these structural and chemical signatures with the intrinsic cation-anion interactions, by considering ILs with anions having significant differences in the molecular geometry, chemical composition, and charge distribution.

This work was supported by the U.S. Department of Energy at the Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

4:15 PM ES07.05.05

In Operando Characterization of SEI Formation and Long Term Cycling in NMC/SiGr Composite Pouch Cells Through Non-Invasive Acoustic Measurements

Clement Knebeler\(^1\); Jianlin Li\(^2\), Shaorui Biwas\(^1\); Jagjit Nanda\(^1\) and Daniel Steinberg\(^1\); 1Mechanical and Aerospace Engineering, Princeton University, Princeton, New Jersey, United States; 2Andlinger Center for Energy and the Environment, Princeton University, Princeton, New Jersey, United States; 3Chemical and Biological Engineering, Princeton University, Princeton, New Jersey, United States; 4Materials Science & Technology Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 5Feasible, Inc., Berkeley, California, United States.

Silicon/Carbon composite anodes for LIBs have been the subject of much research over the past decade, as they are touted to be the material that will enable the arrival, and commercialization, of the 'next-generation' LIB. That being said, there are many problems, ranging from the Si volume change, continuous SEI formation, and loss of Li-inventory in a full cell setting, have hindered its growth. Moreover, characterization of these processes to enable an understanding of structure-property relationships requires either destructive ex-situ methods, or labor and cost intensive in-situ, or in-operando methods, which can be out of reach for academic labs or early incubation start-ups. As such, this work attempts to develop a non-invasive understanding of degradation methods of a Si/Carbon composite in a full-cell, through a simple, non-destructive, and easily applicable in-operando acoustic characterization. Through the acoustic measurements, we are able to show a two step SEI formation process, involving a gassing, and non-gassing phase, as well as the gradual time-of-flight (TOF) increase due to the passivation of the Silicon in the full cell. Coupling these results with a comprehensive dq/dv, and half-cell
Probing Local Structure and Disorder in Graphitic Carbon Nitrides

Diane Haider, Barnaby D. Levin and Peter Czoor; Arizona State University, Tempe, Arizona, United States.

Graphitic carbon nitrides have emerged as promising candidates for driving photocatalytic H2 evolution under visible light, CO2 reduction, and other renewable energy applications owing to their native high surface area, chemical robustness, and inexpensive synthesis routes.1 Calculation of various N-rich precursors yields layered C3N4Hx compounds with interplanar spacings of ~0.32 nm. Although commonly referred to as “g-C3N4,” the average structure of these C3N4Hx’s are consistent with polymeric Melon (C3N4H) whose in-plane structure is composed of amine (N-H) bridged heptazine (C3N4) building blocks.2 In this view, the in-plane structure is polymerized through bridging N-H units to form “zigzag” chains of heptazine molecules terminated by N-H moieties. However, structural differences between different C3N4Hx compounds are not well understood as X-ray diffraction (XRD) and related techniques are limited to the bulk. High spatial resolution techniques, such as transmission electron microscopy (TEM), may be leveraged to investigate the in-plane structure/disorder in C3N4Hx compounds.

Here, aberration-corrected TEM at 300-kV under low dose rate conditions (<70 e/Å2/s), enabled by the use of a direct electron detector (K2-ES, Gatan), was applied to three C3N4Hx powders demonstrating a range in structural condensation. Prior to TEM imaging, the extent of long-range order in each sample was ranked based on the relative Bragg peak broadening observed in XRD patterns. For each sample, large field of view (~60-80 nm) images of the in-plane structure were obtained by imaging regions wherein the extended layers were perpendicular to the incident electron beam. Fourier transforms (FTs) generated from these “in-plane” images from each compound exhibit exceptional spatial resolution compared to that of XRD which is evidenced by the multiple (6θ°) reflections observed up to (1 Å)1 in the most ordered C3N4Hx. When rotationally-averaged FTs are compared to the XRD patterns, a similar trend in Bragg peak broadening is observed suggesting that the low dose rates used have avoided significant structural degradation.

To investigate local variations in the in-plane structure of each C3N4Hx, image autocorrelations were computed over 6.5-nm windows covering the entire field of view. Each autocorrelation represents a pseudo Patterson function (PPF), revealing the heptazine-heptazine nearest neighbor (NN) distances/orientations, associated with a particular region. The PPF analysis suggests that the local structure of the most ordered C3N4Hx is relatively invariant and possesses a “zigzag” chain structure. In contrast, the more disordered forms exhibit considerable rotational variations in the local hexagonally-coordinated NN motif. To visualize the extent of uniformly-oriented in-plane domains for each material, virtual dark field (VDF) images were generated from the same set of TEM images. VDF images of the most ordered C3N4Hx show “domains” covering tens of nanometers whereas in the disordered forms, these domains are much smaller at ~2-7 nm at most.

Preparation of Nitrogen-Doped and Interconnected Hollow Carbon Nanospheres for Superior Lithium-Sulfur Battery

Cheme Ma1, Itjong Wang2, 1, Wenming Qiao2 1 and Licheng Ling1, 2; 1 Key Laboratory of Specially Functional Polymeric Materials and Related Technology, East China University of Science and Technology, Shanghai, China; 2 State Key Laboratory of Chemical Engineering, East China University of Science and Technology, Shanghai, China.

Sulfur is the promising cathode materials for rechargeable lithium batteries with high theoretical specific capacity and energy density. However, sulfur has poor cycling stability due to its low conductivity and polysulfide dissolution. Herein, nitrogen-doped and interconnected hollow carbon nanospheres with particle size of 50-80 nm via direct carbonization of Zn, Co-ZIF coated with resorcinol-melamine-formaldehyde resin have been reported as highly efficient sulfur host for high-performance lithium-sulfur batteries. The interconnected hollow nanospheres are derived from the different carbon yield and shrinkage between Zn, Co-ZIF core and RMFs shell and the as-prepared HPCNs have the specific surface area of 836-881 m2/g, large pore volume up to 1.50 cm3/g and high conductivity. Combining the high conductivity and chemical trapping of lithium polysulfides, the obtained S/HPCNs cathode of 70 wt.% sulfur content in the composite delivered a high specific capacity up to 1300 mAh/g at 0.2 C and 762 mAh/g at 8 C. Moreover, a stable capacity of 950 mAh/g could be maintained even after 200 cycles at 0.2 C. The nature of the interactions between N-doped carbons and lithium polysulfide species was investigated by X-ray photoelectron spectroscopy studies. The unique electrochemical behavior and superior performance of S/HPCN composites open possibilities for new class of cathode materials for high energy and high power density lithium rechargeable batteries.

Surface Functionalization of Graphene Prior to Co2+: Tethering for Oxygen Reduction Catalysis in Both Acidic and Alkaline Media

Simranjit K. Grewal1 and Dr. Min-Hwan Lee2; 1 Bioengineering and Small-Scale Technologies, University of California, Merced, Merced, California, United States; 2 Department of Mechanical Engineering, University of California, Merced, Merced, California, United States.

Oxygen reduction reaction (ORR) is one of the most studied reactions for clean energy devices such as fuel cells and metal-air batteries due to its intrinsically sluggish kinetics.
which often limits device performance. Non-precious transmission metal oxides (TMO) such as FeO,
MnO, and CoO[1] have been intensively probed as alternatives to platinum-based catalysts. To supplement low electronic conductivity of TMOs, they are often dispersed on a highly conductive carbon nanostructure with a large surface area, maximizing catalytically active sites per volume and mass.

We employ a hybrid structure where CeO2 is deposited/decorated on reduced graphene oxide with extreme surface area and excellent electronic conductivity. Since only the wrinkles and edges contain active sites (binding functional groups) on graphene oxide, the basal plane is populated with rather inert epoxide groups. To functionalize the GO surface, hydrobromic and/or oxalic acids are used to create hydroxyl or carboxyl groups. The treated GO is then hydrothermally reacted (at 160 °C for 24 h) with the precursor salt of cerium (III) nitrate hexahydrate. Three different kinds of GO:CeO2 hybrids were synthesized based on as-synthesized, hydrobromic acid-treated, and an additional oxalic acid-treated GOs.

Results have indicated that hydroxyl groups absorb CeO2 nanoparticles better and that CeO2 tethered on hydroxylated GO showed the best performance in acidic media in terms of current density, electron transfer number and onset/half-wave potential, all comparable to the performance of Pt/C. Similar enhanced performance was seen for alkaline media with an exception of enhanced durability compared to Pt/C. An X-ray analysis showed a reoccurring (002) diffraction peak among most hybrids with the exception of hydroxylated CeO2/GO hybrids. This suggests the sample exhibit a strong binding of metal oxides to the basal planes of graphene flakes, thus prohibiting graphene restacking. From a series of experimental analyses, it is concluded that a strong tethering of metal oxide particles on the basal plane of graphene is a prerequisite of high ORR performance, and that the particle-graphene interfaces (as opposed to the particle or graphene itself) dictates the performance and reaction route.

This project was funded by NASA Advanced STEM Training and Research (ASTAR) Fellowship.

The Effect of Synthesis Parameters for the Mesoporous Carbons Using Silica Aerogel Templates

Naime A. Sezgi1, Merve Sarıyırt2 and Timur Dogu2; 1Chemical Engineering, Middle East Technical University, Ankara, Turkey.

Hydrogen is considered as one of the most promising future energy carrier due to its high energy density and its production through ethanol steam reforming reaction (SRE) has the potential to be used for its on board production, in fuel cell powered motor vehicles. Nowadays, novel catalysts are investigated for the steam reforming of ethanol reactions in order to achieve high hydrogen yield with low coke formation. One of the novel catalyst is a mesoporous material templated mesoporous carbon. Mesoporous carbon materials are investigated due to their physical and chemical properties, such as electrical and thermal conductivity, mechanical and chemical stability, low density, high surface area, and large pore size. Using the mesoporous materials such as SBA-15, MCM-48 etc. as a template, having a high surface area and pore diameter carbon supports can be synthesized.

Generally, hard template method is used to achieve well-defined ordered structure. Saccharic and furfuryl alcohol are used as carbon precursors and for the removal of silica materials, washing with HF or NaOH are applied. In this study, for the first time, silica aerogel was used as silica template. Moreover, sucrose was impregnated to the pores of the mesoporous materials as a carbon precursor. The effect of washing with HF or NaOH, adding silylating agent to silica aerogel in the synthesis and calcination temperature of silica aerogel on the structure of the materials were investigated. The results showed that high surface area materials with Type IV isotherm were synthesized. The carbon materials washed with HF gave higher surface areas compared to the materials washed with NaOH. It was evident that NaOH did not remove the all silica materials. The result also proved with the SEM and EDS analysis, showing the unremoved silica structures in the materials. In addition, washing with HF resulted in highly acidic carbon materials considering TPD analysis. When the silica aerogels which did not contain silylating agent as a template, the final carbon materials gave high surface area and pore diameter. Moreover, the calcination temperature of the silica aerogels did not affect the surface area and pore diameter of the carbon materials. The nickel was impregnated into these materials and they were tested in the steam reforming of ethanol reaction. The carbon material washed with HF suppressed the ethanol steam reforming reaction and favored the ethanol decomposition reaction, giving undesired products CH4 and CO. The hydrogen yield was 3.8 using the carbon material washed with NaOH as a catalyst.

Multiscale Simulations of Hole Formation and Growth During Holey Graphene Synthesis via Chemical Etching

Dini Wang; Qiong Nian and Rui Dai; School for Engineering of Matter, Transport and Energy, Arizona State University, Tempe, Arizona, United States.

Holey graphene is a derivative of graphene that has abundant nano-holes on the basal plane of graphene sheets and has shown great potential in electrochemical and biochemical applications. Currently, the most popular synthesis method for holey graphene is the chemical etching approach, during which the mixture of graphene oxide and hydrogen peroxide are heated to generate holey graphene. However, the fundamental mechanism for the hole formation and growth during synthesis has not been fully revealed. To address this problem, this study employs density functional theory simulation to analyze and compare the various reactions between graphene and hydrogen peroxide. Molecular dynamics simulation are carried out to discuss the kinetics of the hole formation and growth. Results show that the carbon atoms around the defect areas on graphene sheets can be removed under high local temperature leaving baby holes on the basal plane. The presence of both hydrogen peroxide and high temperature ensures the cyclic insertion and removal of functional groups around those baby holes, which eventually causes the continuous growth of the in-plane holes.

ES07.06.05

Pillared Reduced Graphene Oxide with Mg in the Interlayer Space as Hydrogen Storage Material

Fene Yang1, Estela Moreton1, Konstantinos Spyrou2, Dimitrios Gournis1 and Piet Budde3; 1Zernike Institute for Advanced Materials, University of Groningen, Groningen, Netherlands; 2Department of Materials Science and Engineering, Cornell University, Ithaca, New York, United States; 3Department of Materials Science and Engineering, University of Ioannina, Ioannina, Greece.

Hydrogen is a promising sustainable alternative to conventional fuels that can push forward the energy transition. The caveat of this technology is the storage, since gravimetric and volumetric density targets have proven hard to reach. Theoretical studies of the gravimetric densities on graphene and in magnesium predict 8.3 wt% and 7.6 wt%, respectively. However, these values are still far from reality because of the weak physisorption and high chemisorption temperature. Herein, a novel pillared reduced graphene oxide with Mg in the interlayer space is proposed for effective hydrogen storage. The material, realized by sol-gel reaction of an organosilicon precursor, was characterized with BET, SEM, XPS, XRD and TEM and shows a crosslinked mesoporous structure with high specific surface area, narrow interlayer distance and enhanced adsorption due to the alkaline hydrides.

ES07.06.06

Influence of Carbon Microstructure on High-Performance Supercapacitor

Amir Reza Aref Laleh1, Ramakrishnan Rajagopalan2 and Clive A. Randall1; 1ESM, The Pennsylvania State University, University Park, Pennsylvania, United States; 2Materials Research Institute, The Pennsylvania State University, University Park, Pennsylvania, United States.

Transport porosity in activated carbon microstructure plays a key role in determining the electrode performance in electrochemical capacitors. In particular, ultramicropores and mesopores can significantly contribute to the charge storage properties in ionic liquid-based EDLCs. We designed and evaluated several carbons derived from polymer precursors with distinct pore texture that exhibit bimodal porosity in order to study and compare the effect of transport pores to the ionic liquid-based EDLC performance. This work provided insight into the synergistic influence of pore size distribution in determining the energy, power, voltage, thermal stability and lifetime of the electrochemical capacitor. The performance of the devices was evaluated using several techniques including floating voltage test, 3-electrode measurements, impedance spectroscopy, and constant current charge-discharge test. In this study, we demonstrated excellent voltage stability and good capacitance retention >90% for bimodal carbons with operating voltage up to 3.8 V.

In addition, the aforementioned activated carbon materials were used as the cathodes materials to fabricate Lithium-ion capacitors. In particular, bimodal activated carbon cathode in conjunction with intercrossed carbon onion anodes shows excellent power and energy density. Hence, we were able to fabricate a capacitor with energy and power density of 52 Wh/kg at 7.3 kW/kg, respectively. The device showed outstanding capacitance retention of 80% after 21000 cycles and remarkable energy efficiency of >90%. Additionally, the temperature stability of the device was tested ranging from room temperature to 60°C.

ES07.06.08
Performance Recovery in Degraded Carbon-Based Electrodes for Capacitive Deionization

Ion batteries, as promising energy storage device have been widely used in portable electronics, power tools, and electric vehicles due to their high electrochemical potential, superior energy density and long cycle life. Considering the relatively high theoretical capacity (170 mAh g⁻¹), cost effectiveness, long cycle life, good thermal stability, and environmental friendliness, lithium iron phosphate (LiFePO₄, LFP) has been demonstrated as a suitable cathode material for LIBs. However, key limitations of LFP are its low intrinsic electronic conductivity (10⁻¹⁰ to 10⁻¹⁴ S cm⁻¹) and limited lithium ion diffusion channel, leading to poor rate capabilities in LFP batteries. To overcome the drawbacks of LFP, an effective way to increase conductivity is combining LFP with conductive materials. Carbon-based materials such as graphite, carbon black, graphene, and carbon nanotubes are one of the best conductive materials for LFP. Especially, carbon quantum dots (CQDs), a new type of carbon-based material, are also of high interest due to their high surface area, low toxicity, cost-effectiveness, and controllable size. However, CQDs contain a high amount of sp³ carbon, resulting in low conductivity. In this work, we investigate high-quality graphitic CQDs with diameters below 10 nm for improving the conductivity of LFP. CQDs can play a key role in energy storage for improving the electrical conductivity and charge transfer reactions in LFP batteries, since increasing the ratio of sp² to sp³ carbon exhibits better electronic conductivity, resulting in enhanced battery performance. We report the synthesis of CQDs by a hydrothermal method at different reaction temperatures (160°C to 200°C) and times (60 min to 180 min) from organic materials. High-quality graphitic CQDs are produced by using a dehydrogenation reaction. The morphology and size distribution of CQDs were characterized by transmission electron microscopy (TEM). The chemical bonding states and sp³/sp² ratio of synthesized CQDs were characterized by Raman spectroscopy and X-ray photoelectron spectroscopy (XPS).

SESSION ES07.07: Carbon-Based Materials for Supercapacitors and Batteries

Performance Recovery in Degraded Carbon-Based Electrodes for Capacitive Deionization

Li and Steven T. Boles; The Hong Kong Polytechnic University, Hong Kong, China.

Limitations of capacitive deionization (CDI) technology and future commercialization efforts are intrinsically bound to electrode stability. In this work, novel regeneration methods are explored which mitigate previously explored degradation mechanisms. Electrode-exchange studies indicate that only the anode undergoes degradation over cycling, during which both the physical and chemical properties change evidently. In particular, acidic functional groups, which are derived from the reported oxygen-containing functional groups, are formed in the anode during cycling and these account for the potential of zero charge (PZC) change of the anode, thereby degrading the overall performance of the cell. Annealing treatment of aged electrodes suggests that low temperature thermal treatments can recover the degraded properties of anode and therefore regenerate the performance of the CDI cell. Thus, the lifetime of electrode can be prolonged by applying intermittent annealing treatments once the severe degradation becomes observable. The regeneration mechanism studies also offer insights into strategies for minimizing electrode degradation or in-situ regeneration as the technology gains momentum for future commercialization.

Asymmetric Flasklike/Bowl-Shaped Carbonaceous Nanoparticles Fabricated by the Synergistic Interaction Between Soft Template and Biomass

Chun H. Chen and Yong Wang; Zhejiang University, Hangzhou, China.

In the past two decades, an expanding library of new nanoparticiles have been developed, among which anisotropic ones, such as concave, janus, and patchy particles, have gained substantial focus due to their high complexity and nanoscale anisotropy in structure. These novel patterned nanoparticles may have possibly new or enhanced traits, and therefore could be highly desirable in both fundamental studies and potential applications in various fields, such as photonics, biomedical applications and building blocks for advanced materials and functional nanodevices.

In addition, most of the asymmetric hollow nanoparticles reported are limited to silica, polymer latex (e.g., polystyrene), or metal oxides, whose synthetic routes are lengthy and typically involve toxic organic polymers or caustic reagents. Because of the advantages of large voids, good biocompatibility, chemical inertness, and high conductivity, hollow-structured carbonaceous materials have been extensively investigated. However, they are mostly spherical in shape. Thus, preparing asymmetric carbonaceous structures remains a great challenge.

The soft template method is broadly applied to the fabrication of hollow-structured nanomaterials. However, due to the instability and the typical spherical shape of these soft templates, the resultant particles have a spherical morphology with a wide size distribution. Herein, we developed a sustainable route to fabricate asymmetric carbonaceous structures with a highly uniform morphology and a narrow size distribution using the soft template method.

The synthetic method can be further classified into two main categories: in-situ polymerization of precursors process forms the anisotropic structures and the ex-situ process such as post-treatment induces the anisotropy.

Scalable Pore Size Tuning Process for Seeking Better Cathode of Lithium-Ion Capacitor and Development of High-Performance Full Cell Device Through It

Jong Ho Won and Jeong Ku Kang; Applied Science Research Institute, Korea Advanced Institute of Science and Technology, Deajeon, Korea (the Republic of); Department of Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Deajeon, Korea (the Republic of).

With the development of the industry, the need for better energy storage devices that can be used in various devices continues to grow, but the pace at which practical alternatives are developed is very slow. Many prior studies have succeeded in increasing the energy density of lithium-ion batteries to a significant level, but they have not been able to lead to actual production due to battery instability, life problems, production and price issues. Many battery manufacturers currently faced the limit capacity of the cathode and are aiming to improve the energy density by developing an energy density of 430 mAh/g by mixing graphite with a high capacity active materials. However, in such a method, it is difficult to satisfy the high power density due to the difference in charge/discharge speed between the graphite and the high capacity active material. So, in reality, current access and pricing policies are not able to create a significant gap in the lithium ion battery platform. For this reason, the study of lithium-ion capacitors satisfying both energy density and power density has received much attention due to its high versatility. Lithium-ion capacitors can use conventional lithium-ion anodes and use carbon materials instead of heavy metal alloys as cathodes. Initial lithium-ion capacitor research was concentrated on an anode capable of high capacity such as a lithium-ion battery. In fact, the main factor that determines the capacity per mass/volume of lithium-ion capacitors is the capacity of the cathode. As the cathode of the lithium-ion capacitor, a porous carbon material which has been used as the electrode material of the electric double layer capacitor has been widely used. However, the electrode of the EDLC stores OH- ions, while the cathode of the...
lithium-ion capacitor should adsorb and store much larger ions such as PF6- ions. Thus, the electrode material originally used in the EDLC may be unsuitable for storing larger ions due to the small pore size. Here we have found improvements that can improve the capacity of lithium-ion capacitors. We intend to develop a cathode material for lithium-ion capacitors that can store larger ions such as PF6- ions in this work. We have developed seven cathode materials that composed of concentrate pores with a certain size using graphene and a template that is vaporized below 100 degrees of Celsius. The size of the pores ranges from less than 5 nm to 150 nm. Although the effects of the number of Angstrom pores have been addressed in the meantime, the impact of macro size pores has not been addressed in the lithium-ion capacitor research. We evaluated the capacity and characteristics of the developed cathode using PF6-, TFSI-, BF4-, CIO4-, and so on. In the experimental results, we confirmed that macro-sized pores have a profound effect on the adsorption and storage of ions and their obvious tendency. To put it briefly, the TFSI- and PF6- ions are significantly different in size, and thus the cathode with the highest capacity is different from each other, which is revealed by the tendency. Additionally, the full cell lithium-ion capacitor with developed cathodes and a commercial MCMB anode recorded the highest energy density of up to 145 Wh/kg and an energy density over 70 Wh/kg at a power density of 7200 W/kg. We have demonstrated the effect of macro-sized pores on the cathode of a lithium-ion capacitor and succeeded in developing a cathode material for an excellent lithium ion capacitor.

9:00 AM ES07.07.04
Laser Ablation and Laser Doping of Natural Carbonaceous for Electronics
Ximing Zang, Sam Iengsgoll, Nicolra Ferralis and Jeffrey C. Grossman; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Recycling natural carbonaceous feedstocks for alternative applications beyond burning would provide new opportunities for these materials. For example, new technologies using coal or coal-derived byproducts such as tar could be engineered to produce thin films for electronics with highly tunable electronic properties. In this work, we illustrate how laser ablation can be used to develop alternative applications for natural carbonaceous materials (coal, tar, pitch) in order to tailor their electronic, magnetic, and optical behavior. This approach enables the use of carbonaceous feedstocks in variety of applications at extremely low cost (i.e. coal at 0.05$/kg, tar at a negative cost). We will present recent work on applications ranging from transparent heater, transistors, and flexible/stretchable electrodes. Furthermore, the laser process can also be integrated into large scale, continuous manufacturing techniques.

9:15 AM ES07.07.05
Geometrically Controlled Nanofibrous Carbon for Functional Devices
Steven Knau, Samuel Brennan and Mark Atwater; Millersville University, Millersville, Pennsylvania, United States.

One of the most significant challenges in developing nanoscale carbon devices is efficiently and precisely producing the carbon. Two recent developments make this possible with carbon nanofibers. The first is a fast, low-cost method of producing carbon for catalyst deposition. A nontraditional processing route of mechanical alloying is used to produce unique catalytic materials that exhibit enhanced kinetics. The second advancement is the ability to create integrated devices in situ. This allows carbon nanofibers to be created in specifically designed geometries with controllable properties. These nanowoven structures can be made with densities as low as aerogels or much higher, allowing the fiber spacing to be varied and a high surface area to be compact and flexible. Carbon nanofibers have been proposed for applications ranging from supercapacitors to hydrogen storage to filtration. Multiscale control has been demonstrated by producing free-standing structures centimeters in scale, and carbon nanofibers have been integrated with traditional carbon materials to create unique hybrids. The methods and capabilities, as well as key device applications, are highlighted.

9:30 AM ES07.07.06
Highly Capacitative Activated Carbon Fiber Clothes for Wide-Voltage (2 V) High-Energy-Density Aqueous Symmetric Supercapacitors
Kwadwo A. Owusu and Liqiang Mai; Wuhan University of Technology, Wuhan, China.

Carbon aqueous symmetric supercapacitors are attractive supercapacitor devices owing to the low-cost and high conductivity of porous carbons. However, the limited capacitive charge storage process in carbon symmetric capacitors in comparison to pseudocapacitors or asymmetric supercapacitors severely limit the energy density. The only effective strategy to enhance the energy density of carbon aqueous symmetric supercapacitor is to extend the cell voltage beyond the thermodynamic stability of aqueous electrolytes (1.23 V).

Also, in recent studies, researchers have focused on preparing high-performance carbon electrodes from commercial carbon fiber clothes by activating the surface usually through chemical and electrochemical routes. However, it is still a major challenge to realize a comprehensive electrochemical performance of high capacitances, excellent rate capability, stability and wide operational potential windows in the activated carbon fiber clothes.

Herein, we successfully activated the surface of commercial carbon fiber clothes using a facile-one-step air calcination at 400 °C for 6 hours strategy to realize a remarkable improvement in the surface area, porosity, and electrochemical performance. The successful activation of carbon fiber clothes is fully confirmed through BET tests, SEM, TEM, Raman and contact angle measurement tests. Specifically, the activated carbon exhibits a 450-fold increase in specific surface area (615 m2/g) which can be of benefit to commercial devices.

9:45 AM ES07.07.07
Capacitance of Functionalized Carbon Powders in Monolayer and Macroscopic Ultracapacitor Electrode Configurations
Steven R. D'Souza; and Jingue Liu; 1 Materials Science and Engineering, Arizona State University, Tempe, Arizona, United States; 2Physics, Arizona State University, Tempe, Arizona, United States.

Ultracapacitors, due to their high specific power, long cycle life, and ability to bridge the power/energy gap between conventional capacitors and batteries/fuel cells, have attracted considerable attention for commercial applications such as plug-in hybrid electrical vehicles. Functionalization of activated carbon powders with oxygen and nitrogen redox-active functional groups plays a dual role in (i) incorporating pseudocapacitance along with double-layer capacitance and (ii) providing anchoring points for further incorporation of stable metal/metal oxide nanoparticles to improve the energy density of the ultracapacitors of interest. We report here the sequentially doped commercial scale, microporous activated carbon (AC) with various amounts of oxygen and nitrogen moieties, and fabrication of the functionalized AC into monolayer and macroscopic (5 μm and 100 μm thick respectively) carbon powder electrodes structures. A comparison of electrochemical performance metrics in acidic and alkaline electrolyte indicates that the monolayer electrode configuration yields a significantly enhanced capacitance (250 F/g) than that of the macroscopic electrode (135 F/g), primarily due to increased accessible specific surface area, reduced diffusion length of the electrolyte molecules and reduction of contact resistance. While the behavior of pseudocapacitance and double-layer capacitance was clearly manifested in the monolayer electrode configuration, the macroscopic electrode configuration did not display these characteristics, presumably due to a large potential gradient. We have demonstrated that the capacitance of AC based ultracapacitors can be significantly enhanced by incorporating functional groups within the interior pores of the AC powders, which can be of benefit to commercial devices.

10:00 AM BREAK
All-solid-state batteries (ASSBs) with ceramic-based solid-state electrolytes (SSEs) and lithium metal anode enable high safety and high energy density that are inaccessible with conventional lithium-ion batteries. However, the large interfacial resistance between Li and SSEs has significantly hindered the development of ASSBs. Take Li/garnet SSE system as an example, garnet presents “lithiophobic” surface and poor contact with Li metal anode. To date, several groups have proved that coating a layer of “lithiophilic” material on garnet can improve the Li/garnet contact by the interfacial reaction. Here, we report a new strategy to solve the interface problem by adding carbonaceous materials into Li metal. The lithium-carbon (Li-C) composite shows dramatic change in wettability with garnet due the increased viscosity. The carbon can be graphite, carbon nanotube, graphene or their mixture. An intimate Li-C/garnet interface have been demonstrated and delivered a much smaller interfacial resistance compare to pure Li/garnet.

11:00 AM ES07.07.09
Design of Nanohybrid Materials to Enable Efficient Junctions for Strong Electrolyte Binding in Ionic Liquid-Based Supercapacitors Feili Lai, Martin Oschatz and Markus Antonietti; Max Planck Institute of Colloids and Interfaces, Potsdam, Germany.

Due to the temporal, fluctuating character of sustainable energy and the increasing use of rechargeable electronic devices, there is an urgent need for the development of more efficient electrochemical energy storage technologies. Electrical double-layer capacitors (also known as supercapacitors) have become attractive due to their rapid charge-discharge rate, high power density, long lifetimes, remarkably low price base, and potential sustainability of the involved materials. The use of ionic liquids (ILs) as electrolytes with a wide electrochemical stability window is the most promising strategy to improve the poor energy density of supercapacitors but the actual energy storage mechanism in absence of a solvent in the electrolyte remains poorly understood. Charge storage in a compression double-layer is not possible in ILs and thus new energy storage terms such as order-disorder transitions or solvation-desolvation processes likely play a rather important role. It will be shown that strong metal oxide-support interaction is crucial to activate high energy storage modes of carbon-supported hybrid electrodes in IL-based supercapacitors.

11:15 AM ES07.07.10
Designed N/O/S Tri-Doped Carbons for CO$_2$ Capture and Supercapacitors Zhihong Tian$^1$,$^2$, Feili Lai$^2$, Martin Oschatz$^2$, Shaokui Cao$^2$ and Markus Antonietti$^2$; $^1$School of Materials Science and Engineering, Zhengzhou University, Zhengzhou, China; $^2$Colloids Chemistry, Max Planck Institute of Colloids and Interfaces, Potsdam, Germany.

Porous functional carbons stand out for their special physical and chemical properties, including high chemical stability, large surface area, high porosity and good conductivity, and have been regarded as the most promising candidates for gas separation, energy storage and electrocatalysis. Recently, one sees rising attention for the development of designer carbons with controlled structure and local material composition, due to this enormous potential in practical application. However, it is still difficult to achieve preconceived carbon structures, which is ascribed to the irregular nature of current synthetic methods. Consequently, we strongly need approaches to circumvent this limitation, in which one possible way is to use the suitable precursors with “encoded information”. Here we present a new class of well-defined C$_{10}$N$_2$S$_2$ carbons that have both high content of N/O/S heteroatoms and large specific surface area (up to 1704 m$^2$ g$^{-1}$), which can be efficiently synthesized by the simple condensation using gallic acid and thiourea as the building blocks. To be noted, as a multi-functionally inexpensive natural chemical, gallic acid is well known to decarboxylate into pyrogallol at higher temperatures, so that the carboxylic acid unit can be regarded as a “protecting/leaving group” that enables a controlled substitution chemistry to realize the high structural definition. In this synthesis, thiourea is the direct source for both nitrogen and sulphur after decomposing at 180 $^\circ$C.

11:30 AM ES07.07.11
Improving the Performance of Lignin-Derived Supercapacitor Electrode by Inducing Lignin Crosslinking and Controlling its Derived Carbon’s Morphology Hoi Chun Hu$^{1,2}$, Ngoc Nguyen$^1$ and Amit Naskar$^1$; $^1$Oak Ridge National Lab, Oak Ridge, Tennessee, United States; $^2$The University of Tennessee, Knoxville, Knoxville, Tennessee, United States.

Supercapacitor, a promising energy storage solution of the future, can meet the demand for our escalating energy storage needs for electric vehicles and the implementation of renewable energy. However, high cost and low energy density are preventing its wider adoption.

Within a supercapacitor device, the carbon electrodes are the costliest material, contributing up to half of a device’s raw material cost. Efforts in finding an alternative supercapacitor electrode carbon are needed to minimize its cost. Lignin, an underutilized renewable industrial waste and a major component in plants, can be the alternative supercapacitor electrode carbon precursor. It has been estimated that 50 million tons of lignin are produced annually in the US just from the paper and pulp industry alone. Because of lignin’s structural complexity and hyperbranching nature, researchers struggle to design lignin-derived carbon with a controllable morphology. Currently, lignin is mostly burned for heat and electricity.

In this study, we utilized the abundant thermal sensitive linkages present on lignin. By fine-tuning their crosslinking via a simple thermal stabilization step in air along with a 10% acrylonitrile-butadiene rubber (NBR) dope, the derived carbon’s porosity and morphology can be controlled. Because a supercapacitor’s performance directly correlates to the electrode carbon’s porosity, when made into supercapacitor electrode, the resulting lignin-derived carbon capacitance can be improved.

The increased degree of lignin and NBR-doped lignin crosslinking was first revealed from differential scanning calorimetry and thermogravimetric analysis by their thermal stability. After a one-step carbonization and chemical activation with potassium hydroxide, we found that NBR doping prior to carbonization and activation-induced macroporosity of the carbon. When porosity was further studied with nitrogen adsorption-desorption experiments, it was revealed that NBR doping improved lignin-derived carbon from 1750 m$^2$ g$^{-1}$ to 2120 m$^2$ g$^{-1}$ due to NBR templating. Thermal stabilization in air, however, reduced carbon’s surface area to 1585 m$^2$ g$^{-1}$. We hypothesized the drop was due to the change in lignin’s molecular weight and the shrinkage force induced from the additional crosslinking.

When the lignin-derived carbon was made into supercapacitor electrodes, as expected from the improved porosity, NBR doping improved lignin-derived carbon’s capacitance from 175 F g$^{-1}$ to 215 F g$^{-1}$. On the contrary, thermally stabilized lignin displayed a reduction of capacitance to 154 F g$^{-1}$. The best performing NBR-doped lignin-derived carbon electrode was then further tested with its long-term capacitance cyclability by cycling for 5000 cycles and showed an impressive 100% capacitance retention, suggesting a desirable electrochemical reversibility and stability. The 22% improvement in lignin-derived carbon’s porosity and capacitance demonstrated the feasibility of using simple NBR doping of lignin for an alternative supercapacitor electrode carbon source.
Graphite dual-ion batteries represent a potential battery concept for large-scale stationary storage of electricity, especially when constructed free of lithium and other chemical elements with limited natural reserves. Owing to their non-rocking-chair operation mechanism, however, the practical deployment of graphite dual-ion batteries is inherently limited by the need for large quantities of electrolyte solutions as reservoirs of all ions that are needed for complete charge and discharge of the electrodes. In this work, we will provide a balanced analysis of the overall cell-level energy density of graphite dual-ion batteries as a function of electrolyte concentration and cathodic capacity of graphite. We will discuss also other issues associated with this technology, one being the low oxidative stability of most metallic current collectors at high potentials of 4.5-5 V vs. Li+/Li. Finally, we will present a novel lithium-free graphite dual-ion battery utilizing a highly concentrated electrolyte solution of 5 M potassium bis(3-fluorosulfonyl)imide in alkyl carbonates. The resultant battery offers an energy density of 207 Wh kg\(^{-1}\), along with a high energy efficiency of 89% and an average discharge voltage of 4.7 V.

SESSION ES07.08: Carbon-Based Materials in Batteries

Thursday Afternoon, April 25, 2019
PCC North, 100 Level, Room 127 A

1:30 PM *ES07.08.01

On the Role of Heteroatom Doping of Carbon-Based Catalysts for Water Splitting Reactions and the Oxygen Reduction Reaction
Ulrike Kramm, Ali Shahraei, Natalsha Weidler and Markus Kübler; Catalysts and Electrocatlysts, Department of Materials and Earth Sciences and Department of Chemistry, TU Darmstadt, Darmstadt, Germany.

Carbon-based catalysts play an important role in energy conversion devices such as fuel cells, metal air batteries and electrolysers. The group of Me-N-C catalysts (with molecular MeN\(_2\) sites) is formed by a high-temperature pyrolysis of metal, nitrogen and carbon precursors. Sulfur addition can be used to increase the density of MeN\(_2\) sites [1-3]. But sulfide species might also play an important role as active sites for some catalytic reactions, as shown for the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER).

In addition to this, in our recent work we showed that the integration of carboxylic groups in close vicinity to active sites can be used to tune the catalytic activity [4-5]. In this work, we will present different strategies of multi heteroatom doping for tuning the OER activity and stability of cobalt-based catalysts [6] as well as ORR activity and selectivity of Me-N-C catalysts. It will be shown that with the integration of dopants all three parameters, namely activity, selectivity and stability, can be tuned to optimize the catalysts for the desired applications.

Disordered Carbon Anodes for Na-Ion Battery and Their Sodium Storage Mechanism
Yaxiang Lu, Yunming Li, Chenglong Zhao, Yuheng Zheng, Xingguo Qi, Xiaohui Rong, Hong Li, Xuejie Huang, Liquan Chen and Yong-Sheng Hu; Key Laboratory for Renewable Energy, Institute of Physics, Chinese Academy of Sciences, Chinese Academy of Sciences, Beijing, China.

Na-ion batteries have been recently reconsidered for storing the electricity from renewable energy due to the abundant sodium resources and low cost. Furthermore, we can use Na\(^+\) ions as the charge carrier to explore new chemistry and new materials to further decrease the cost. For example, Na cannot form the alloy with Al, therefore Al foil can be used as the current collector for the anode without the overdischarge problem. Among all available anode candidates, disordered carbon still shows the best overall performance in terms of capacity, cycling stability and cost. In this talk, I will present several superior low cost disordered carbon anodes made from pitch, renewable biomass and coal. In particular, some carbon exhibits Na storage capacity of 400 mAh/g with a high Coulombic efficiency. I will also discuss their Na storage mechanism. Then, prototype Na-ion pouch cells will be presented. Finally, the first mini-electric vehicle powered by Na-ion batteries was demonstrated in the world.

2:30 PM *ES07.08.03

Dual-Functional, Tunable, Nitrogen-Doped Carbon for High Performance Li-S Full Cell
Hongli Zhu; Mechanical and Industrial Engineering, Northeastern University, Boston, Massachusetts, United States.

Due to the high energy density and abundance of sulfur, lithium-sulfur (Li-S) batteries are attracting broad interest. However, several hurdles need to be tackled before commercialization. For example, the batteries experience the polysulfide shuttle effect in cathode and dendrite growth in the lithium metal anode. Herein, for the first time, a mesoporous carbon sphere (MCS) that simultaneously boosts the performance of the sulfur cathode and the metallic lithium anode was designed in this work. The MCS homogenizes the flux of lithium ions and inhibits the growth of lithium dendrites, due to its high-surface-area honeycomb structure and abundance of nitrogen sites. Upon covering multiple mesoporous carbon spheres (CMCS) with a layer of amorphous carbon, individual carbon cage encapsulated sulfured inside. This reduced the polysulfide shuttle, which improved the cycle-stability of the Li-S battery. As a result, the Li@MCS cell exhibited a small overpotential of 29 mV and long lifespan of 350 h under the current density of 1 mA cm\(^{-2}\) for the cycling performance. Meanwhile, the Sci@CMCS maintained 200 cycles from the capacities of 411 mAh g\(^{-1}\) to 400 mAh g\(^{-1}\) at a current density of 2 C (3350 mA
H. Tabassum, Asif Mahmood, approach for the implementation and the development of a new bottom-up technique for hierarchical hybrid nanostructured electrodes based on vertically aligned carbon nanotubes (CNTs) composite has attracted considerable attention due to LTC’s high reversible capacity and physical and chemical merits of CNTs, which supplement LTC’s structural instability and low electrical conductivity. Despite the recent advances in LTC-CNT electrodes, there are still remaining critical issues limiting commercialization. The most difficult one is controlling the state of CNTs in LTC since the aggregation of CNTs resulted in undesirable structure and increased electrical resistance. These aggregated CNTs also lower the surface coverage of CNTs within the LTC, interrupting the electrons on CNTs to meet ions in the LTC and consequently decreasing the accessible redox sites. Therefore it is essential to control the aggregation of CNTs in materials to fully utilize the merits of CNTs and guarantee the accessible redox sites, which is denoted as maximizing “triple junction” where ions and electrons meet, suggesting that the origin of the high electrochemical performance is the perfect harmony of ion, electron, and redox sites together.

Herein, N-doped hierarchical porous carbon with highly aligned CNTs was prepared by co-polymer single nozzle electrosprining, carbonization, and KOH activation. Densely and uniaxially packed CNTs not only improve the electrical conductivity but also act as a structural scaffold, enhancing electrochemical performance of the anode. A partially graphitized N-doped LTC shell was designed to expand the redox sites from the surface of the material to the whole material by having a rapid ion accessible pore network and abundant redox sites. This material exhibited a superior reversible capacity of 1814.3 mAh g\(^{-1}\) at 50 mA g\(^{-1}\) and 850.1 mAh g\(^{-1}\) at 1000 mA g\(^{-1}\). Furthermore, comparative electrochemical analysis enabled that the use of CNTs, template polymer and KOH activation have their own effect on this material’s superior electrochemical results including rate capability, cycle stability and high reversible capacity. This study not only analyze the synergetic roles between uniaxially packed CNTs and LTC, but also suggest the rational design of the ideal structure of CNT-based carbonaceous 1D anode material to maximize triple junction.

**Rational Design of 1D Partially Graphitized Nitrogen Doped Porous Carbon with Highly Aligned Carbon Nanotubes for Lithium-Ion Batteries**

Hanse In Cho, Yo Chan Jeong and Chong Rae Park; Seoul National University, Seoul, Korea (the Republic of).

The demand for high performance energy storage systems, such as electrical vehicles and electric storage stations has increased dramatically. Low temperature carbon (LTC) prepared at low temperatures (~1200 °C) and carbon nanotubes (CNTs) composite has attracted considerable attention due to LTC’s high reversible capacity and physical and chemical merits of CNTs, which supplement LTC’s structural instability and low electrical conductivity. Despite the recent advances in LTC-CNT electrodes, there are still remaining critical issues limiting commercialization. The most difficult one is controlling the state of CNTs in LTC since the aggregation of CNTs resulted in undesirable structure and increased electrical resistance. These aggregated CNTs also lower the surface coverage of CNTs within the LTC, interrupting the electrons on CNTs to meet ions in the LTC and consequently decreasing the accessible redox sites. Therefore it is essential to control the aggregation of CNTs in materials to fully utilize the merits of CNTs and guarantee the accessible redox sites, which is denoted as maximizing “triple junction” where ions and electrons meet, suggesting that the origin of the high electrochemical performance is the perfect harmony of ion, electron, and redox sites together.

Herein, N-doped hierarchical porous carbon with highly aligned CNTs was prepared by co-polymer single nozzle electrosprining, carbonization, and KOH activation. Densely and uniaxially packed CNTs not only improve the electrical conductivity but also act as a structural scaffold, enhancing electrochemical performance of the anode. A partially graphitized N-doped LTC shell was designed to expand the redox sites from the surface of the material to the whole material by having a rapid ion accessible pore network and abundant redox sites. This material exhibited a superior reversible capacity of 1814.3 mAh g\(^{-1}\) at 50 mA g\(^{-1}\) and 850.1 mAh g\(^{-1}\) at 1000 mA g\(^{-1}\). Furthermore, comparative electrochemical analysis enabled that the use of CNTs, template polymer and KOH activation have their own effect on this material’s superior electrochemical results including rate capability, cycle stability and high reversible capacity. This study not only analyze the synergetic roles between uniaxially packed CNTs and LTC, but also suggest the rational design of the ideal structure of CNT-based carbonaceous 1D anode material to maximize triple junction.

**New Hybrid Nano-Architecture of Li/Si Electrodes for Rechargeable Li-Ion Batteries**

Mariappan P. Paranthaman; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Novel Carbon Electrodes for Next Generation Intercalation Batteries

Carbon has recently been recovered from discarded tires and demonstrated a high capacity, higher rate capability and the potential to replace commercial graphite as an active anode material in lithium-ion batteries. The tailored morphology of the tire-derived carbon using a sulfonation process followed by pyrolysis yielded a high-quality carbon and the applicability of these hard carbons was demonstrated in several intercalation batteries including lithium-ion batteries, sodium-ion batteries, and potassium-ion batteries. We will report on our recent neutron studies on the surface chemistry of the carbon material, vibrational spectroscopy of the molecular structure, chemical bonding such as C–H bonding, and intermolecular interactions of the tire-derived carbon materials. Commercial graphite and unmodified/non-functionalized tire-derived carbon are also used for comparison. A capacity of over 200 mAh g\(^{-1}\) was achieved for carbon electrodes with Na-ion intercalation batteries. It is also possible to achieve even enhanced capacities by ball milling carbon with Si for Na-ion batteries. We will also report the current status of the tire-derived carbon composite powder scale up efforts and its use in energy storage applications.

**Novel Carbon Electrodes for Next Generation Intercalation Batteries**

Marjan Abadi; Imperial College London, UK; Jesus Martin; The University of Reading, UK; and Costel Cojocaru; 1Ecole Polytechnique, Palaiseau, France; 2CNRS, Palaiseau, France.

Today’s lithium-ion battery is the most maturing and widely used technology in the market. The optimization of the storage properties of batteries requires either the search for new materials offering specific capacities which are superior to current materials either the miniaturization of electrode materials. Incorporation of nanomaterials with high specific capacities has proven to be an effective method to improve the electrochemical performance of the lithium-ion battery. The present work explores a promising and original approach for the implementation and the development of a new bottom-up technique for hierarchical hybrid nanostructured electrodes based on vertically aligned carbon nanotubes (VACNTs) decorated with nanoparticles (NPs), i.e. NPs@VACNTs. The non-metallic lithium battery is composed of Li/Si@VACNTs as positive electrode and Si@VACNTs as negative electrode. This battery provides a theoretical energy of 1500 Wh kg\(^{-1}\), which is four times more than the theoretical energy of existing lithium-ion batteries based on LiCoO\(_2\) and graphite (~ 36 Wh kg\(^{-1}\)). Moreover, the nanostructured design of the two electrodes overcomes the problems associated with the use of sulfur compounds and silicon in lithium-ion batteries, including poor electrical conductivity and large volumetric variations. [1-2] This hierarchical hybrid nanostructured electrodes battery with low life and low cost shows a superior capacity of 2 mAh cm\(^{-2}\) based on the mass of the active material in the electrode.

**Metal Organic Framework Derived Metal Species Encapsulated into BCN Nanotubes for Energy Conversion and Storage Devices**

Hassina Tabassum and Zou Ruqiang; Peking University, Beijing, China.

Metal organic frameworks derived metal species have received great attention for boosting the performance of lithium-ion batteries because of their obvious advantages in solving the problems associated with large volume change, low conductivity, and short diffusion path for Li\(^{+}\) ion transport. A high concentration of B–N bonds in a carbon framework whereas the one with a lower molecular weight leads to B, N co-doped graphene nanotubes (BCN nanotubes) with segregated B–C and N–C bonds. Therefore, a universal strategy for making metal species like hollow transition metal oxide, metal phosphide, metal sulfide nanoparticles (NPs) encapsulated into BCN nanotubes through combining pyrolysis with extended treatment is adopted. The as-made products exhibit best performance for lithium-ion storage, electrocatalysts and supercapacitor devices. In this study, we tracked and studied the evolution of the structural defects with increasing accumulated metal species in the BCN nanotubes for electrocatalyst and lithium ion batteries. These results will help to efficiently optimized the best electrocatalysts and electrodes for lithium ion batteries.

Dual Template-Assisted Fabrication of High-Surface-Area Hollow Carbon Nanospheres for Enhanced Energy Storage Mingei Chen, Zhe Su and Donghui Long; East
Hollow carbon spheres (HCSs) with diverse shell structures and inner space have attracted much attention owing to their wide applications in different fields such as adsorption, catalysis, energy storage, etc. Up to now, extensive synthetic strategies have been developed to obtain HCSs. Herein, we propose a dual-template assisted route, using volatile alkane as hollow-forming soft template and organosilane as in situ hard template for the first time. The obtained HCSs possess carefully controlled characteristics, including tailored outer diameters (0.5–1 μm), controlled shell thickness (50–100 nm), specific surface area (1500–2500 m² g⁻¹), and pore volume (1.5–2.7 cm³ g⁻¹). Adjustable pore structure of HCSs can realize function-oriented applications. When used as the electrode materials for supercapacitors, hierarchically porous HCSs demonstrate an energy density of 23 Wh kg⁻¹ at a high power density of 25 kW kg⁻¹. In addition, these HCSs can serve as sulfur host for Li-S battery, resulting in superior long-cycle stability and rate performance.

Moreover, the absorber can maintain its superior performance at 1000 K under air and 1173 K under vacuum, respectively. To the best of our knowledge, this performance achieved simultaneously when coated on various IR reflectors, including Au, stainless steel, Al, and TiN. Particularly, the absorbers with TiN reflectors exhibited a high solar spin-coating a perhydropolysilazane (PHPS) solution, acted as the protection and anti-reflection coating. Both full-spectrum sunlight absorption and strong IR reflection were absorption of sunlight around their resonance wavelengths. Due to the in-plane plasmonic coupling of close-packed TiN nanoparticles, the resonance wavelengths were able to red- and controllable sunlight absorption coating using well-dispersed colloidal TiN nanoparticles (20-80 nm). The absorption bandwidth, i.e., the cut-off wavelength, can be tuned been proven to exhibit stronger optical losses in the visible-near-infrared (NIR) range compared to traditional metallic plasmonic materials. In this work, we constructed a uniform Titanium nitride (TiN), as an emerging plasmonic ceramic material, offers tunable plasmonic properties, as well as excellent thermal and chemical stability. TiN nanoparticles have development of high-performance solution-processed selective absorbers is urgently demanded.

Concentrating solar power (CSP) plants and future solar thermochemical processes require high-performance solar absorber coating with suitable photothermal properties as well as high-temperature stability. Traditional coating materials are often lacking some of the desirable properties or are difficult to be tailored to meet various stringent requirements. While various nanostructures, including particles and multilayers, have been studied, they are often not stable at high temperature. Over the last few years, we have been developing spinel metal oxide nanostructures with tailored photothermal properties for solar absorber coating applications. These oxides have high melting points and are chemically stoichiometric, so they are expected to be stable in air at high temperature. First, we studied nanostructures of Cu(I) containing spinel oxide nanoparticles, including CuO-Cr$_2$O$_3$, Cu$_2$O-Cr$_2$O$_3$, Mn$_2$O$_4$, CuFeMnO$_6$, etc. These particles were made from either bottom-up hydrothermal or top-down ceramic processing. Coatings made of these Cu spinel oxide nanoparticles exhibit higher solar absorptance and more importantly, better high-temperature stability in air over an extended period of testing time (2000 hours), compared to the state-of-the-art coating Pyromark. The influence of chemical compositions, particle size, coating conditions on the optical properties will be discussed. Thermal stabilities are studied via photothermal property measurement and structural analysis. Second, we explored new morphologies of metal oxide nanostructures, including nano-needles and nano-flowers. These unique structures can possess record-high solar absorptance (over 99%) even with very thin coating, owing to the strong light trapping effect. With suitable chemical compositions and surface passivation, the nanostructures can maintain their structural integrity at high temperature in air. The structures can be further tailored to show vastly different infrared properties. Finally, we showed that the recent high-entropy alloy concept can be applied to the spinel metal oxides to synthesize entropy-stabilized oxides, which may provide a new route to achieve unprecedented high-temperature stability for future solar-thermal coatings. Our studies demonstrate that nanostructures of spinel metal oxides offer tremendous opportunities for future high-temperature solar-thermal coating applications, by providing both high performance and excellent high-temperature stability.

Our studies demonstrate that nanostructures of spinel metal oxides offer tremendous opportunities for future high-temperature solar-thermal coating applications, by providing both high performance and excellent high-temperature stability.

Developing solar absorber coatings that can absorb sunlight while enduring high temperatures is a challenging task, but they can be successfully synthesized with careful engineering. Our team has recently designed an ultra-absorptive array of cobalt oxide nanoneedles. This cobalt oxide nanoneedle array is spectrally selective and its nanostructure increases the optical pathway of light, allowing the coating to possess over 99% solar absorptance; however, it is fragile, and degrades at high temperatures. Through altering the chemical composition and adding passivating layers, the nanoneedle maintains its distinctive shape, even after long-term high-temperature annealing. In this talk, we will also analyze the solar-to-thermal energy conversion efficiency before and after long-term thermal annealing.

Concentrating solar power (CSP), as a well-known high-temperature solar-thermal technology, is a promising approach to harvesting solar energy due to its efficient utilization of full-spectrum sunlight, and high availability in energy storage. To further pursue higher Carnot efficiency and greater cost reduction, next-generation CSP plants operating at higher temperatures (≥1000°C) are widely accepted as a promising approach. A selective solar absorber, as a critical component in CSP systems, is required to maintain high sun light absorption and low absorption (i.e., emission) beyond a cut-off wavelength in the infrared region to avoid thermal re-radiation even at elevated temperatures. To date, all the state-of-the-art selective absorbers such as cermet and photonic crystals with superior performance (i.e., high selectivity and great thermal stability) were manufactured with complicated and expensive high-vacuum micro-fabrication or nano-fabrication techniques, leading to high costs and challenges for largescale deployment. Therefore, the development of high-performance solution-processed selective absorbers is urgently demanded.

Titanium nitride (TiN), as an emerging plasmonic ceramic material, offers tunable plasmonic properties, as well as excellent thermal and chemical stability. TiN nanoparticles have been proven to exhibit stronger optical losses in the visible-near-infrared (NIR) range compared to traditional metallic plasmonic materials. In this work, we constructed a uniform and controllable sunlight absorption coating using well-dispersed colloidal TiN nanoparticles (20-80 nm). The absorption bandwidth, i.e., the cut-off wavelength, can be tuned through rationally controlling the concentration of the TiN colloid and the spinning speed. The excited plasmonic resonance of TiN nanoparticles resulted in highly selective absorption of sunlight around their resonance wavelengths. Due to the in-plane plasmonic coupling of close-packed TiN nanoparticles, the resonance wavelengths were able to red-shift to NIR range. As a result, selective sunlight absorption can be attained in the UV-visible-NIR range below the cut-off wavelength. An amorphous SiO$_2$ layer, prepared by spin-coating a perhydropolysilazane (PHPS) solution, acted as the protection and anti-reflection coating. Both full-spectrum sunlight absorption and strong IR reflection were achieved simultaneously when coated on various IR reflectors, including Au, stainless steel, Al, and TiN. Particularly, the absorbers with TiN reflectors exhibited a high solar absorptance of 93.5% and a low IR emittance of 21.1% at an elevated temperature of 1000 K, producing a solar-thermal energy conversion efficiency of 81.3% under 100 suns. Moreover, the absorber can maintain its superior performance at 1000 K under air and 1173 K under vacuum, respectively. To the best of our knowledge, this performance
surpasses or equals those of state-of-the-art selective absorbers fabricated by high-vacuum micro and nano-fabrication techniques. The high efficiency and great thermal stability achieved in such low-cost solution-processed solar absorbers will benefit the development of next-generation CSP plants by providing large cost reductions in mass-production.

Black Oxides in the Spinel Group—Promising Materials for Highly Durable Solar Selective CSP Absorber Coatings Andreas Schuler; Solar Energy and Building Physics Laboratory, Swiss Federal Institute of Technology EPFL, Lausanne, Switzerland.

In this presentation I will review some recent developments in the field of black spinel-type oxides for solar selective absorber coatings. The interesting optical properties of ternary and quaternary spinel-type oxides allow for manifold interband transitions, yielding a dark or even black appearance of many spinel oxides, which show remarkable stability at elevated temperature in air and vacuum. In order to overcome the barrier of initial investment cost, wet-chemical derived solar absorber coatings might be especially attractive. By sol-gel dip-coating and subsequent thermal annealing, we produced multilayered mixed Cu-Co-Mn-Si oxide [1,2]. After optimization of the multilayer design, a solar absorbance of 0.95 and a thermal emissivity of 0.12 at 100 °C have been achieved. For the energy-efficient thermal annealing of 2 m long receiver tubes, a special induction heating process has been developed. On highly infrared-reflecting substrates, spinel oxide based layer stacks can be very selective. For a three layer configuration composed of a CuMnO thin film and two consecutive antireflective coatings, FeMnCuO4 and SiO2 on aluminum substrates, a solar absorbance of 0.957 and a thermal emissance of 0.290 were measured at 100 °C achieved [3]. Aiming at operation temperatures of up to 550 °C, the absorptance of the multilayer structure coated through this way increased from 0.82 to 0.915 and the thermal emissance decreased from 0.434 to 0.290. Defects on the surface of WC-Co coatings were gradually reduced, the multilayered film stacks were compact and the surface roughness was reduced [4]. Copper-oxide spinel coatings can alternatively be deposited by spray-coating. Black metal oxide nanoparticles comprising copper-cobalt oxides (CuCoO4) and copper-manganese oxides (CuMnO4) were synthesized for solar absorptive potential by hydrothermal syntheses. To extend the spectrally-selective absorbance capability, the coating surfaces are geometrically-textured, using sacrificial polymer beads that are jointly implemented in the spray-coating process [5]. Also crystalline CuNiCo3Ox films have interesting optical properties. By optimizing the concentration of the solution, withdrawal speed and annealing temperature, a solar absorptance of 0.91 and an emittance of 0.14 were achieved for a single layer coating with composite oxide formation [6]. The remarkable stability at elevated temperatures in air and vacuum makes such black spinel oxide coatings an interesting candidate for solar applications involving concentrated solar radiation, such as the generation of solar electricity (concentrated solar power CSP), industrial process heating and solar cooling.

SESSION ES08.03: Corrosion Mitigation in CSP Plants
Session Chairs: Elena Guillen and Andreas Schuler
Thursday Morning, April 25, 2019
PCC North, 100 Level, Room 123

8:45 AM ES08.03.01

Over the past seven years, the US Department of Energy has developed a framework where chloride based salt eutectics can serve as the heat transfer fluid and thermal energy storage medium in concentrating solar power (CSP) plants at a cost competitive with traditional power plants in the United States. However, catastrophic corrosion remains the highest risk to this framework. A series of completed and ongoing research and development initiatives have significantly evolved the understanding of corrosion control in chloride salt systems. These have brought to focus viable corrosion mitigation strategies and system requirements for an operable power plant at the megawatt scale. This work presents these integrated results and describes a path from present day understanding into the next generation of CSP plants.

9:00 AM *ES08.03.02

The United States Department of Energy (DOE) launched the SunShot Initiative in 2011 to achieve high thermal-to-electric conversion efficiency and to make solar technologies cost-competitive with conventional electric power generation. The sun’s energy is captured and stored in the form of heat in concentrating solar power (CSP) technologies. By using low cost materials that are stable for decades, CSP with the help of thermal energy storage (TES) systems is able to deliver renewable energy while providing important capacity, reliability and stability attributes to the grid, thereby enabling increased penetration of variable renewable electricity technologies. Current CSP systems are integrated with conventional steam-Rankine power cycles. Today’s advanced technologies are power tower with 2-tank molten-salt TES, delivering thermal energy at up to 655°C using molten nitrates. Next generation CSP (Gen3 CSP) are targeting higher efficiencies by integrating the power tower with the TES to a supercritical CO2 (scCO2) Brayton power cycle. To achieve this integration, Gen3 CSP needs to operate at temperatures above 550°C requiring high-temperature advanced fluids in the range of 550°C to 750°C. Because nitrates are unstable at temperatures above 60°C, new salts are required. These high-temperature salts, such as chlorides, need to compatible with containment materials. To meet the cost of production of electricity, cost targets must be met using alloys and materials with acceptable corrosion and mechanical strength. The selected heat transfer fluid (HTF) candidates based on cost are chlorides, but they introduce a set of technological and engineering challenges because of their very corrosive characteristics for typical materials. Corrosion mitigation approaches are been investigated to control material’s degradation below 20 μm/year. Corrosion in molten chlorides is being controlled in atmospheres with the absence of oxygen and water. Catastrophic mechanical failure will occur if these impurities are present because intergranular attack will occur. Current studies are focused on: 1) redox potential control using active metals in atmospheres with no-oxygen/water; 2) surface treatments to allow passivation, diffusion coatings; 3) coatings such as nickel-based (NiCoCrAlY,Ta,Ha,Si); and 4) aluma forming alloys (AFA). Untreated In800H and 3108S alloys corrode rapidly (~2,500 to 4,500 μm/year) in molten chlorides, but when coated the lowest corrosion rate of 190 μm/year is obtained. Because the coatings were pre-oxidized before molten salt immersion, metallographic characterization of showed that the formation of a uniform thin alumina scale. The presence of this layer presumably reduced the corrosion of the alloy in the molten chloride in an atmosphere containing oxygen and water as impurities. Electrochemical impedance spectroscopy tests and metallographic characterization showed that the best performing AFA in molten chlorides without controlled atmosphere was Inconel 702 pre-oxidized in zero air (ZA) at 1045 °C, due to the formation of protective, dense and continuous alumina layers. When using an argon atmosphere during corrosion evaluations, these layers were unstable. AFAs to contain molten chlorides in air are promising for Gen3 CSP applications because protective alumina layers were stable and able to grow from 5 μm (before immersion) to 13 μm (after 185 h of immersion) in the oxygen-containing atmosphere. The use of these alloys could be commercially feasible and cost-effective because of the possibility of using oxygen-contaminating atmospheres instead of keeping enclosed systems with inert atmospheres to protect alloys from corrosion in molten chlorides.

9:30 AM ES08.03.03
Nickel-Aluminide Based Anticorrosion Coatings Prepared by Plasma Spray for Concentrating Solar Power Applications Sarah Yasin; Jose I. Endrino1, Elena Guillen2, Ramon Escobar Galindo3 and Adrianus I. Aria1; Cranfield University, Cranfield, United Kingdom; 2Profactor GmbH, Steyr, Austria; 3Universidad de Cadiz, Cadiz, Spain.

The use of solar energy for power generation provides an efficient sustainable energy solution. Among a number of technologies developed for power generation using solar energy, concentrating solar power (CSP) is encouraging because of the capability of thermal energy storage that makes it possible for the 24-hour energy production. Although the use of molten salts as heat transfer fluid and thermal storage in CSP has various advantages, they have a major disadvantage as they make the component systems highly susceptible to corrosion. Different approaches have been adopted to suppress hot corrosion including the use of high alloy steels and the use of high purity molten salts; both contribute to a substantial increase in construction and operating costs.

In this study, we investigate the use of protective coatings to enhance the corrosion resistance of the component systems against molten salts at an elevated temperature. Nickel aluminide coatings are deposited using highly scalable plasma spray technique with few different deposition parameters to obtain a variety of stoichiometries and morphologies. A low value of porosity is anticipated for corrosion resistance along with good adhesion with substrate, minimum unmelted-particles and adequate lamellar structure for optimum coatings. Optimized coatings deposited on SS347 and SS304 stainless steel substrates were exposed to a mixture of NaNO3 / KNO3 molten salts at 600°C for up to 2500 hours. The uncoated
substrates were also included in the test for comparison. After the test, the samples were characterised by electron microscopy, energy dispersive x-ray spectroscopy, and x-ray diffraction to evaluate their corrosion behaviour. In this presentation, the corrosion test results and the potential of nickel aluminate coatings to suppress hot corrosion by molten salts in an environment that simulates that of concentrating solar power plants will be presented and discussed.

Nanostructured Solid Ionic Hydrogen Barrier Coatings—Engineering Defect Chemistry and Interfaces for Corrosion Resistance  
William J. Bowman, Jing Yang, Xiaohui Yao and Bilge Yildiz; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Hydrogen embrittlement of metallic components is a leading cause for corrosion failure in high-temperature heat-exchange systems, whose components operate in extreme environments. Hydrogen is a byproduct of corrosion in water- or H2S-containing environments commonly associated with heat transfer media employed in high-temperature heat-exchange systems. To mitigate surface corrosion, protons should ideally be discharged from the solid-liquid interface into the liquid phase as gaseous H2. Though some atomic and/or ionic H is absorbed by the solid as point defects, ultimately inducing embrittlement and making the metal increasingly susceptible to fracture. For H uptake to occur, it must penetrate a synthetic or native surface layer (e.g. oxide, sulfide, carbonate), which involves interfacial and bulk solid-state ionic processes, including surface adsorption and absorption, as well as bulk diffusion. Hence, there is a significant opportunity to elucidate these processes, and to engineer solid ionic barrier coatings that mitigate H uptake and embrittlement in high-temperature thermal energy systems and metal components employed elsewhere.

Here we aim to develop a solid ionic H barrier coating by employing design and engineering approaches to (i) minimize the H point defect solubility and mobility in the coating material, and (ii) elucidate the role of interfaces in corrosion barriers during the H blocking process. We employ a doping strategy for a model non-stoichiometric oxide monoclinic ZrO2 following a recently-developed theoretical framework based on density functional theory and statistical thermodynamics that predicts point defect concentrations in metal oxides, including H point defects [1]. We measured electrical conductivity and H solubility in doped monoclinic ZrO2 compositions that had not be reported prior, and these experiments provided quantitative and qualitative validation of the theoretical modeling framework [2]. Temperature programmed water desorption was employed to quantify H solubility in these oxides and to elucidate the nature of H defects. Doping was found to effectively modulate hydrogen solubility in ZrO2, and we modified the oxide microstructure and performed solubility measurements under varied oxygen partial pressure to elucidate the H-containing defects, and to illustrate the influence of porosity and grain boundaries on H pick-up. Additionally, we electrochemically investigated the H flux through oxide thin film coatings grown on steel, with the intention of investigating the impact of solid-liquid interfaces and microstructure on H barrier coating performance.

PCC North, 100 Level, Room 123

10:30 AM †ES08.04.01  
Aging Models of Environmental Stress Factors for Solar Mirrors Lifetime Prediction  
Olivier Raccurt1, Coralie Avenel1,2, Sandrine Therias2 and Jean Luc Gardette2; 1Univ Grenoble Alpes, CEA LITEN, Grenoble, France; 2Univ Clermont Auvergne – CNRS – SIGMA Clermont, ICCF, Clermont-Ferrand, France.

The durability of solar mirrors is a critical factor for the deployment of concentrating solar power (CSP) plants [1,2]. Accelerated aging models currently applied in the polymer, electronic and photovoltaic fields have recently been reviewed [3], and the issues of their application to solar mirrors have been discussed. Lifetime prediction of solar mirror requires determining the kinetic laws of the degradation related to the stress factors level and the associate models. Temperature and humidity has been identified to be major stress factors for solar mirrors [4-6]. Accelerated aging in temperature and temperature with humidity at different levels were performed to assess the dependent parameters of models selected from the literature. Results from three different mirrors technology will be presented and analyzed to extract kinetics parameters for models. These parameters include the apparent activation energy for the Arrhenius temperature law, the Peck and Eyring coefficients for humidity. The experimental values were then assessed for specular reflectance loss of solar mirrors. Finally, using these parameters, acceleration factors were calculated for solar mirrors. An effective temperature taking into account the Arrhenius degradation law was used rather than the commonly used mean temperature. The relevance and utility of this effective temperature compared to a simple mean have already been discussed in the literature [7-9]. The problem of coupling all previous laws together is also addressed. Finally, a calculation of acceleration factor related to different CSP sites around for standard dump heat test (85°C, 85%RH) will be presented and discussed.

WITHDRAWN 4/4/2018 ES08.04.02 Hydrophobic CaF2 Film for Anti-Reflective Applications  
Raxish K. Jain1, Iatinder Kaur1, Atul Khamma1 and Amit K. Chawla2; 1Physics, Guru Nanak Dev University, Amritsar, India; 2Center of Nanoscience & Nanotechnology, University of Petroleum & Energy Studies, Dehradun, India.

Thin films of CaF2 were deposited on microscopy glass substrates by thermal evaporation and their structural, optical, and wettability properties were characterized. Thin films of the well-known anti-reflective material MgF2 were also synthesized and their optical and wettability properties were compared to those of CaF2. X-ray diffraction studies showed that CaF2 films are crystalline whereas MgF2 films are amorphous. The cross-sectional FESEM images found that the thickness of the CaF2 and MgF2 films were in the range of 100-130 nm. The optical transmittance and reflectance properties were studied by UV-vis spectrosopy. The average specular reflectance values were 10.8%, 7.9% and 8.6% for bare glass slide, MgF2 and CaF2 coated samples respectively, which showed that both films have good anti-reflecting properties. The water contact angle measurements were carried out to study the wettability properties of the samples and both CaF2 and MgF2 films were found to be hydrophobic with an average water contact angles of 131±2° and 98±2°, respectively. It is concluded that CaF2 films have a very good potential to be used as hydrophobic anti-reflecting coatings. The water contact angle of CaF2 film sample is...
significantly higher than that of MgF₂ film which makes the former more suitable for applications in eye lenses, car wind-shields and coatings on covering glass of solar cell panels and display devices where hydridic coating with low optical refraction is required.

11:15 AM *ES08.04.03 Monolithic Glass-Based Antireflective Coatings—Broadband/Omnidirectional Light Harvesting and Superhydrophobic Anti-Soiling Characteristics

Tokyo Aoyagi, Andrew Lupini, Poornan Joshi, Ilia N. Ivanov, Rajesh Menon; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; The University of Utah, Salt Lake City, Utah, United States.

Mitigation of the soil accumulation is imperative to decrease the maintenance cost while increasing the long-term energy efficiency and energy generation of solar power installations. Here we describe the formation of atomically bonded, optical-quality, nanostructured porous thin glass film coatings, utilizing metastable spinodal phase separation in a low-alkali borosilicate glass system. The coatings, which are optically imperceptible, simultaneously provides graded-refractive-index antireflectivity and superhydrophobic anti-soiling capabilities, with excellent mechanical durability. In particular, through its inherent antireflective characteristics, these nanostructured surfaces are found to promote a general and an invaluable 3–7% relative increase in current output of multiple direct/indirect bandgap photovoltaic cells. Besides, the coatings maintain optical transparency and superhydrophobic attributes when subjected to simulated sand/dust-storm conditions (based on NOAA reported conditions in desert environments). The present concept represents a fundamental basis for development of advanced coated optical quality products that can significantly improve the performance of CSP components.

11:30 AM *ES08.04.04 Design and Optimization of Solar Thermo Electric Energy Conversion Devices

Siddarth Viswanathan, Tristan Emm, Peter Thomas and Rama Venkatasubramanian; Novus Energy Technologies, Cary, North Carolina, United States.

Solar thermal energy to electric power conversion can be a very cost effective and scalable approach to harnessing the abundant solar energy. Solid state thermo-electric devices are reliable, scalable, and can be made cost-effectively for low $/Watt scenarios. In contrast to solar PV systems, solar-thermoelectric devices can offer high electric power density (W/unit area of active semiconductor), can be made to operate even when sunlight is not available using thermal storage systems, and particularly, in addition to providing electric power, can also provide hot-water from the heat that is not converted to electric power. As a low-cost route to solar thermo-electric conversion demonstration, we will report on our early studies in developing a solar thermo electric generator (STEG) system. We used a 1 m² Fresnel lens to collect direct solar light over a large area and directed it onto a ~0.01 m² area thermo-electric generator modules (TEG), equivalent to a x100 concentration. The planar Fresnel lens was not coated with any anti-reflection coating in these early studies, but are planned. The TEG modules consisted of ~300 °C-capable Bi₂Te₃-based modules, arranged in a linear 1.5 m x 4 m array. Since all the heat impinging on the TEGs is not converted to electric power, we developed a water-based heat removal system on the cold-side of the TEG modules. The thermal management system consisted of a circulating water loop and a heat-rejection finned heat-sink with a fan. The testing of the STEG module was conducted outdoors. Without any high-emissive (i.e., absorptive) coating on the TEG hot-side, the STEGs produced a voltage of 2.14 V. Even with a modest improvement in emissive/absorptive coating, for the same Fresnel lens configuration, we noted a significant increase in the voltage output to 5.72 V. The x2.7 increase voltage output, with essentially the same internal electrical resistance of the TEG module, would translate into x7.2 more power output. Under extremely sunny conditions, we have observed that the voltage output could go up to 8 V. Clearly, the influence of the heat-absorption coatings on the TEG modules indicates the need for further optimization as well as anti-reflective coating on the front-end planar Fresnel lens light focuser. With further optimization of Fresnel lens geometries, absorptive coatings, and thermal resistance of the TEG devices, higher temperatures can be obtained on the hot-side and therefore higher Carnot efficiencies can be obtained. For these applications, Novus is developing scalable, large-area high-temperature TEG modules based on half Heusler materials. We believe the STEG approach is an attractive way to harness the abundant solar energy in a scalable and cost-effective way.

11:45 AM *ES08.04.05 Low-Cost, High-Efficiency Concentrated Solar Heat System Based on Nano- and Microstructured Polymer Lenses Fabricated by Roll-to-Roll Extrusion Coating

Maria Matschuk and Henrik Pranck; Heliax ApS, Horsholm, Denmark.

Heliax has developed a concentrator concept largely based on modified, but well-known industrial processes. The solar concentrator itself consists of a Fresnel-like lens made in a thin polymer film which is glued onto planar glass for geometrical stability. The lens with focal distance of 2 meters focuses the light onto a heat-exchanger type flat receiver made by the welding of two corrugated steel plates, forming channels where a circulating liquid will be heated by the incident sunlight. Both components are fixed on a dual axis solar tracker, each holding 8 lenses and receivers. Advantages of the system are many; a flat lens greatly reduces the wind cross section (when positioned in horizontal mode), reducing the strength requirements for the whole structure, including the foundation. Flat lenses also make cleaning easier, and simplifies logistics compared to e.g. parabolic mirrors.

Furthermore, the two-dimensional focusing reduces the precision requirements from tens of millidegrees to degrees, allowing for use of low-cost gear-motors. Also, the acceptance angle of the sunlight is much higher than on mirror-based systems, as the result of combined two-dimensional focusing and a refractive lens. We have measured an acceptance angle of approximately 7 degrees, which is a large advantage if there is atmospheric spreading of the light, either due to cloud cover or smoggy conditions. All these advantages sum up to a much lower cost, where expected sales price is in the range of 350€/kWp(thermal) to 450€/kWp(thermal) depending on plant size. Installation is fast, and the system is modular. First plant for district heating (95°C) are being brought in operation Q1 2019. Next plant will feature a higher operating temperature (350°C) and for that partners and solutions to implement higher temperature operation are sought.

SESSION ES08.05: High Temperature Solar Receiver Coatings

1:30 PM *ES08.05.01 Spectrally Selective Coatings for Thermosolar Power Plants Working at High Temperatures

Javier Barriaga, IK4-TEKNIKER, Eibar, Spain.

The optimisation of solar selective coatings (SSC) for solar receivers plays a critical role in the efficiency of a concentrated solar power (CSP) plants. In this work two different SSC has been developed: one of them to operate in vacuum for parabolic through collectors (PTC) and the other to operate in air for linear Fresnel collectors. The final achieved multilayer stack designs were obtained after a combination of PVD parameters optimisation, characterisation and optical simulation of the individual layers. Multi-layered coating for evacuated receivers: SiO₂/AIW/Mo/W deposited using magnetron sputtering showed excellent optical selective properties α = 94.0% and εdash = 4.8% and long-time thermal stability at the operation temperature of CSP plants. SSC has been scaled up to 4 m long tubes and its efficiency is going to be tested in real plant. Chromium oxynitrides, AlCrO/AICrON/AlCrN deposited by magnetron sputtering were selected to develop solar selective coating to operate in air due to its exceptional thermal stability and oxidation resistance at high temperatures. Again, excellent optical selective properties, total solar absorptance above 90% and thermal emittance below 10% were measured. Thermal stability of the coatings was tested by means of an accelerated ageing test based on Arrhenius calculations.

2:00 PM *ES08.05.02 Multilayer Multifunctional Advanced Coatings for Receivers of Concentrated Solar Power Plants

Ludovic Charpentier, Danying Chen, Johann Colas, Frédéric Mercier, Michel Pons, Didier Pique, Gaël Giusti and Marianne Balat-Pichelin; PROMES, CNRS, Font-Romeu Odeillo, France; SIMAP, Université Grenoble-Alpes, CNRS, Grenoble INP, Grenoble, France; Siltronix ST, Archamps, France.

The extending market of the concentrated solar power plants requires the use of high-temperature materials for solar surface receivers that would ideally heat an air coolant beyond 1300 K. The currently used Ni-based alloys present operating working points between 970 and 1070 K as severe damages due to oxidation would occur beyond these temperatures and therefore a complementary heating of the coolant using fossil source or biomass is required. Ceramics like SiC are resistant to oxidation at higher temperatures (1470 to 1770 K), but are sensible to cracking that would quickly break the solar module. The collaborative project “Multilayer Multifunctional Advanced Coatings for Concentrated Solar
Ultrathin Silicon Carbide-Metal Nanocomposites as High Temperature Solar Selective Coatings

In this paper, we discuss the high temperature (up to 800 °C) performance of metallic absorbers. We present the results of short high temperature oxidation (up to 80 minutes) performed in solar furnaces and compare them to the ones of longer oxidation tests (up to 1,500 h) performed in industrial furnaces. These results will be shown and discussed. In addition, the coatings were tested under solar facilities available at PROMES-CNRS in Odeillo, France, to perform high temperature cyclic oxidation in air with thermal shocks (temperature rates during heating and cooling are up to 100 K s⁻¹) using the “Reacteur Hautes Pression et Température Solaire” (REHTPS), and high temperature optical measurements using the “Moyen d’Essai et de Diagnostic en Ambiance Spatiale Extrême” (MEDIASE). Room temperature optical measurements were also performed to investigate the consequences of the high-temperature treatments on the optical properties of the materials. Structural characterizations were performed using Scanning Electron Microscopy coupled with Energy-Dispersive X-ray Spectroscopy (SEM/EDS), X-Ray Diffraction (XRD) and micro-Raman analyses in order to identify surface evolution and damages due to high temperature oxidation. The results of short high temperature oxidation (up to 80 minutes) performed in solar furnaces were compared to the ones of longer oxidation tests (up to 1,500 h) performed in resistive furnaces.

The first results showed the difficulties to protect TZSM from fast oxidation: smokes of gaseous molybdenum oxide appeared from 670 K due to grain boundary diffusion through the coating. Tests on aluminate and silicide coatings are going on in order to add an additional barrier to Mo and O₂ diffusion. Kanthal APMT™ supports oxidizing atmospheres at 1400 K due to the formation of a protective layer mainly made of alumina. AlN and SiC/AlN coatings slightly changed the oxidation resistance and improved the solar absorbance of the substrate. After oxidation and the built-up of an oxide layer, this improvement was maintained. Nevertheless, the coatings cracked after a few fast thermal shocks from 1400 K to 900 K. According to our simulations, this is the result of high stress levels (2.5 GPa) that go beyond the failure limit of the coating (1.8 GPa). High temperature oxidation resistance and optical properties of metallic alloys were improved by the different coatings. However, the high temperatures reached (> 1300 K) led to a rapid diffusion of oxygen and alloying elements of the refractory alloy and the fast thermal shocks led to high stress levels not compatible with metal-ceramic systems with large differences in thermal expansion coefficients.

2:15 PM ES08.05.03
Microstructural and High-Temperature In-Air Stability Study of Solar Absorber Coatings Based on Aluminum Titanium Octynitrides Irene Heras, Matthias Krause, Gonzalo Rincon, Elena Guillen Ibañez, Ibon Azkoná, Frank Luzgitz, Daniel Janke, Franz Munnik, Jose Carlos Rodriguez, Jesus Fernandez and Ramon Escobar Galindo

The development of Generation 3 (GEN3) C-based solar absorber coatings implies an increase of the temperature of the heat they deliver to the power cycle in order to increase the plant efficiency and lower the costs. In particular, current central tower systems operate at maximum temperatures of 550 °C mainly due to the severe degradation that the state of the art absorber paints (i.e. Pyromark®) suffer at higher temperatures. In previous works [1,2] aluminum titanium oxynitrides Al₆Ti₄N(O,N)₂ were shown to be excellent candidate materials for solar selective coatings (SSC). These results confirmed that the designed SSCs based on these materials withstand breakdown at 600 °C in air after 900 hours of thermal cycling. In this paper, we discuss the high temperature (up to 800 °C) stability of a solar absorber based on Al₆Ti₄N(O,N)₂ deposited by cathodic vacuum arc (CVA) at higher working pressure (P = 2.1 Pa) than those discussed in [1] and [2]. The composition, morphology and microstructure of the films were characterized by ion beam analysis, scanning and transmission electron microscopy and X-ray diffraction. The optical properties were determined by ellipsometry and spectrophotometry (UV-Vis-NIR, FTIR). The microstructural and spectroscopic characterization shows the formation of a solid solution of Al₂O₃/TiN crystalline nanoparticles embedded in an amorphous Al₂O₃(N,N)₂ matrix. This microstructure provides the coating with a high absorption coefficient within the whole wavelength range of interest (0.3 to 25 μm) as modeled by spectrophotometric ellipsometry. Hence, this single layer absorber shows an absorption, α, of 92% and an emissivity, ε_RT, of 70%. The addition of an antireflective Al₂O₃ layer and post-deposition treatments improved the optical properties of the absorber to better values (α = 96% and ε_RT = 60%) than those of Pyromark®. The thermal stability in air of the absorber was firstly analyzed by cyclic heating tests, showing no degradation after 300 h of cycles in air at 700 °C. Subsequently, the samples were tested in a solar furnace at 650 °C and 800 °C for 12 hours at environmental conditions. Therefore, this oxynitride nanocomposite absorber coating presents the best thermal in-air stability studied so far by our group.

2:30 PM ES08.05.04
Ultrathin Silicon Carbide-Metal Nanocomposites as High Temperature Solar Selective Coatings Aikifia Raza, Ruhong Gao, Afira S. Alketbi and TieJun Zhang; Department of Mechanical and Materials Engineering, Masdar Institute, Khalifa University of Science and Technology, Abu Dhabi, United Arab Emirates.

Solar thermal technologies, converting the abundant solar energy into heat and electricity, have attracted extensive attention in recent years. It is desirable to increase the operating temperature of concentrated solar power plants for higher conversion efficiency, which requires the design of high-temperature components and, in particular, the solar absorber coatings. Recent advances in photochemical conversion, the solar absorber surface must have high solar absorptance (α ≥ 0.98) and a low thermal emittance (ε ≤ 0.05) at the operational temperature (T ≥ 500 °C). For this purpose, we propose spectrally selective SiC-metal (Si-M) based nanocomposite absorbers with low infrared emissivity above 500 °C. The as-fabricated ultrathin nanocomposite absorber with sandwich-like configuration, consisting of SiC/SiC-M/SiC on reflective layer coated on stainless steel substrate, has exhibited an absorptance of 80-85% in the wavelength range of 280-2000 nm. The surface plasmon polaritons of metal inclusion within the SiC matrix of ultrathin nanocomposite layer have contributed to the broadband light absorption, while the top most layer of SiC acts as anti-reflection layer. The bottom reflective layer of tungsten coated on stainless steel substrate reduces the infrared emittance and improves the thermal stability of the absorber. With the exceptional thermal shock resistant and anti-corrosive properties of SiC as well as the rational design of metal inclusions in the SiC matrix, the proposed absorber can achieve near-perfect absorption in the solar spectrum and also get truncated with a sharp slope in the infrared region for mid to high temperature solar thermal applications.

2:45 PM ES08.05.05
High Temperature In-Air Stability Studies of SnO₂:Ta Thin Films Used as Solar-Selective Transmitter in CSP Ahvarto Méndez Fernández, Iván Fernández Martínez, AmbÚrn Wenneberg, Sandra Muñoz Piña, Jose Carlos Rodriguez, Frank Luzgitz, Daniel Janke, Ramon Escobar Galindo and Matthias Krause; 1NANOENERGY SLNE, Madrid, Spain; ²NanoComposite Division - Ion Beam Center, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany; 3Concentrating Solar Systems Unit, CIEMAT - Plataforma Solar de Almería, Tabernas, Spain; 4Departamento de Ciencia de los Materiales e Ingeniería Metalúrgica y Química Inorgánica, IEEMYAT - Universidad de Cádiz, Puerto Real, Spain.

The importance of finding more effective and cleaner ways of producing energy other than fossil fuels is growing fast in order to reduce CO₂ emissions that contribute to the greenhouse effect. Concentrating solar power (CSP) uses reflectors to redirect and concentrate the solar radiation onto a receiver, where it is transformed into heat. Downstream heat exchangers and gas turbines are the final elements of the plant responsible for transforming the heat into electricity. Current CSP plants are operated at a maximum of 550 °C, but an increase of the operation temperature to 800 °C, in combination with solar-selective coatings, would significantly improve their efficiency by more than 10 %. In order to approach this issue, a transparent conductive oxide (TCO) thin film based on SnO₂ doped with Ta was developed and optimized by reactive magnetron sputtering [1]. This material was shown resisting 800 °C in vacuum for 4 hours, transmitting incident sunlight and blocking infrared emission from the underlying blackbody absorber. As such, it exhibits all properties required of a solar-selective transmitter for high-temperature CSP usage. In this work, thermal stability tests were carried out in air using an electric furnace for a total of 12 hours at 650 °C and 800 °C, respectively, for laboratory samples and industrially produced coatings. These results will be shown and discussed. In addition, the coatings were tested under environmental conditions at 650 °C and 800 °C in a solar furnace, again for a total of 12 hours each, providing information about their behaviour and performance in a situation much closer to the final application. Spectrophotometry, Rutherford backscattering spectrometry and conductivity measurements, among other techniques, were used to track the evolutions of the properties and performance of SnO₂:Ta thin films under these conditions.

This work was supported by the EU H2020 RISE project “Framework of Innovation for Engineering of New Durable Solar Surfaces” (FRIENDS®, GA-645725).
Preparation and Characterization of Solar Thermal Absorbers by Nanoimprint Lithography and Sputtering

Tina Mitteramskogler\textsuperscript{1}, Amböörn Wennberg\textsuperscript{2}, Iván Fernández Martínez\textsuperscript{2}, Felipe Tessarollo Ramos\textsuperscript{1}, Michael J. Haslinger\textsuperscript{1}, Michael M. Muehlberger\textsuperscript{1}, Matthias Krause\textsuperscript{1} and Elena Guillén\textsuperscript{2}; Profactor GmbH, Steyr-Gleink, Austria; \textsuperscript{2}Nano4Energy SL, Madrid, Spain.

We present a scalable top-down fabrication method based on nanoimprint lithography (NIL) to be used in the manufacturing of selective solar absorbers. By using a deposition mask, nanodisk arrays are fabricated to create plasmonic metamaterial absorber structures.

The deposition mask is a two-layer system. The underlying lift-off layer aids the subsequent mask lift-off, whereas the NIL fabricated top layer is defining the location and shape where the nanodisks are grown during metal deposition. The chosen pattern layout is not optimized for a solar absorber application, however, due to the versatility of this process, the absorber features could be tailored by choosing an optimized nanopattern for the nanoimprint step.

As proof-of-concept we show the fabrication of elliptical tungsten nanodisks on top of metallic substrates with 100 nm oxide layers, creating a metal nanoparticles-insulator-metal reflector structure. Two different material deposition methods are compared: direct current sputtering and high-power impulse magnetron sputtering. We characterize the fabricated nanodisks by AFM and SEM imaging and comment on the selective absorptivity and thermal stability compared to unstructured absorbers.

Materials Structuring for Enhanced Solar Energy Absorption and Retention

Sungho Jin\textsuperscript{1} and David Wait\textsuperscript{2}; \textsuperscript{1}NanoSD, LLC, San Diego, California, United States; \textsuperscript{2}Solar Reserve, LLC, Santa Monica, California, United States.

Concentrating solar power (CSP) technology has been one of the current renewable electricity generation methods, which has attracted much attention in recent years due to its integration with cost-effective thermal energy storage systems. In order to further reduce the cost of CSP technology, it is imperative to operate the CSP plants at higher temperatures (e.g., \textgreater{}800°C) with enhanced efficiency (e.g., solar-to-thermal figure-of-merit (FOM) as close to the theoretical upper limit of \textasciitilde{}95% as possible), with reduced thermal emission loss. It is also highly desirable to retain or store as much of the absorbed solar energy as possible. In standard CSP tower structures, the metal alloy substrates are considered as geometrically flat, which represents a good IR reflector. However, with specifically designed surface structures such as controlled microcavity or nanocavity array, even the metallic surface can be converted to an excellent solar absorber, especially when combined with a small amount of sunlight-absorbing ceramic coating like the black oxide.

Such unconventional metal surface structures have been prepared which demonstrated very high solar absorptivity values close to 99%, yet exhibited desirable reduced emissivity at high operating temperatures around \textasciitilde{}800°C. These light-trapping micro or nano cavity structures can be fabricated by industrially inexpensive methods. Effects of various structural configurations on light-absorption and emissivity control, and some practical implications will be discussed. Other aspects of solar absorption and desired retention/storage of solar energy will also be discussed.

Fractal-Like Designs for Increased Solar Absorptance and Efficiency of High-Temperature Solar Thermal Receivers

Clifford Ho, Jesus Ortega, Joshua Christian and Julius Yellowhair; Sandia National Laboratories, Albuquerque, New Mexico, United States.

Novel designs to increase light trapping and thermal efficiency of concentrating solar receivers at multiple length scales have been conceived, designed, and tested. The fractal-like geometries and features are introduced at both macro (meters) and meso (millimeters to centimeters) scales. Advantages include increased solar absorptance, reduced thermal emittance, and increased thermal efficiency. Radial and linear structures at the meso (tube shape and geometry) and macro (total receiver geometry and configuration) scales redirect reflected solar radiation toward the interior of the receiver for increased absorptance. Hotter regions within the interior of the receiver can reduce thermal emittance due to reduced local view factors to the environment, and higher concentration ratios can be employed with similar surface irradiances to reduce the effective optical aperture, footprint, and thermal losses. Coupled optical/fluid/thermal models have been developed to evaluate the performance of these designs relative to conventional designs. Modeling results showed that fractal-like structures and geometries can increase the effective solar absorptance by 5 – 20% and the thermal efficiency by several percentage points at both the meso and macro scales, depending on factors such as intrinsic absorptance. Meso-scale prototypes were fabricated using additive manufacturing techniques, and a macro-scale bladed receiver design was fabricated using Inconel 625 tubes. On-sun tests were performed using the solar furnace and solar tower at the National Solar Thermal Test facility. The test results demonstrated enhanced solar absorptance and thermal efficiency of the fractal-like designs.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.

Colloidal Inorganic Nanocrystals with Reduced Symmetry  
P. Davide Cozzoli,
1, 2; 1University del Salento, Lecce, Italy; 2UOS Lecce, CNR NANOyCT - Institute of Nanotechnology, Lecce, Italy.

Colloidal inorganic nanocrystals (NCS), free-standing crystalline nanostructures grown in liquid phase with the aid of surfactants or soft organic templates, stand out in the realm of functional inorganic nanomaterials owing to the precision with which their properties can be controlled through structural and geometric tailoring in the synthesis stage and the flexibility with which they can be exploited in disparate technological fields. A smart, yet challenging paradigm to engineer, differentiate and enrich the physical-chemical prerogatives of NCS relies on designing and creating unconventional architectures, in which diverse compositional, geometric and topological motifs are combined and/or blended across multiple structure and dimensionality levels within reduced-symmetry frameworks. Yet, due to current limitations in synthetic capabilities and related mechanistic knowledge, low-symmetry nanostructures are generally under-represented in the colloidal domain. In this talk I will illustrate progress made by us in the controlled growth and characterization of asymmetric NCS, forged into single-crystalline habits with mixed 1D-2D dimensionality and 2D-3D connectivity, or into multicomponent nanoheterostructures integrating different materials. The technological potential offered by such brand-new NCS will be highlighted.

11:00 AM ES10.01.02  
A Non-Power Strategy for Photo-Generated Charge Carrier Separation—Effect of Lorentz Force in Photocatalytic System  
Wenqiang Gao; Shandong University, Jinan, China.

The promotion of the separation and suppression of the recombination of photo-generated charge carrier have attracted extensive attention in the field of photocatalysis, and constructing heterogeneous junction of photocatalyst by passive types as the core is one of the most effective ways. However, the construction of heterogeneous junction is an uncontrollable and spontaneous process, which may have many disadvantages to improve the photocatalytic performance. In addition, taking advantage of the external fields to enhance charge carrier separation such as electric field enhanced charge carrier separation will bring more energy consumption. Therefore, we proposed a non-power strategy to act on the process of charge carrier transport through Lorentz force and apply in the TiO2 nanobelts to improve the photocatalytic performance. In this work, the results of photoluminescence spectra, photocurrent density and theoretical calculation proved the reaction mechanism that the Lorentz force can effectively promote the separation and inhibit the recombination in the process of the charge carrier transport. It is believed that the new strategy based on the magnetic effect will start a new thinking of the charge separation, and our work will be extremely illuminating to the future researches in the field of photocatalysis.

11:15 AM ES10.01.03  
Isolating Nonthermal Light Effects in Plasmon-Enhanced Catalytic Reactions  
Xueqian Li, Jie Liu and Henry O. Everitt; 1Chemistry, Duke University, Durham, North Carolina, United States; 2Army AMRDEC, Redstone Arsenal, Alabama, United States; 3Physics, Duke University, Durham, North Carolina, United States.

Traditional heterogeneous catalysts that requires high temperatures to overcome reaction barriers often activates undesired side reactions and shortens catalyst lifetimes. The use of illuminated metal nanoparticles in plasmonic photocatalysis has led to accelerated catalytic activities, reduced activation energies, and the ability to select for desired products at reduced temperatures for important chemical reactions. A key challenge in studying such reactions is the separation of the thermal vs. nonthermal contributions. Here, we implement rhodium nanoparticles as a compelling ultraviolet plasmonic photocatalyst for carbon dioxide hydrogenation. Using direct and indirect illumination in conjunction with precise temperature measurements, effects on the overall reactivity of the catalyst from photo-generated hot carriers can be isolated and extracted to reveal the true nonthermal contribution. It is demonstrated that light and heat work together to accelerate important chemical reactions.

11:30 AM ES10.01.04  
Primary Amines Enhance Triplet Energy Transfer from CdSe Nanocrystals for Photon Upconversion  
Emily Moses, Kevin Lee, Jefferson Sun and MingLee Tang; Chemistry, University of California, Riverside, Riverside, California, United States.

Primary amines have been shown to increase the photoluminescence quantum yield (PLQY) of CdSe nanocrystals (NCS), yet little is known about how the binding of amines effects the energy transfer properties of these materials. It is well known that surface effects play the largest role in energy transfer efficiencies in nanocrystalline materials, better understanding, and subsequently controlling surface states is the key to unlocking the full potential of NCS in energy transfer processes, such as upconversion. In this study, CdSe NCS were placed in varying concentrations of 1-propylamine, with and without 2-anthracenecarboxylic acid transmitter ligands attached. This poor transmitter ligand allows for better observation of PL enhancement due to the primary amine. It is shown that adding a primary amine increases the PLQY of the NC, as well as increasing the photon upconversion quantum yield. This effect is maximized at low (11 mM) concentrations of propylamine, while the PLQY can be enhanced further by increasing the amine concentration. By using transient absorption, this work studies the underlying energy transfer processes both enhanced and suppressed by the addition of amine. Through this work the importance of surface trap states are quantified along with the band edge emission of the NC, allowing for a better understanding of important surface chemistry in these complicated systems.

SESSION ES10.02: Self-Assembly and Photocatalysis

Self-Organized Oxide Nanotubes—Critical Factors in Photocatalytic Applications  
Patrik Schmuki, Ning Liu, JeongEun Yoo and Marco Altomare; Univ of Erlangen-Nuremberg, Erlangen, Germany.

TiO2 nanomaterials have over the last 30 years attracted tremendous scientific and technological interest. Particularly various 1D and highly defined TiO2 morphologies were explored for the replacement of nanoparticle networks and were found in many cases far superior to nanoparticles or their assemblies. Nanotubes or wires can be grown by hydrothermal or template methods, or even more elegantly, by self-organizing anodic oxidation. The latter is not limited to TiO2 but to a full range of other functional oxide structures that on various metals and alloys can be formed. These advanced and doped morphologies can be grown on conductive substrates as ordered layers and therefore can be directly used as functional electrodes (e.g. photo-anodes). The presentation will focus on these highly ordered nanotube arrays of TiO2 (and similar) and discuss most recent progress in synthesis, modification and applications towards photocatalytic and photoelectrochemical applications, such as noble-metal-free H2 generation or the site-selective placement of active centers onto/into these tube layers.

Literature:
Design and engineering of the size, shape, and chemistry of photoactive building blocks enable the fabrication of functional nanoparticles for applications in light harvesting, photocatalytic synthesis, water splitting, phototherapy, and photodegradation. Here, we report the synthesis of such nanoparticles through a surfactant-assisted interfacial self-assembly process using optically active porphyrin as a functional building block. The self-assembly process relies on specific interactions such as π-π stacking and ligand coordination between individual porphyrin building blocks. Depending on the kinetic conditions, resulting structures exhibit well-defined one- to three-dimensional morphologies such as nanowires, nanooctahedra, and hierarchically ordered internal architectures. At the molecular level, porphyrins with well-defined size and chemistry possess unique optical and photocatalytic properties for potential synthesis of metallic structures. On the nanoscale, controlled assembly of macrocyclic monomers leads to formation of ordered nanostructures with precisely defined size, shape, and spatial monomer arrangement so as to facilitate intermolecular mass and energy transfer or delocalization for photocatalysis. Due to the hierarchical ordering of the porphyrins, the nanoparticles exhibit collective optical properties resulted from coupling of molecular porphyrins and photocatalytic activities such as photodegradation of methyl orange (MO) pollutants and hydrogen production. The capability of exerting rational control over dimension and morphology provides new opportunities for applications in sensing, nanoelectronics, and photocatalysis.

1:00 PM *ES10.02.01 Interfacial Self-Assembly of Hierarchically Structured Nanoparticles with Photocatalytic Activity Hongyou Fan; University of New Mexico/Sandia National Laboratories, Albuquerque, New Mexico, United States.

Gold-palladium (Au-Pd) bimetallic nanoparticles were prepared with a series of alloy and core-shell nanostructures to synergistically couple a plasmonic (Au) and catalytic (Pd) metal to tune their optical and catalytic properties. Catalysts utilizing plasmonic metals that exhibit a localized surface plasmon resonance (LSPR) can be harnessed for light-driven enhancement of small molecule oxidation via augmented carrier generation/separation and photothermal conversion. The colloidal AuPd bimetallic nanoparticles were used as catalysts to study the ethanol (EtOH) photo-oxidation cycle, with an emphasis towards driving carbon-carbon (C-C) bond cleavage at low temperatures. The AuPd nanoparticles were coupled to semiconductor photocatalysts and irradiated with targeted wavelength ranges to probe their effects on plasmonically-assisted photocatalytic oxidation of EtOH. The oxidation of EtOH to CO₂ under solar-simulated-light irradiation was confirmed by monitoring the yield of gaseous products during photo-oxidation experiments using a gas chromatography-mass spectrometry-multiheadspace extraction (GC-MS-MHE) analysis method. The coupling of Au to Pd in an alloy or core-shell nanostructure at higher Au content maintains SPR-induced charge separation, mitigates the carbon monoxide poisoning effects on Pd, and allows for improved hydrocarbon oxidation. Under visible light (>420 nm) irradiation, carrier generation/separation and photothermal conversion was achieved, resulting in the photogenerated “hot” holes driving the photo-oxidation of EtOH, providing a method to selectively cleave C-C bonds. Bimetals provide a pathway for driving desired photocatalytic and photoelectrochemical reactions with superior catalytic activity and selectivity.

1:45 PM ES10.02.04 Hole Transport in Selenium Semiconductors Using Density Functional Theory and Bulk Monte Carlo Atreyo Mukherjee1, Dragica Vasileska2 and Amirhossein Goldan1; 1Electrical Engineering, Stony Brook University, The State University of New York, Stony Brook, New York, United States; 2Arizona State University, Tempe, Arizona, United States.

Amorphous semiconductors are useful as they can mimic the properties of their crystalline counterparts while having the ability of being deposited uniformly over a large area at a rapid rate in a thin film geometry. For a great many years, the non-dispersive transport of holes in glassy-amorphous selenium has been of interest. This interest originates from the importance of elemental Selenium as a high-resolution, large-area, wide bandgap, and room-temperature semiconductor with many successful commercial applications such as 2D and 3D medical x-ray imaging. Amorphous selenium is the only amorphous material that undergoes ionization where only holes avalanche at high electric fields and is emerging as a viable large-area imaging detector with avalanche multiplication gain for low-light and low-dose radiation detection applications. This leads to a small Excess Noise Factor which is a very important performance comparison matrix for avalanche photodetectors. Thus, there is a need to model high field avalanche in amorphous selenium. At high fields, the transport in amorphous selenium changes from low values of activated trap-limited drift mobility to higher values of band transport mobility, via extended states. When the transport shifts from activated mobility with high degrees of localization to extended state band transport, then the waveform of the amorphous material resembles that of its crystalline counterpart. Thus, we expect the general details of the extended-state hole-phonon interaction in the amorphous phase to be described by the band-transport lattice theory of its crystalline counterpart’s namely monocrinic and trigonal selenium. To that effect and due to the intrinsic meta-stability of the monocrinic phase and high trap density in prepared specimens, we study hole transport in crystalline trigonal selenium semiconductors using a bulk Monte Carlo technique to solve the semi-classical Boltzmann transport equation (MC-BTE).

In this work we perform molecular dynamic simulations (MD) of vapor-deposited amorphous selenium thin-films using a well-established empirical three-body interatomic potential. On comparing the simulated reduced radial distribution function (RDF) obtained from the MD simulations of amorphous Selenium with monoclinic Selenium and trigonal Selenium, we saw strong correlations over a distance of 10 Å. Thus, we showed that the molecular arrangement for the amorphous phase has considerable local order which may be an explanation for the amorphous general feature of the electronic structure with its crystalline counterparts. Next we utilized density functional theory (DFT) simulations to calculate the density of states and acoustic/optical deformation potentials for the crystalline phases. The accuracy of our DFT model was validated by the very similar results that was previously reported for the ab initio self-consistent energy band structure and previously measured phonon dispersion data for trigonal Selenium. The results from our DFT calculations were then used to calculate the phonon scattering rates which were utilized in the bulk MC algorithm to stochastically interrupt hole free flights. Using our MC-BTE model we calculated phonon-limited low-field drift mobilities which are comparable to published experimental values for trigonal Selenium in both perpendicular and parallel directions to the c-axis for a wide range of temperatures (100-500 k).

To summarize, we showed that holes in selenium can undergo both elastic and inelastic collisions and yet get 'hot', thus gaining more energy from the electric field than they lose to lattice vibrations. This study makes a strong case for the need of a microscopic dynamical model to study hole transport in selenium semiconductor devices.

3:00 PM BREAK

3:30 PM *ES10.02.05 Programmable Assemblies of Inorganic Colloids for Photocatalytic Applications Mikhail Zamkov1, Bowing Green State University, Bowling Green, Ohio, United States.

Colloidal assemblies of complementing nanoscale or molecular components represent a promising class of multifunctional materials. Their composite architecture can allow several reaction steps to progress at the same site with minimal mass and energy transfer distances, which is an important factor for optimizing energy conversion processes in
Nanostructured porous electrodes offer significant advantages for chemical and energy transformations due to their extremely high internal surface area and flexible accommodation of active components, and they have found a wide range of applications including photocatalysis. Their performance is determined by the rate of transport of charge carriers and/or reactants through the porous network as well as their photophysical and chemical properties, however many details remain to be understood. In this talk we will present an analysis of how charge flow and reactant transport are interconnected in a specific type of system, a dye-sensitized solar cell (DSSC) with a 1:1 redox couple, using detailed numerical reaction-diffusion simulations. The DSSC is chosen as a model system for the more general case because a substantial amount of the available literature available on it for model construction and validation. The stochastic, multiscalar computational technique used in this work allows detailed modeling of processes over a very large dynamic range of distances and time, thereby predicting macroscopic observables such as current at the same time as revealing extensive detail about the processes occurring within the porous nanostructured material. The calculations show that at low dye photoexcitation frequencies, the electron distribution in the system and the currents reflect a balance between production of the anode and dye redox cycling that consumes the anode-electrolyte interface in the anode. Electron generation and current flow at high photoexocitation frequencies are controlled by the distribution of the redox electrolyte, which becomes highly nonuniform both in the pores and the electrolyte bulk. Trends in photocatalysis characteristics with pore density and geometry will be described, and some comments on general implications of the DSSC results for other types of systems will be made.

4:15 PM ES10.02.07 Mesoporous Semiconductors—A New Model to Assess Accessible Surface Area and Increased Photocatalytic Activity Alexey S. Cherevan2, Dominik Eder3 and Roland Marschall1, 2 University of Bayreuth, Bayreuth, Germany; 3Technische Universität Wien, Vienna, Austria. Mesoporous photocatalysts have gained great advantage in the last decade by demonstrating that increased surface area and porosity can strongly improve their performance. In fact, all reports on mesoporous semiconductors support this scenario. But is it possible to quantify and compare the reported advantages of the mesopores and the increased surface area between different works? In this contribution, we present a model that can evaluate the improvements in photocatalytic activity achieved by the introduction of mesoporosity independent on synthetic or test conditions. We exemplify this methodology focusing on photocatalytic hydrogen/oxygen evolution with sacrificial reagents, but also include examples of CO2 reduction and electrocatalysis. By correlating the relative increase in surface area to the relative increase in activity – in comparison to non-porous counterparts – we show that the origin of mesoporosity can have a pronounced influence on the activity enhancement, and that different semiconductor materials behave quite differently. Our model can serve as a starting point for the community to extract and compare key photocatalytic data, to put results into context of existing data, and to compare the performances of various catalytic systems much better.

4:30 PM ES10.02.08 Revealing Structure-Activity Relationships in Pt-Functionalized Graphitic Carbon Nitride Photocatalysts Diane Haibet and Peter Crozier; Arizona State University, Tempe, Arizona, United States. Graphitic carbon nitrides (gCNs) offer immense potential as inexpensive photocatalysts for solar fuel generation (e.g., H2 from water) owing to their facile synthesis from a range of precursors, ability to absorb visible light, and high surface area.1 Recent experimental and theoretical work has highlighted the importance of n-type N-H2 defects in facilitating interfacial charge transfer to supported Pt cocatalysts.2 Typically, gCNs are functionalized with Pt via photodeposition at high loadings (e.g., ~1-5 wt%) but recent work has shown that single-atom Pt photocatalyst can also be used for H2 evolution at much lower loadings.2 Nanoscale characterization should reveal more precise structure-function relationships leading to rational design strategies for Pt@gCN photocatalysts that maximize energy conversion efficiency and minimize Pt consumption. A systematic study correlating the hydrogen evolution rates (HERs), bulk characterization of the gCN supports, and Pt dispersion determined from annular dark field scanning transmission electron microscopy (ADF-STEM) was performed to understand photocatalytic activity in Pt@gCNs. Three gCNs demonstrating a range in structural condensation were selected including a commercially-produced “Nicanite” and two urea-derived gCNs. The C/N stoichiometry and bandgap onset energies vary widely with the most structurally condensed gCN (i.e., Nicanite) exhibiting increased visible-light absorption while the least condensed gCN demonstrating moderate structural condensation (i.e., U0.5gCN). The HER of U0.5gCN under visible light is >2x higher than that of Nicanite or U0.5gCN; all were loaded with 1.6 wt% Pt via photodeposition and tested under identical conditions. ADF-STEM imaging of the used Pt@gCN photocatalysts reveals that the Pt dispersion varies widely on each support with U0.5gCN exhibiting the highest Pt dispersion. Moreover, the large Pt nanoparticles and low percentage of Pt photodeposited from solution (i.e., 33% on all supports) widely observed points to an inefficient use of Pt. We find that a photocatalyst containing single-atom Pt, a photocatalyst dispersion with only 0.15 wt% supported on Nicanite can achieve a ~20% greater HER than that of the conventional preparation while reducing Pt consumption by >10x. While promoting, deactivation of the photocatalyst occurred which was attributed to single-atom coarsening. Due to the vast differences in Pt dispersion and visible light absorption among the gCN supports, we argue that the HER (as mass of photocatalyst) is not a suitable metric for photocatalytic activity, although commonly used in this manner. Rather, by normalizing the HER by the total Pt surface area and integrated photon flux above the bandgap onset energy, different gCNs’ photocatalytic activity can be reliably compared. In this view, the order of photocatalytic activity was as follows: U0.5gCN > U0.5gCN > Nicanite. This analysis suggests that “optimal” structural condensation in gCNs should maximize photocatalytic activity whereas both under-/over-polimerization results in poor charge separation/migration. In addition to a discussion of our findings, we will emphasize methods for determining photocatalytic activity and improving the stability of single-atom Pt supported on gCNs.

4:45 PM ES10.02.09 Towards Enhancing Photocatalytic Hydrogen Generation—Which is More Important, Alloy Synergistic Effect or Plasmonic Effect? Zhonghe Xu1 and Dongling Ma2; Shenyang University of Chemical Technology, Shenyang, China; 2University of Quebec, Varennes, Quebec, Canada. Hydrogen generation by solar energy from water splitting is a promising means for replacing traditional fossil fuels. Hitherto, many different tactics have been adopted to improve the efficiency of water splitting. Among them, the use of an alloy structure for achieving synergistic effect and the integration of plasmonic nanostructures for exploiting beneficial plasmonic effect in catalysis appear most promising. In depth understanding and comparison of their respective contributions in certain promising systems is highly desired for catalyst development, yet not investigated so far. We report herein our thorough investigations on a series of highly interesting nanocomposites composed of Pt and Au and C3N4 nanocomponents, which are designed to benefit from both synergistic and plasmonic effects. Detailed analyses led to an important conclusion that the contribution from the synergistic effect was at least 3.5 times that from the plasmonic effect in the best performing sample, Pt3Au25 alloy decorated C3N4. It showed remarkable turnover frequency of >1.6 (mol H2 h-1 kg catalyst)-1 at room temperature. Our work provides physical insights for catalyst development by rationally designing samples to compare long-known synergistic effect with recently emerging, attractive plasmonic effect and represents the first case study in the field.[1]

Peering into Water Splitting Mechanism of g-C_{3}N_{4}-Carbon Dots Metal-Free Photocatalyst

Dan Qu and Zaicheng Sun; Beijing Institute of Technology, Beijing, China.

Photocatalytic water splitting is considered one of the promising ways to provide clean fuels. Extensive efforts have been made in the past to develop various inorganic and organic materials systems as photocatalysts for water splitting by using visible light. Among these photocatalysts, it was recently demonstrated that incorporation of carbon dots (CDs) into graphitic carbon nitride (g-C_{3}N_{4}) results in new metal-free composites (gC_{3}N_{4}-C) with excellent stability and impressive performance for photocatalytic water splitting. However, fundamental questions still remain to be addressed such as how added CDs influence the photocatalytic reaction through the bandgap tunability, charge transfer route, and efficiency, as well as the specific function of CDs in the photocatalytic process. Understanding the chemical and physical behaviors of added CDs for the control of gC_{3}N_{4}-C architecture is a critical need for its emergence from the fundamental design of more efficient photocatalysts to practical applications. In this article, we report new materials with well-controlled architecture allowing for fine-tuning band gaps for broader visible light absorption and controlled understanding of the photocatalytic process. The well-defined model materials allow us to address the fundamental question regarding chemically bonding of CDs and how the chemical bonded CDs promote charge separation and transfer for highly efficient generation of H_{2}.

ES10.03.02

Orbital Energies Determine Interactivity of Hole Transport Materials with Iodide Species in Degrading Perovskite Devices

Andrew Shapiro1, Ross A. Kerner1, Lianfeng Zhao1, Nakita K. Noel1,2 and Barry P. Rand1,2; 1Electrical Engineering, Princeton University, Princeton, New Jersey, United States; 2Princeton Research Institute for the Science and Technology of Materials, Princeton, New Jersey, United States; 3Andlinger Center for Energy and the Environment, Princeton University, Princeton, New Jersey, United States.

With improving efficiencies of metal halide perovskite-based photovoltaic and emissive devices, research interest is increasingly focused on understanding and improving device stability. In particular, the effects of mobile ions moving within and escaping from the perovskite material are of interest as they are posited to be a major source of device degradation. While significant research has been conducted on the interactions of these ionic species with the perovskite material as well as the metal contacts of the device, research on the interactions with organic carrier transport or blocking layers is lacking. Using methyliammonium lead triiodide (MAPI) as a prototypical metal halide perovskite, we show that interactions between adjacent organic films with iodine-containing species ejected from the degrading perovskite are significant and material dependent. In the presence of iodine vapor, common small-molecule and polymer hole transport materials (HTMs) are shown to be permeable and susceptible to reversible doping based on their highest occupied molecular orbital (HOMO) energy. Similarly, when in contact with an illuminated MAPI film, the conductivity of the HTM after illumination increases depending on the HOMO level of the material, suggesting iodide doping of the HTM. The strength of the HTM interaction with iodide is found to be linked to the HOMO energy proximity to the iodide/triiodide redox couple energy. Based on these observations, we suggest that the HTM could facilitate perovskite material degradation through loss of iodide, transmit corrosive iodide/triiodide from the perovskite to the device’s metal contacts, and contribute to hysteresis via ionic capacitance from reversible HTM doping. Ultimately, our data bring to light the importance of the HOMO energy and interactivity with respect to the iodide/triiodide redox energy when designing or selecting organic HTMs for perovskite devices.

ES10.03.03

Insight into the Phase Stability of Cesium Lead Iodide Perovskite

Zihan Zhang1, Xi Wang1 and Hanwei Gao1,2; 1Physics, Florida State University, Tallahassee, Florida, United States; 2Condensed Matter Science, National High Magnetic Field Laboratory, Tallahassee, Florida, United States.

As a promising alternative to organo-metal halide perovskite, metal halide perovskite CsPbX (X = Cl, Br, or I) has gathered great research interest because of its better stability against light and heat. Among this kind of perovskite materials, the black-phase CsPbI possesses the optimal bandgap (~1.7 eV) for harvesting solar energy but suffers from the spontaneous phase transition to the photo-inactive yellow-phase in the ambient air at room temperature. In this work, we achieved improved phase stability by confining nanocrystals of black-phase CsPbI in a solid-state matrix. Using microscopic imaging tools, we discovered the correlation between the improved stability and the microscopic morphology of the thin films. Remarkably, the electrical conductivity and photoresponse can be improved simultaneously using this method, indicating its potential for photovoltaic applications.

ES10.03.04

Mixed-Halide Perovskites with Stabilized Blue Emission

Xavier A. Quintana1 and Hanwei Gao1,2; 1Physics, Florida State University, Tallahassee, Florida, United States; 2Condensed Matter Science, National High Magnetic Field Laboratory, Tallahassee, Florida, United States.

The unique bandgap tunability in mixed halide perovskites is desirable for multiple applications such as solar cells, light emitting diodes (LEDs), and sensors. By simply mixing halides ions, the bandgap can be tuned through the entire visible range, such as the blue emission of CsPb(Br,Cl,1-x)I_x. However, suffered from phase segregation, the desired bandgap is not sustainable under operation conditions such as continuous illumination when used in the down conversion LEDs. In this work, we found that the stability of mixed halide CsPb(Br,Cl,1-x)I_x phase is related to the morphology. The morphologically modified mixed halide perovskites exhibited stable photoluminescence peaks with desired wavelengths and narrow bandwidths under extended illumination. Our results demonstrate a facile approach of creating stable halide perovskites with all-inorganic composition and desirable optoelectronic functionalities such as blue LEDs, narrow-band sensors.

ES10.03.05

Reactive Ion Beam Assisted Deposition of Rare Earth Cuprates

Stephen McCoy and Shane Cybart; Materials Science, University of California, Riverside, Riverside, California, United States.

Since the discovery of superconductivity in certain cuprates, these materials have been widely used for research in probing the phenomena of high temperature superconductivity. In particular, YBCO has been extensively studied. To further investigate this material, we have developed and tested a novel approach to growing films of thin films. During reactive sputtering we will introduce a reactive ion source (Reactive Ion Beam Assisted Deposition). We then looking at the transport properties as well as surface morphologies via SEM and AFM and compare film composition and phases with EDX and EBSD. We then make a comparison between reactive ion beam assisted film growth and ion beam assisted samples. We have developed unique single crystal thin films with rare earth series of cuprates containing Holmium and Lanthanum doped YBCO as well as PrBCO and others. We have combined these rare earth series of cuprates onto substrates that have not yet been investigated for rare earth cuprate growth such as NdGaO as well as LaAlO_xSr2TaAlO_y. We have shown transport properties of these materials that further back our claim of thin film single crystal materials.
ES10.03.06
Development of Ozone Gas Sensors Based on Delafossite Thin Films
Joao Afonso; Luxembourg Institute of Science and Technology, Belvaux, Luxembourg.

Ozone gas sensors development is a growing need in modern days, due to its increase use in several industry areas. A major problem is its production in office environment by lab equipments and laser printers. Ozone exposure can cause several long run cardiopulmonary problems. With this in mind there is the urge to develop efficient, cheap and office compatible sensors. Delafossite is an interesting p-type material that has shown its responsibility to ozone. With this in mind we will deeply explore delafossite properties and its responsibility to ozone as well as its integration into devices and understand the underlaying relation. Our delafossite films, are off-stoichiometry Cu$_{1-x}$Cr$_x$O$_2$ These films have interesting electrical properties having proven conductivities up to 100 S/cm. Our films are deposited by Metal Organic Chemical Vapor Deposition (MOCVD) and undergo annealing steps in order to control its electrical properties. These films are compatible with large area deposition and so scalable to industrial processes. We have been developing a state of the art etching process for delafossite with interesting results, leading into the patterning and the integration of the first devices, showing the responsibility to ozone depending on the device geometry.

ES10.03.07
Synthesis of Hydrated KTaWO$_4$ Nanoparticles and Sn(II) Incorporation for Visible Light Absorption
Morton Weiss, Thomas Bredow and Roland Marschall; Justus-Liebig-University Giessen, Giessen, Germany; 2University of Bayreuth, Bayreuth, Germany; 3University of Bonn, Bonn, Germany.

The defect-pyrochlore structured semiconductor KTaWO$_4$ has been prepared via hydrothermal synthesis, resulting in single-crystalline nanoparticles with adjustable crystallite size between 15 and 24 nm.[1] With subsequent ion-exchange of K with Sn(II) the band gap of this complex semiconductor can be reduced by 1.3 eV. We show that the ion-exchange is greatly facilitated by the incorporation of water molecules into the crystal lattice. Moreover, we have systematically investigated the effect of Sn(II) exchange on the band structure and subsequent photocatalytic properties. Different tin precursors show varying influence on the resulting band gap. While the optimum conditions diminish the band gap by up to 1.4 eV, the increase in visible light absorption does not correlate with an increase of photocatalytic activity. The incorporation of Sn(II) may result in smaller band gaps and an increased absorbance of visible light, but this is most likely due to coordination of water or methanol molecules to the incorporated Sn(II) atoms, leading to reduced optical band gaps. This is supported by quantum-chemical calculations of optical spectra.

ES10.03.09
Characterization of TiO$_2$/ZnO Nanocomposite Thin Films on Brass Substrates Prepared by Dip-Coating Process
Kai-Wen Cheng, Yung-Ling Chen and Kun-Dar Li; Material Science, National university of Tainan, Tainan, Taiwan.

In the past decades, the photocatalytic materials that directly convert solar light into chemical energy had been extensively explored for energy and environmental applications. There are some ways used to improve the photocatalytic activity of TiO$_2$, such as doping metal or non-metal ions, or combining TiO$_2$ with another semiconductor. The combination of two semiconductors provides a route to a more efficient charge separation, an increased lifetime of electron-hole pair, and enhanced interfacial charge transfer to absorbed surface of substrates. In this study, we demonstrate a simple method to synthesize TiO$_2$/ZnO nanocomposite thin films on brass substrates. First, TiO$_2$ seed layers are prepared by the sol-gel dip-coating process on brass substrate with a following heat treatment at 500°C for 1 h. Then, TiO$_2$/ZnO nanocomposite thin films with featured morphologies would be formed on the brass substrate. From AES depth profile analysis, it is rationally believed that the diffusion of zinc atoms and reaction with oxygen on the brass substrate surface could be the main mechanism of ZnO formation. As the numbers of coating layers are increased, the (101) peak of TiO$_2$ anatase phase becomes more obvious in XRD analysis and has a small value of FWHM with 0.236 and 0.280 for 5 and 7 layers, respectively. It is also found that the crystallinity of TiO$_2$/ZnO nanocomposite thin films is improved with the increase of film thickness. Furthermore, the photocatalytic activity is evaluated through the degradation efficiency of methyl blue under UV irradiation. In this study, the photocatalytic degradation efficiency of methyl blue for TiO$_2$/ZnO nanocomposite thin films can be achieved more than 46.73%. This investigation has provided a convenient and inexpensive method to synthesize TiO$_2$/ZnO nanocomposite thin films to enhance the development of nanostructures for photocatalytic applications.

ES10.03.10
Alloying Cu and Co with Pt Co-Catalyst Loaded on TiO$_2$ Nanosheets Enhances the Generation of Reactive Oxygen Species and Photocatalytic Degradation
Weixue He and Zhi Zheng; Xuchang Univ, Xuchang, China.

Semiconductor photocatalysis convert solar light to chemical energy represent a promising solution to addressing the current energy and environmental demands. The modification of semiconductor nanomaterials with metallic nanoconponents can promote the separation of electron/hole from photoexcited semiconductors by forming heterojunctions, thus exhibit enhanced photocatalytic activities and potential applications in this study, Pt based NPs, including Pt, PtCu and PtCuCo are employed as model co-catalysts to comparatively study their capability to enhance the photocatalytic activity of TiO$_2$ nanosheets. It was found that each of Pt, PtCu and PtCuCo can greatly enhance the photocatalytic activity of TiO$_2$ toward degradation of organic dyes. Using electron spin resonance spectroscopy, we demonstrated that deposition of Pt based NPs resulted in more production of reactive oxygen species including hydroxyl radicals, superoxide, and singlet oxygen. The enhancing effects of Pt based NPs on generation of ROS and photocatalytic activity showed same trend: PtCuCo > PtCu > Pt. The mechanism underlying the enhancement differences in Pt based NPs may be mainly related to electronic structure change of Pt in alloying with Cu and Co. These results are valuable for designing hybrid nanomaterials with high photocatalytic efficiency for applications in water purification and antibacterial products.

ES10.03.11
Focused Helium Ion Beam Induced Superconductor Insulator Transition in YBCO
Holly Grezdo, Ethan Cho, Hao Li, Jay LeFebvre and Shane Cybart; University of California, Riverside, Riverside, California, United States.

YBCO is a ceramic superconductor discovered in the late 80s with a transition temperature much higher than conventional metal superconductors. It has been difficult to incorporate into electronic applications because of its complexity and difficulty to process. YBCO electronics fabricated utilizing ion beam disorder to directly write electrical patterns show great promise. The key to this method is that modest levels of ion irradiation causes YBCO to change from a metal superconductor to an insulator. Controlling the dose with a finely focused helium ion beam allows for patterning of nanowires and Josephson tunnel devices. The degree of irradiation can be controlled to inflict various levels of damage. As the damage is increased, changes in the normal-state resistivity and temperature dependence can be seen.

We present the superconductor insulator transition as a function of ion irradiation using a helium ion microscope (HIM) to irradiate very thin films of YBCO. To study the junction barrier properties, we use the HIM in the broad beam mode to irradiate a well-defined region. By holding the energy constant, and only varying the dose, we can study the impact at different levels of damage. As the YBCO shifts from superconductor to insulator, the resistivity also changes. To study this effect, we compare and contrast structural materials characterization with electrical transport measurements. Specifically, we measure the resistivity of the irradiated region as a function of temperature and analyze the superconducting transition, normal state resistivity, and temperature independent residual resistivity.

ES10.03.12
Fabrication of ZnO/TiO$_2$ Nanofibers and Their Photocatalytic Activity for Particulate Matter Removal
Chang-Gyu Lee, Kyeonghan Na, Wan-Tae Kim, Dong-Chool Park and Won-Youl Choi; 1Dept. of Advanced Materials Engineering, Gangneung-Wonju National University, Gangneung, Korea (the Republic of); 2WithMtech Co. Ltd., Suwon, Korea (the Republic of); 3Research Institute for Dental Engineering, Gangneung-Wonju National University, Gangneung, Korea (the Republic of).

TiO$_2$ nanomaterials have potential electrical and photochemical applications because of their unique physical and chemical properties. One-dimensional TiO$_2$ nanofibers have been studied in particulate matter (PM) removal applications due to their large specific surface area and high photocatalytic reactivity. To improve the photocatalytic activity, ZnO/TiO$_2$ nanofibers having high adsorption is recently suggested. To fabricate the ZnO/TiO$_2$ nanofibers, electrospinning method which can efficiently produce a nanofiber at low cost was used. The precursor including zinc nitrate hexahydrate, polyvinyl acetate, and titanium isopropoxide was prepared and applied to various electrical fields. The in-
situ ZnO/TiO$_2$ nanofibers were analyzed by Thermogravimetric Analysis (TGA) to get an information of combustion behavior. The rutile phase and diameter of 200 to 300 nm in annealed ZnO/TiO$_2$ nanofibers at 600 were observed by X-ray diffraction (XRD) and field emission scanning electron microscopy (FE-SEM), respectively. To analyze the photocatalytic activity in the atmosphere, NO gas was used as a reaction model material. The photochemical reaction rate of 7% was measured by the reaction time, and the photocatalytic activity in ZnO/TiO$_2$ nanofiber were higher than 3% that in TiO$_2$ nanofiber. Photocatalytic properties of ZnO/TiO$_2$ nanofiber will be able to apply to various fields such as moisture separation, environmental purification, super surface, sensor, and disinfection.

**ES10.03.13**

**Dopant Incorporation in Polycrystalline Diamond for PN Junction Fabrication**

Amber Wingfield, Gary L. Harris and Aaron Jackson; Howard University, Washington, District of Columbia, United States.

Diamond, via its extreme properties, presents itself as a material capable of pushing the electronics industry beyond current limitations. It’s ultra-high thermal conductivity, wear resistant, electrically insulating and chemically inertness are just some of diamond’s outstanding properties. Although diamond is an insulator by nature, its wide band gap should allow for incorporation of a variety of donors and acceptors. With an appropriate concentration of either, the material will take on n-type or p-type semiconductor characteristics that can lead to the fabrication of diamond p-n junctions. These p-n junctions have potential application as high temperature and high power operating devices.

In this research, we will detail the characteristics of boron doped p-type and phosphorus doped n-type polycrystalline diamond grown on 6H silicon carbide using a hot-filament chemical vapor deposition system (HF-CVD) in preparation of p-n junction fabrication. Diamond nanoparticles are used to prepare the surface of silicon carbide substrates to enhance nucleation during heteroepitaxial growth. Boron doping is performed by two different methods: 1. In situ during diamond growth via vaporization of solid boron and 2. a pre-deposition followed by a drive in using a boron oxide diffusion source. Phosphorus doping is performed in the same manner as the second method stated using a phosphorus oxide diffusion source. Raman spectroscopy, Hall measurements, and secondary ion mass spectroscopy (SIMS) analysis is conducted to verify diamond quality, active incorporation, and dopant concentrations.

This work is supported by the STC Center for Integrated Quantum Materials, NSF Grant No. DMR-1231319. This work was performed in part at the Harvard University Center for Nanoscale Systems (CNS), a member of the National Nanotechnology Coordinated Infrastructure Network (NNCI), which is supported by the National Science Foundation under NSF award no. 1541959.

**ES10.03.14**

**Thermal Rectifier in a Melamine Containing Bi-Component Hydrogel**

Ting Meng, Xianjian Wu, Chao Wu, Xiao Zhang, Juekuan Yang, Ping Gu, Jinglei Yang and Yang Zhao; 1; Micro&Nano Thermal Science Lab, University of Science and Technology of China, Hefei, China; 2; University of Science and Technology of China, Hefei, China; 3; Southeast University, Nanjing, China; 4; The Hong Kong University of Science and Technology, Hong Kong, Hong Kong.

Thermal rectifier, which transports heat preferentially in one direction, plays a significant role in thermal circuits. An efficient thermal rectifier should exhibit great different thermal conductivity with the forward and reversed temperature gradient. Thus, the rectifying coefficient defined by the ratio of $k_r$ and $k$. However, the majority of thermal rectifiers show low rectifying coefficient or have a rigorous temperature requirements. In this work, we show an efficient thermal rectifier in a temperature-sensitive hydrogel containing melamine and 6,7-dimethoxy-2,4[(H$_3$H$_3$)]-quinazolinolindone in molar ratio 1:1 at 303K. DSC and rheology results indicate that a thermoreversible first order phase transition occurs when the temperature rises above its upper-critical-solution-temperature (UCST), which can be owned to H-bonding breakage suggested by the Raman-spectra. In this study, the suspended micro-device based on the differential bridge method is applied to measure the thermal conductivity of single hydrogel nanofiber picked out from the dispersion. The thermal conductivity of hydrogel nanofiber reveals an abrupt change with the phase changes. This study provides an efficient realization of a thermal rectifier for heat management that could be implemented in moderate temperature with high rectifying coefficient.

8:30 AM *ES10.04.01*  

**Water Splitting Using Photocatalyst Systems with Hierarchical Structures**

Takashi Hisatomi and Kazunari Domen; Shinsyu University, Nagano, Japan.

Sunlight-driven water splitting has been studied actively for production of renewable solar hydrogen as a storabe and transportable energy carrier [1,2]. Both the efficiency and the scalability of water-splitting systems are important factors because of the low areal density of solar energy. Photocatalyst systems do not involve any secure external electric circuit and thus can be spread over a wide area by inexpensive processes.

The authors’ group has been developing panel-type reactors that can accommodate particulate photocatalysts thinly fixed on substrates [3]. Al-doped SrTiO$_3$ is a photocatalyst that can split water at an apparent quantum yield of up to 69% at 365 nm [4]. Photocatalyst sheets based on Al-doped SrTiO$_3$ contained in a panel-type reactor split water into hydrogen and oxygen and release gas bubbles at a rate corresponding to a solar-to-hydrogen energy conversion efficiency of 10% under intense UV illumination even when the water depth is merely 1 mm. Moreover, it is possible to maintain the intrinsic activity of the photocatalyst sheets when the size of the panel is extended to the scale of 1 m$^2$. It is likely feasible to build panel-type photocatalytic reactors suitable for scale-up using lightweight materials inexpensively. Accordingly, development of photocatalyst systems that can split water under visible light irradiation efficiently is a key issue of the research field.

We have developed particulate photocatalyst sheets consisting of hydrogen evolution photocatalysts (HEPs) and oxygen evolution photocatalysts (OEPs) embedded into conductive layers by particle transfer [5-9]. The photocatalyst sheet shows significantly higher water splitting activity than the corresponding powder suspension systems, because conductive matrices transfer photogenerated electrons between HEP and OEP particles effectively. In addition, evolution of hydrogen and oxygen in close proximity prevents generation of the pH gradient during the water splitting reaction. Therefore, the photocatalyst sheet is scalable without sacrificing the high activity. A photocatalyst sheet consisting of La- and Rh-codoped SrTiO$_3$ as the HEP and Mo-doped BiVO$_4$ as the OEP embedded into a carbon conductor exhibits a solar-to-hydrogen energy conversion efficiency of 1.0% at ambient pressure [8]. Photocatalyst sheets can also be prepared by ambient-pressure processes, namely by screen-printing photocatalyst ink containing transparent conductive oxide colloids [9].

It has been known that Ta$_x$N$_y$ has a band structure suitable for water splitting under visible irradiation of up to 600 nm since 2002 [10,11], but overall water splitting had not been achieved because of high densities of trap states. We have activated Ta$_x$N$_y$ in overall water splitting under visible light by developing an innovative nitrlation process [12]. Ta$_x$N$_y$ single crystal nanorods can be directly evolved on particulate KTaO$_3$ by short-time nitrlation accompanied by gradual evaporation of K contents. Ta$_x$N$_y$ single crystal nanorods have low defect densities and can utilize photoexcited carriers in the water splitting reaction when being loaded with appropriate cocatalysts.

In this talk, development of photocatalyst systems involving hierarchical structures will be presented.

Semiconductor Electrodes for Integrated Photo-Electrochemical Water Splitting Lianzhou Wang; University of Queensland, St Lucia Brisbane, Queensland, Australia.

Semiconductor materials hold the key for efficient photocatalytic and photoelectrochemical water splitting. In this talk, we will give a brief overview of our recent progresses in designing semiconductor nanomaterials for photoelectrochemical energy conversion including photocatalytic solar fuel generation. In more details, we have been focusing the following a few aspects; 1) band-gap engineering of layered semiconductor compounds including layered titanate, tantalate and niobate-based metal oxide compounds for visible light photocatalysis, and 2) two-dimensional nanosheets/nanoplates of TiO\textsubscript{2}, Fe\textsubscript{3}O\textsubscript{4}, WO\textsubscript{3}, BiVO\textsubscript{4} as building blocks for new photoelectrode design, and 3) the combination of a high performance photocatalyst BiVO\textsubscript{4} with perovskite solar cells can lead to unassisted solar driven water splitting process with solar-to-hydrogen conversion efficiency of >6.5%.\textsuperscript{1,4} The resultant material systems exhibited efficient visible light photocatalytic performance and improved power conversion efficiency in solar energy, which underpin important solar-energy conversion applications including solar fuel generation and simultaneous environmental application.

Studying Photo-Induced Charge Transfer with Quantum Dots and Molecular Catalysts Assembly for Photocatalytic Applications Nihaarika Krishna Botcha, RR Gutha, SM Sadeghi and Anusree Mukherjee; The University of Alabama in Huntsville, Huntsville, Alabama, United States.

Photocatalytic water splitting using solar energy for hydrogen production offers a promising alternative form of storable and clean energy for the future. Light driven proton reduction requires a three-component system with a photosensitizer (light harvesting unit) that transfers electrons to a catalyst that reduces protons and a sacrificial donor. To make this process cost-effective, we need an inexpensive, durable and efficient catalyst that is capable of reducing protons from water to produce hydrogen and we need to couple this catalyst to a photosensitizer that could supply the energy required for water splitting.

Quantum dots (QDs) have high extinction coefficients across a broad range in the solar spectrum and can simultaneously absorb multiple photons, or continuously absorb multiple photons even after the electrons and holes are accumulated. These characteristics make QD the perfect candidates for photosensitizers in solar fuel generation when they are properly coupled to efficient catalyst for hydrogen generation.

Nature provides an attractive inspiration for the reductive cycle of water splitting in the form of hydrogenases using earth abundant and inexpensive transition metals in the active site. Transition metals are useful because of their redox activity, their capability to bind and exchange ligands and their high charge density. As a result, many homogeneous catalytic systems incorporate transition metals.

The fundamental step for photocatalysis is to generate a charge separated state. In order to couple a catalyst for proton reduction to a photosensitizer, it is essential to understand the mechanism of charge transfer or photoinduced electron transfer from the photosensitizer to the catalyst. Hence our work is focused on the study of light driven production of hydrogen from QD systems by modification with reduction catalysts. We synthesized and characterized a variety of nickel and copper complexes of tetradeutate ligands with amine and pyridine functionalities (N\textsubscript{2}/Py\textsubscript{2}) and studied their interactions with Cadmium Telluride QDs stabilized by 3-mercaptopropionic acid (MPA-CdTe QDs). The studies performed include absorbance and emission spectroscopic behavior as well as lifetime measurements that will give us a direct insight into the photo-induced charge transfer process.

Self-Optimized Photocatalysts—Hot-Electron Driven Selective Photo-Synthesis of Catalytic Nanoparticles Evgenia Kontoleti, Sven Askes and Erik Garnett; AMOLF Institute, Amsterdam, Netherlands.

It is well known that plasmonic gold nanostructures feature extraordinary capability of absorbing visible light and concentrating the excitation energy in subwavelength volumes. Recently, they have also been applied for catalyst production for the production of chemical fuels from sunlight. Upon excitation of these nanostructures, the energy is transferred to single electrons that for a brief period of time become highly energetic. Recent scientific advances demonstrate that these highly energetic, “hot” electrons can be extracted and used to drive chemical reactions, such as the conversion of protons to molecular hydrogen. However, to greatly improve the production rate, expensive and rare cocatalysts such as platinum are required.

In order to make effective use of as little catalyst material as possible, it is therefore important to localize the cocatalyst at the places where it is best coupled to the photogenerated hot electrons. To this end, we use the hot electrons themselves to deposit the cocatalyst and to construct photocatalytically active nanostructures. Briefly, a photocathode consisting of ITO-gold nanoslands-TiO\textsubscript{2} was illuminated with red light in presence of PtCl\textsubscript{6}\textsuperscript{4-}, which resulted in the local deposition of platinum nanoparticles on the gold nanoslands. We furthermore compare the photocatalytic performance of these photocathodes, where the platinum nanoparticles were selectively deposited, with those that were fabricated by a random-deposition technique, i.e. electrodeposition. Indeed, the samples where the cocatalyst was locally-deposited, with hot-electron chemistry, showed higher catalytic activity in photocurrent measurements in presence of a phosphate buffer. Therefore, it seems that indeed the location of the cocatalytic material on the plasmonic photocathodes, and maybe generally on photoactive materials, plays a crucial role.

Overall, these results demonstrate that plasmonic hot electron chemistry can be used for fabricating photocatalytic nanostructures with sub-wavelength control over localization. This careful design of photoelectrodes with nanoscale precision, could open up a new way for higher photocatalytic efficiencies as well as lower fabrication costs.

Photocatalytic water splitting and CO\textsubscript{2} reduction are attractive reactions to convert photon energy to chemical energy, and hence they are called as artificial photosynthesis. The...
photocatalyst systems for water splitting and CO\(_2\) reduction can be divided into powdered and photoelectrode types. In both types, photogenerated electrons have to migrate to photocatalyst particles to other particles or conductive substrates. In the present study, we successfully developed new photocatalyst systems for water splitting and CO\(_2\) reduction upon combining photocatalysts and a conductive reduced graphene oxide (RGO).

In a powder-based photoelectrode system in which the photocatalyst particles are loaded on a conductive substrate, photogenerated carriers in a particle need to migrate to the conductive substrate through other particles. We found that the photoelectrochemical performance is improved upon incorporating the RGO in the photoelectrode due to the boosted electron transfer from the particles to the substrate by the RGO. The incorporation of the RGO was effective for both n- and p-type semiconductor materials.

A powdered Z-scheme system consists of two different photocatalysts and an electron mediator. Although ionic redox couples are usually used as the electron mediator, we found that the RGO works as a solid-state electron mediator. Additionally, we successfully utilized photocorrosive metal sulfides as an H\(_2\)-evolving photocatalyst when the RGO was used. The developed Z-scheme system showed the activity for CO\(_2\) reduction as well as water splitting under visible light irradiation.

Janus-Type MnO\(_x\)-Ag\(_x\) Nanoparticles as Self-Sensitized Photochemical Water Oxidation
Jie He; University of Connecticut, Storrs, Connecticut, United States.

Janus nanoparticles (NPs) containing two chemically distinct materials in one system are of great significance in nanocatalysis in terms of harnessing catalytic synergies that are not exist in either component. We herein present a novel synthetic method of Janus-type MnO\(_x\)-Ag\(_x\) NPs consisting of n-type MnO octahedrons and p-type Ag NPs for efficient photocatalytic water oxidation. The synthesis of Janus-type MnO\(_x\)-Ag\(_x\) NPs is based on the oxidative nucleation and growth of Ag domains on MnO first and the subsequent iodization of Ag. A mild, non-disruptive iodization strategy is developed to yield Janus MnO\(_x\)-Ag\(_x\) NPs in which converting Ag to AgI domains with iodomethane (CH\(_3\)I) is achieved through the partial iodization. Simultaneously, Mn\(^{2+}\) species in the primary MnO octahedrons are oxidized during the growth of Ag NPs, leading to the formation of n-type MnO\(_x\) domains. Therefore, as-resultant Janus-type MnO\(_x\)-Ag\(_x\) NPs combining two semiconductors into an integrated nanostructure can be used as an efficient self-sensitized photocatalyst for visible light-driven water oxidation. Janus MnO\(_x\)-Ag\(_x\) NPs show a superior photocatalytic activity (358 mmol O\(_2\) per mg\(_{\text{catalyst}}\) in 4 min) even in the absence of [Ru(bpy)]\(^{3+}\) as a photosensitizer. This intriguing synthesis may open up a new opportunity to develop silver halide asymmetric nanostructures that will potentially be efficient photocatalysts for solar-driven water splitting.

Comparing Catalyst-Mass-Normalized Activity and Approximated Quantum Yields for Polychromatic Photocatalytic Systems
Larissa Y. Kunz, Anan Majumdar and Matteo Cargnello; Stanford University, Stanford, California, United States.

In spite of the potential of using photocatalysts to sustainably produce fuels and chemicals, overall reaction rates remain prohibitively low, limited by recombination of photogenerated electrons and holes. Extensive work can be found in the literature on suppressing this recombination by addition of co-catalysts. However, much of the reported data on photocatalytic activity are rendered ineffectual in the rational design of new, improved catalyst systems by the common practice of reporting activity on a catalyst mass basis. In this work, using a model system of TiO\(_2\) and g-C\(_3\)N\(_4\) with Pt, we show that normalizing photocatalytic rates by mass is non-physical and can even artificially enhance the apparent performance of a two-photosabsorber system relative to that of the individual components. A mathematical method is presented for approximating a system’s quantum yield from measured reaction rates under simulated solar or otherwise polychromatic light. A sensitivity analysis was performed on this method, demonstrating how the approximated quantum yield can be used to evaluate the degree of relative enhancement introduced by mass-normalizing photocatalytic reaction rates for any set of photosabsorbing co-catalysts.

SESSION ES10.05: Photocatalytic Water Splitting II

Cocatalysts Decorated Amorphous Silicon Photoanodes for Efficient Bias-Free Water Splitting
Jian Zhang; Guilin University of Electronic Technology, Guilin, China.

Silicon materials have many advantages, including earth-wide, wide spectra absorption, high solar to chemicals conversion efficiency, suitable band edge. However, the amorphous silicon-based photoelectrode is very easily to be corroded by electrolyte. In the presentation, cobalt oxide by magnetron sputtering at ambient temperature was introduced as a protective layer in water oxidation, and atomic Pt as HER cocatalysts prepared by magnetron sputtering method on thin film silicon was used for water reduction. The photoanode delivered a current density of 7.3 mA cm\(^{-2}\) at 1.23 V vs. RHE, and the onset potential was negative shift to 0.62 V. The photocathode current density at the 0 V vs RHE was increased to 12.03 mA cm\(^{-2}\) in 1M KOH electrolyte with the onset potential of 0.82 V. The Pt/Si faradic efficiency was ~100% and the fill factor was 38% that was the highest value among Si-based PEC system. Pt and CoO\(_2\) strengthened the inner electric field and passivated the surface of photoelectrodes. The dual-amorphous silicon photoelectrodes integrated CoO\(_2\) and Pt realized the bias-free water splitting at 0.81 V with a photocurrent of 1.5 mA cm\(^{-2}\) and 0.92 % of the solar to hydrogen efficiency. The novel amorphous silicon photoanode provides a promising strategy for photo-electrochemical energy conversion and storage.

Plasmonic Driving of Chemical Reactions
Jianfang Wang; Department of Physics, The Chinese University of Hong Kong, Shatin, Hong Kong.

Plasmonic metal nanocrystals can interact strongly with light, efficiently converting light into heat and generating hot carrier charges. Both plasmonic photothermal conversion and hot carrier generation can accelerate chemical reactions. The use of plasmons to drive chemical reactions has recently become a new and active research field. Plasmonic hot charge carriers can not only enhance the reaction yield and selectivity, but also introduce new reaction pathways.

The lifetime of plasmonic hot charge carriers is on the femtosecond scale. Without immediate usage, they will rapidly relax, converting their energy into heat. We have employed two approaches to enable the use of plasmonic hot charge carriers. The first is the integration of Au or Ag nanoparticles with Pt or Pt nanoparticles. Au and Ag nanoparticles possess strong localized plasmons, while Pt and Pt nanoparticles are excellent catalysts for many chemical reactions. Combination of the two types of metal nanoparticles can lead to efficient light absorption and generation of plasmonic hot charge carriers, which can subsequently inject into molecules that are adsorbed on the Pt or Pt component. We have applied this approach to enhance Suzuki coupling reactions by localized plasmons.
The second is the integration of plasmonic metals with semiconductors. A barrier is formed at the interface. The generated hot electrons and holes can quickly inject into the bandgap or valence band and therefore get separated. The injected charge carriers can then drive chemical reactions. We have synthesized Au/ TiO\textsubscript{2}, Au/CoO; and Au/ BiOCl hybrid structures as plasmonic photocatalysts to drive the photo-generation of reactive oxygen species, the selective oxidation of alcohols, and N\textsubscript{2} photofixation. Specifically, oxygen vacancies have been introduced in the metal oxides to “work in-tandem” together with plasmonic hot charge carriers. For example, during the use of Au/BiOCl hybrid structures for the photocatalytic selective oxidation of benzyl alcohol, oxygen vacancies on BiOCl facilitate the trapping and transfer of plasmonic hot electrons to adsorbed O\textsubscript{2}, producing superoxide anion radicals, while plasmonic hot holes remaining on the Au surface mildly oxidize benzyl alcohol to corresponding carbon-centered radicals. The ring addition between these two radical species leads to the production of benzaldehyde along with an unexpected oxygen atom transfer from O\textsubscript{2} to the product. In contrast, the oxygen atom in the product is from the benzyl alcohol reactant.

In another example, Au nanoparticles are anchored on ultrathin TiO\textsubscript{2} nanosheets with oxygen vacancies. The oxygen vacancies on the nanosheets chemisorb and activate N\textsubscript{2} molecules, which are subsequently reduced to ammonia by hot electrons generated from plasmon excitation of the Au nanoparticles. The hybrid photocatalyst can accomplish photodriven N\textsubscript{2} fixation in the “working-in-tandem” pathway at room temperature and atmospheric pressure. The apparent quantum efficiency of 0.82% at 550 nm for the conversion of incident photons to ammonia is higher than those reported so far. The oxygen vacancies play three roles. They act as the active sites for N\textsubscript{2} molecules; they cause defect states within the bandgap for trapping plasmonic hot electrons and therefore lengthening their lifetime; and they function as a bridge between plasmonic hot electrons and the activated N\textsubscript{2} molecules. This work offers a new approach for the rational design of efficient catalysts towards sustainable N\textsubscript{2} fixation through a less energy-demanding photocatalytic process compared to the industrial Haber-Bosch process.

4:00 PM ES10.05.03
Silicon Photocathodes with Integrated Catalysts Perform Selective CO\textsubscript{2} Reduction to Hydrocarbons and Oxygenates
Gurunavlaj Gurunavala\textsuperscript{1, 2} and Joel W. Ager\textsuperscript{1, 2}; 1Joint Center for Artificial Photosynthesis, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2School of Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States.

Photocathodic (PEC) devices combine light capture, charge separation, and electrocatalysis to drive solar to chemical energy conversion. Silicon based photocathodes integrated with co-catalysts have been studied extensively for solar fuels production, especially for the hydrogen evolution reaction of PEC water splitting. In contrast, Si photocathodes that drive the more challenging CO\textsubscript{2} reduction (CO\textsubscript{2}R) reaction are fewer in number and, with only a few exceptions, produce 2 electron products such as CO or formate.\textsuperscript{2} Here we show that Si photocathodes integrated with nanostructured bimetallic catalysts perform light-driven conversion of CO\textsubscript{2} to C\textsubscript{2}H\textsubscript{4} and C\textsubscript{2}H\textsubscript{5}OH products. In contrast to conventional photocathode designs which employ p-type absorbers, we employ a back illumination geometry with an n-type Si absorber to permit the use of absorbing metallic catalysts which would otherwise block the light. Back and front interfaces were configured by ion implantation and by surface passivation to achieve carrier selectivity. Surface texturing of the Si was used optimize light absorption on the illuminated side and increase the surface area available for catalysis on the electrolyte side. Based on our prior work with bimetallic cascade catalysis,\textsuperscript{3} we employed a hierarchical Au-Cu or Ag-Cu nanostructures to drive CO\textsubscript{2}R to C-C coupled products.

The photovoltaic, 550-600 mV under simulated 1-sun illumination, confirms the carrier selectivity and passivation of the front and back interfaces. Compared to planar controls, textured photocathodes generate higher current densities, exceeding 30 mA/cm\textsuperscript{2}. Under simulated diurnal illumination conditions in CO\textsubscript{2}-saturated 0.1 M CsHCO\textsubscript{3} electrolyte, over 60% faradic efficiency to C\textsubscript{2}- hydrocarbon and oxygenate products (mainly ethylene, ethanol, propanol) is maintained for several days. Over longer testing periods, contamination from the counter electrode is observed, which causes an increase in hydrogen production. This effect is mitigated by a regeneration procedure which restores the original catalyst selectivity. A tandem, self-powered CO\textsubscript{2}R reduction device was also demonstrated by coupling a Si photocathode with two series-connected semitransparent CH\textsubscript{3}NH\textsubscript{2}PbI\textsubscript{3} perovskite solar cells, achieving an efficiency for the conversion of sunlight to hydrocarbons and oxygenates of 1.5% (3.5% for all products).

4:15 PM ES10.05.04
Photocatalytic Hydrogen Generation in CdSe Quantum Dot–Pb\textsubscript{1.1}Pb\textsubscript{0.9}V\textsubscript{2}O\textsubscript{5} Nanowire Heterostructures, Mediated by Midgap States
Junsang Cho\textsuperscript{1, 2}; Sarbajit Banerjee\textsuperscript{3} and David Watson\textsuperscript{1}; 1Chemistry, University at Buffalo, The State University of New York, Buffalo, New York, United States; 2Chemistry, Texas A&M University, College Station, Texas, United States; 3Materials Science and Engineering, Texas A&M University, College Station, Texas, United States.

We are integrating theory and experiment to design, synthesize, and characterize semiconductor heterostructures with programmable light harvesting and charge transfer for photocatalysis. Heterostructures consist of M\textsubscript{V\textsubscript{2}}O\textsubscript{5} nanowires (NWs), where M is an intercalated metal cation, interfaced with quantum dots (QDs). Intercalation of metal cations gives rise to midgap electronic states in the NWs, which are well-positioned to accept photogenerated holes from QDs, facilitating charge separation and redox photocatalysis. We previously demonstrated that photocatalysis of cadmium chalcogenide QDs, within heterostructures, is followed by the transfer of holes to midgap states of NWs on sub-picosecond time scales.\textsuperscript{1} This presentation will focus on recent research to evaluate the heterostructures in photoelectrochemical hydrogen evolution and photocatalytic water splitting. Photoelectrochemical measurements revealed that CdSe/Pb\textsubscript{1.1}Pb\textsubscript{0.9}V\textsubscript{2}O\textsubscript{5} heterostructures exhibited (3.2 ± 0.4)-fold greater photocurrents than corresponding CdSe/V\textsubscript{2}O\textsubscript{5} heterostructures (where the V\textsubscript{2}O\textsubscript{5} NWs lack midgap states) following selective excitation of CdSe QDs and (5.7 ± 0.3)-fold greater photocurrents under white-light illumination. Photocurrents arose from the reduction of aqueous H\textsuperscript{+} to H\textsubscript{2} with high Faradic efficiencies of 92% ± 5% in 0.33 M sulfuric acid solution. These results are consistent with a mechanism in which excited-state interfacial hole transfer facilitates charge separation and photocatalysis, and suggest that the CdSe/Pb\textsubscript{1.1}Pb\textsubscript{0.9}V\textsubscript{2}O\textsubscript{5} heterostructures are indeed promising architectures for light harvesting and photoelectrochemical water splitting. This presentation will highlight these results, as well as recent experiments on second-generation heterostructures with optimized interfacial energetics.

4:30 PM ES10.05.05
The Optical Spectrum of UVLED Excitation Using NTC Nanometer Particulate Exchange to Replace Rare Earth Doping
Lihong Su\textsuperscript{1}; Kan Chen\textsuperscript{1}; Yongqiang Liu\textsuperscript{1}; Ziao Zou\textsuperscript{1}; Lihua Su\textsuperscript{2} and Juancheng Wang\textsuperscript{3}; 1Northwest Polytechnical University, Xi'an, China; 2Shaanxi Zoomview Company, Xi'an, China; 3University of Southampton, Southampton, United Kingdom; 4Xi'an Communicate Institute, Xi'an, China.

Ultraviolet light-emitting diodes (UVLEDs) with phosphor materials have considerable advantages over traditional illumination devices. Doping with rare earth ions can modify the optical spectrum of phosphor materials, but rare earths are very expensive. Thus, replacing rare earths with a common material would provide a great potential for the wide application in the future. In this study, we discovered that a novel type of semiconductor nanometer powder, namely manganese cobalt nickel copper oxide (MCNC), is able to emit blue-green wavelength spectrum when excited by 365–400nmUVLED. In addition, MCNC shows less attenuation of luminescence efficiency than other UVLED phosphor materials doped with rare earths with temperature increase. It is thus concluded that MCNC is a promising low-cost material to replace rare earths to adjust the optical spectrum wavelength of UVLED. This is the first time that nano-scale MCNC is reported to change the optical spectrum wavelength of UVLED. This provides a new mechanical and nanometer phosphor material without rare earth doping to shift the wavelength spectrum.
Plasmonic materials have attracted much attention owing to their unique surface plasmon effect (SPP) by photoluminescence. As a typical anisotropic plasmonic material, gold nanorods (GNRs) have advantages of good biocompatibility, adjustable light response between 550 - 1550 nm and high chemical stability. In recent years, studies show gold nanorods can enhance the photocatalytic activity of semiconductor materials, but most of the inorganic semiconductors are used for photocatalysis which absorb spectrum lies in ultraviolet region. In order to improve the utilization of visible light, efficient photocatalysts with visible light responsive need to be designed and prepared. Porphyrin assembly is an organic semiconductor material with excellent photoelectric properties. Compared with traditional inorganic semiconductor materials such as TiO$_2$, the absorption spectrum of the porphyrin is located in the visible light region, which can make use of solar energy more effectively, but Pt must be added as co-catalyst. Therefore, the paper chooses gold nanorods and porphyrin assemblies to make a composite, in order to make use of more efficient solar energy utilization materials. Here, we synthesized a gold nanorods-porphyrin core-shell structure via a surfactant-assisted self-assembly induced acid-base neutralization micelle encapsulation method. The fabrication of composite was achieved by adjusting the length diameter ratio of GNRs, the type and concentration of surfactants, and pH. By regulating the reaction parameters, the composite structure with regular morphology, uniform size and good monodispersibility was prepared by using CTAB/NaOH coated GNRs with a length/diameter ratio greater than 4. Combined with TEM and the dynamic tracking experiment indicated the composite structure was the core-shell structure of porphyrin assemblies covering GNRs. The XRD result showed the GNRs-ZnPpy core-shell structure had good lattice structure. The photocurrent test showed that the photocurrent density of GNRs-ZnPpy-core-shell structure and ZnPpy core-assemblies was about 2.0 μA/cm$^2$ and 0.8 μA/cm$^2$ respectively, and the core-shell structure was 2.5 times as high as that of self-assemblies. Using ascorbic acid (AA) as electron donor, the visible light photocatalytic hydrogen production without Pt of different catalyst systems were carried out under pH ≈ 5.0. Under the same condition, the GNRs-ZnPpy core-shell structure had a H$_2$ production rate of 37 nmol/g, which was 15 times of the physical mixing.

Ultra Small Metal Oxide/Phosphide Clusters Anchored on TiO$_2$ Nano-Sheets Remarkably Enhance Photocatalytic H$_2$ Generation Yun Gao, Xiao Luo, Yuwen Bao and Jingting Si; Hubei University, Wuhan, China.

Converting solar energy into hydrogen fuels through photocatalytic water splitting is a promising way for solving the energetic and environmental problems. The development of an efficient, robust, low cost and noble-metal-free catalyst for H$_2$ evolution is of great importance for both scientific research and technological application. Downscaling the co-catalyst particles to sub-nano clusters and even single atom helps to enlarge the active sites and thus dramatically improves the H$_2$ generation. Therefore, it is important to develop a general method to synthesize the sub-nano cluster co-catalysts. In this presentation, we report the synthesis of sub-nanometer Fe, Co, Ni oxide and phosphide as co-catalysts anchored on the 2D ultrathin TiO$_2$ nanosheets by a facile two-step hydrothermal method. The 2D ultrathin TiO$_2$(B) nanosheets are prepared firstly by a hydrothermal method. In the second step, the prepared TiO$_2$(B) nanosheets are added into the solution as the nucleate substrate for the formation of transition metal oxide and phosphide. The microstructures of the samples are examined by HAADF-STEM performed on a JEOL JEM-ARF200F. In the water splitting measurement, 20% methanol aqueous solution is used as the hole sacrificial agent, and the generated hydrogen production is sampled and analyzed by gas chromatography (GC-2018, Shimadzu, Japan, TCD). The energy band structure at the interface of the hybrid catalysts is analyzed to understand the H$_2$ generation mechanism. It is found that, the cluster sizes of transition metal oxide and phosphide anchored on the surface of TiO$_2$ nanosheets are drastically reduced to sub-nanomter range, while their counterpart products without adding TiO$_2$(B) nanosheets keep the size larger than tens nanometers. A remarkably enhanced and highly stable photocatalytic activity is obtained by using the hybrid composite catalysts. In addition, the photocatalytic activity is affected by the PH value in the water splitting process. As the size of transition metal oxide and phosphide is reduced to certain scale by carefully adjusting the hydrothermal reaction condition, the maximum photocatalytic activity of the composite catalysts could exceed that using Pt cluster as the co-catalysts. When metal oxide is used as co-catalyst, the charge transfers from TiO$_2$ to the co-catalyst, reducing the oxide into metallic cluster, and thus enhances the photocatalytic activity. On the other hand, metal phosphide clusters act as the active site and accept the photo-generated electrons transferred from the conduction band of TiO$_2$. This leads to a significant improvement of the H$_2$ generation efficiency. In conclusion, the 2D ultrathin TiO$_2$(B) nanosheets with huge specific surface area and abundant surface defects provide plenty of effective scaffold and nucleation sites for the Fe, Co, Ni metal oxide and phosphide to nucleate and firmly anchor on the surface of TiO$_2$(B) nanosheets. The stable nucleation interface not only provides a high efficient charge separation and transfer route, but also helps to maintain the microstructure of the composite catalysts and keep the long term stability of the H$_2$ generation efficiency. The composite catalysts developed in this work can be used to replace and indeed out-perform noble metals, such as Pt, as effective and stable H$_2$ evolution co-catalysts.

Controlling Stoichiometry and Morphology in Tin-Halide Perovskite Films Deposited by Carrier-Gas Assisted Vapor Deposition Catherine P. Clark; Ersay S. Aydil and Russell J. Holmes; 'Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, Minnesota, United States; 'Tandon School of Engineering, New York University, Brooklyn, New York, United States.

Carrier-gas assisted vapor deposition (CGAVD) is used to systematically control the growth of CH$_3$NH$_3$SnBr$_3$ thin films across a wide range of stoichiometries and morphologies. Our home-built CGAVD system enables more precise morphological control as compared to high-vacuum physical vapor deposition methods, as well as the ability to grow multi-layered perovskite stacks which are typically inaccessible using solution processing. Here, tin-halide perovskite films are grown via co-deposition of CH$_3$NH$_3$X and SnX$_2$ (X = I, Br), where each component vapor is carried from a hot source to a cool substrate by means of a N$_2$ carrier gas stream. CGAVD offers a broad selection of processing parameters, allowing us to tailor stoichiometry, grain size and film texture. Chief among these are the source material temperature (T$_{source}$ = 140 °C – 290 °C), carrier gas flow rate (V$_{flow}$ = 2 sccm – 100 sccm), substrate temperature (T$_{sub}$ = 8 °C – 40 °C), and chamber pressure (P = 350 mTorr – 10 Torr). In varying these parameters, we have realized corresponding changes in grain orientation and grain size from ~100 nm to over 1 µm. Moreover, the morphologies accessed using this technique are consistent across many substrates, including quartz, silicon, ITO, CaTiO$_3$, and PEDOT:PSS, allowing facile integration of CGAVD films into different device-relevant architectures while maintaining the same morphology. Having established optimized deposition conditions for CH$_3$NH$_3$SnBr$_3$, CGAVD can be applied to other halide perovskite systems to enable growth of previously inaccessible morphologies and multi-layer perovskite structures.

Defect Chemistry-Inspired Design of Ir$^{3+}$/FeO$_2$ Single-Atom Catalyst for Water Splitting Photoanode Wonho Joo; Hyoung Gyun Kim; Ho-Young Kang; Mi-Young Kim and Young-Chang Joo; 'Seoul National University, Seoul, Moldova (the Republic of); 'LG Chem Ltd., Seoul, Korea (the Republic of).

Single-atom catalysts where active metal atom is dispersed on the surface of the support have received great attention due to their high specific activity and unique selectivity. It is well known that single-atom is anchored on the defect site of the catalyst. However, there has been little effort to correlate the number and type of defects and the resultant catalytic activity. Hematite is one of the most prominent photoelectrochemical catalysts for water oxidation reaction, in virtue of its good optical property and cost-effectiveness. However, its widespread adaptation to commercial usage has been limited due to its modest charge transport property and poor surface reaction kinetics. To overcome these, in this work, the concept of single atom catalyst is applied and the contribution of defect to the catalytic activity is investigated. Hematite is defect chemically modified by atmosphere change and doping, varying type (Fe-vacancy or O-vacancy) and number of defects. Subsequently, iron, which is known to be the best water oxidation catalyst yet very expensive, is incorporated into the hematite by co-doping, varying type (Fe-vacancy or O-vacancy) and number of defects. Under the same condition, the GNRs-ZnPpy core-shell structure had a H$_2$ production rate of 37 nmol/g, which was 15 times of the physical mixing.

**ES10.06.05**
Quantifying Strain and Dislocation Density in Assembled and Epitaxially Welded Nanocubes Harish Aarawal; Biplap K. Patra; Thomas Altantzis; Sara Bals; Annick De Backer; Sandra Van Aert and Erik Garnett; 'Center for Nanophotonics, AMOLF, Amsterdam, Netherlands; 'Electron Microscopy for Materials Research, University of Antwerp, Antwerp, Belgium.
Nanoparticles self-assembly followed by epitaxial welding has been utilized extensively to make 1D and 2D structures even with complex shapes like a honeycomb lattice. Theoretical simulations along with in-situ observation of assembly with high-resolution transmission electron microscopy (HRTEM) and small angle x-ray scattering (SAXS) has helped to shed light on the underlying mechanism of assembly and welding. Nevertheless, little is known about the strain and dislocations at the interface of the particles after epitaxy and understanding strain/dislocations at the interface is crucial for applications like photovoltaics and thermoelectrics as it can radically alter material functional properties and in turn the resulted performance. Towards this end, in this work, we examine interfacial defect and strain formation during self-assembly and epitaxial welding at room temperature of 7 nm Pd nanocubes capped with polyvinylpyrrolidone (PVP). After dropcasting the Pd nanocubes solution on a substrate (Si,N₄ grid), the PVP is removed from the surface of the nanocubes with aqueous sodium borohydride (NaBH₄) solution which was verified with X-ray photoelectron spectroscopy (XPS). During this process, the cubes move over large distances on the substrate, leading to both spontaneous self-assembly and welding to form single crystals. Subsequently, Scanning TEM, a technique that compares the positions of individual atomic columns to their position in an ideal, relaxed lattice was used to calculate the strain/dislocations at the interface of the welded cubes with different (lateral/augular) misorientations. The cubic shape characterized by its 6 chemically equivalent and atomically flat (100) faces eases welding via atomic merging and helps provide improved alignment preferentially forming single crystals leading to dislocation-free interfaces and huge reductions in strain. Even 3° angular misalignment tolerance was observed without the formation of grain boundaries.

ES10.06.06 Highly Efficient Plasmonic Membrane Activation of Peroxide for Quantized Oxidation

Hao Tang, Guozheng Shao and Bruce Hinds; University of Washington, Seattle, Washington, United States.

Many industrial oxidation processes based on peroxide, have a difficulty of over oxidation in homogeneous solution principally due to faster oxidation rates of already oxidized species and high statistical probability of secondary oxidation near the completion of reaction. Ideal for stepwise oxidation is to limit the residence time of target molecule in a reaction zone to allow for single (or quantized) reaction events. This can be achieved in a membrane geometry where catalysis along a pore length and set flow velocity can precisely control residence time for oxidation. It is also known that Au nanoparticles can catalytically activate peroxide under light irradiation due to the formation of concentrated surface plasmon electric fields and thus hypothesized to be present in nanoporous planes. A plasmonic membrane was synthesized by evaporation of 25 thick Au films onto porous anodized aluminum oxide membranes (AAO) with pore diameters of 20-200nm. This allowed solutions of peroxide, benzene, methyl blue to flow through membrane and interact with Au surface plasmon upon exit of the membrane. Under light illumination of 10-100 mW/cm² quantum efficiencies (photon/peroxide radical) of 200-800% were seen, indicating a mechanism of field induced activation of peroxide compared to a hot electron injection mechanism. Dye and benzene to phenol oxidation are demonstrated.

ES10.06.07 Elucidating Interfacial Visible Light Absorption in TiO₂-Supported CeO₂ Nanoparticles

Photoelectrode Haiker, Kartik Venkataraman, Tu-Uyen Phan and Peter Crozier; Arizona State University, Tempe, Arizona, United States.

Generating solar fuels such as H₂ gas from water will require photocatalysts that can absorb visible light and facilitate swift charge separation/migration for surface electrochemical reactions. Photocatalysts containing “mixed metal oxide” (MMO) interfaces between TiO₂ and CeO₂, both of which are UV-absorbers on their own, have garnered attention due to their ability to drive H₂O₂ evolution from water under visible light.1,2 Visible light absorption is hypothesized to originate from partially-occupied Ce-4f states, which act as donor states within TiO₂’s bandgap, that arises from an enrichment of Ce³⁺ at the MMO interface.3 In this view, TiO₂-supported CeO₂ photocatalysts may offer a unique hierarchical geometry that confines visible-light harvesting (and charge generation) near the surface. Direct probing of the optical properties about such MMO interfaces would provide insights into the unique supported CeO₂ morphologies that produce strong, and potentially tunable, visible-light absorption.

TiO₂ supports were synthesized through a two-step hydrothermal process to yield batches of “small” (S) and “large” (L) anatase nanoparticles with average particle sizes of 15 and 66 nm, respectively, determined by powder X-ray diffraction (XRD). Subsequently, both were loaded with 6 wt% Ce via wet impregnation followed by appropriate calcination heat treatments to remove precursors. UV-visible diffuse reflectance spectroscopy shows no change in the bulk optical properties on the modified TiO₂(L) nanoparticles whereas a red-shifted bandgap from 3.2 to 2.7 eV is observed on the Ce-loaded TiO₂(S) powder which is accompanied by a white-to-yellow color change in the as-loaded powder. To compare the hydrogen evolution rates (HERs), both powders were photodeposited with 0.5 wt% Pt under visible light (∼400 nm) for one hour followed by UV-visible illumination to measure evolved H₂ gas. The HER of 6 wt% Ce/TiO₂(S) is >2x higher than that of 6 wt% Ce/TiO₂(L) owing to its increased visible-light absorption.

Aberration-corrected annular dark field scanning transmission electron microscopy (ADF-STEM) was utilized to image the two powders at atomic resolution, revealing unique CeO₂ morphologies dominating each support. On TiO₂(L), larger CeO₂ nanoparticles (e.g., ~10 nm) are ubiquitous. In contrast, TiO₂(S) is decorated by Ce single atoms and smaller CeO₂ nanoparticles. Thus, TiO₂(S) appears to contain more MMO interfaces which is consistent with its significant visible-light absorption.

Monochromated electron energy-loss spectroscopy (EELS), in the STEM, was then applied to 6 wt% Ce/TiO₂(S) to obtain valence EELS spectra from regions containing MMO interfaces. The valence EELS spectra from all regions shows the characteristic bandgap onset for TiO₂ at ~3.5 eV. However, when the probe is placed near areas containing TiO₂(CeO₂) interfaces, a broad peak centered at ~1.5 eV (with almost half of the intensity as the bulk TiO₂ bandgap signal) emerges. The relative intensity of this peak decreases in thicker regions and disappears in areas where no CeO₂⁺ species are present. This preliminary evidence suggests the presence of “interfacial” bandgap state(s) that facilitate absorption of visible light as low as 1.5 eV, which is not apparent from bulk optical spectroscopy. Future work will extend the valence EELS analysis to more regions of the sample and attempt to correlate the nanoscale optical properties with local Ce³⁺ concentration and MMO morphology (e.g., single atom vs. nanoparticles).

ES10.06.09 Interface Reconstruction Suppression Using PEALD Group-III Nitrides for Quantum Dots Solar Cells

Xinhua Zheng, Huiyan Wei, Peng Qiu, Mingzeng Peng, Sanjie Liu, Yingfeng He, Yirong Song, Yanlai An and Meiling Li; Department of Applied Physics, University of Science and Technology Beijing, Beijing, China.

Quantum dots sensitized solar cells (QDSCs) show significant potential applications due to its excellent properties including high absorption coefficient, tunable band gap and multiple excitation generation (MEG). Theoretically, the power conversion efficiency (PCE) of QDSCs can reach 44%, breaking through traditional Shockley-Queisser limit. The existence of charge recombination in the interface, however, seriously hinders further improvement of QDSCs. Use of oxides (i.e. Al₂O₃, ZrO₂, SiO₂) and/or sulfides (i.e. ZnS) as a transition layer of interface recombination is the most common method to reduce charge recombination. To the best of our knowledge, there are no reports about the application of nitrides (AIN, GaN, InN) in QDSCs. The key factor is the growth temperature of nitrides using metalorganic chemical vapor deposition or molecular beam epitaxy is extremely high, which leads to the desorption of supported quantum dots (QDs). In this study, we successfully fabricate GaN and AlN onto the QDs at a very low temperature by plasma enhanced atomic layer deposition (PEALD). The existence of nitrides can reduce recombination loss in the interface. An enhancement of open-circuit (Voc) from 0.58 V to 0.64 V is achieved for an insertion of AlN between the QDs and electrodes, while short-circuit current density (Jsc) is significantly increased up to 20% when an alternative ultrathin GaN is introduced. This results in improved efficiency of device performance are discussed in this paper. The results could open up a new way in designing and fabricating the QDSCs.

ES10.06.10 Microstructural Effects on Photocatalytic Performance in Bi₅Mo₇O₂₃AgsPO₄, Z-Scheme Systems

Kaleab M. Ayalew, Jayun Moon and Xavier Morgan-Lange; University of Nevada Las Vegas, Las Vegas, Nevada, United States.

As the world population continues to grow and access to modern industry becomes increasingly common, humanity finds itself in the midst of an environmental and energy crisis. Natural resources such as clean water are becoming increasingly scarce. A recent development in the scientific community is the study of semiconducting photocatalytic nanomaterials as a potential solution. Photocatalysts are among the most promising solutions since these materials can directly convert abundant solar energy into usable energy resources via the photoelectric effect, and produce hydroxyl group radicals which can proceed to decompose pollutants or deactivate certain microbes in a given medium.
However, it is often difficult to find an individual photocatalyst that satisfies all the requirements for an exceptional photocatalyst, such as high redox ability, narrow energy bandgap, and efficient charge-separation. The artificial heterogeneous $z$-scheme photocatalytic systems made by amalgamation of two or more photocatalysts is a replica of the natural photosynthesis process that enables the materials to overcome the shortcomings of a single component photocatalyst. In a $z$-scheme, materials with high oxidation potential, as determined by their conduction and valence band position, are paired with those that have a higher reduction potential, $\text{Ag}_2\text{PO}_4$, and $\text{Bi}_2\text{MoO}_6$. In this instance, thus creating a channel for photo-induced electron-hole pairs to recombine sacrificially. This arrangement creates the $z$-shaped path of the charge carriers and ensures the availability of electrons at the conduction band with the highest reduction potential and holes at the valence band with the highest oxidation potential. This mechanism enables composites to maintain better charge-separation and redox ability simultaneously.

Surface morphology, interface, and composition between component photocatalysts play a significant role in efficient light absorption and charge separation. Numerous strategies including morphology control have been developed recently to enhance the photocatalytic performance by maximizing the amount of light energy capture. Considering $\text{Bi}_2\text{MoO}_6$ and $\text{Ag}_2\text{PO}_4$ can absorb a broad visible light spectrum from the sun due to their relatively low bandgap energy, which makes them suitable for morphology manipulation. In this study, the correlation between the photocatalytic performance of $\text{Bi}_2\text{MoO}_6/\text{Ag}_2\text{PO}_4$ and their varied morphology and chemical characteristics is investigated. The $\text{Bi}_2\text{MoO}_6/\text{Ag}_2\text{PO}_4$ $z$-scheme is of particular interest for its exceptional photocatalytic performance, as reported by previous investigators. Therefore the purpose of this study is to design, synthesize, and test the best configuration of $\text{Bi}_2\text{MoO}_6/\text{Ag}_2\text{PO}_4$ and further improve upon an already impressive performance.

$\text{Bi}_2\text{MoO}_6/\text{Ag}_2\text{PO}_4$ $z$-scheme composite was synthesized within a facile in-situ chemical method. The crystallinity, morphology, microstructure, and light absorption wavelength range are characterized using, x-ray diffraction (XRD), field emission electron microscopy (FESEM), transfer electron microscopy (TEM), energy dispersive spectrometer (EDS) and UV–visible diffuse reflectance spectroscopy (DRS). Finally, photocatalytic performance is evaluated and reported by degrading Methylene Blue (MB) under a solar simulator with UV and visible wavelengths.

**ES10.06.11 Biomimetic Erythrocyte-Like Nanostructure for Selective Oxygen Transport**

**Grace Jiang and Lyna Zhang; Angstrom Thin Film Technologies LLC, Albuquerque, New Mexico, United States.**

H2 and O2 generation via photocatalytic water splitting process is an emerging technique in energy conversion. Selectively oxygen permeable membrane with high flux and selectivity is important for this application. In this work, we report a biomimetic ultra-thin membrane for Oxygen separation fabricated by molecular self-assembly and atomic layer deposition (ALD). ALD is a layer-by-layer deposition method that builds up a thin film with atomic precision in structure and compositions. Here we introduce the membrane fabrication by using a “plasma-defined” ALD process where the location of ALD modification is confined by plasma irradiation. Using this approach, sub-micron membrane with precisely engineered naoporous structure was fabricated. Followed by a chemical solution process, erythrocyte-like structure was achieved, leading to a highly oxygen selective membrane for oxygen purifications.

**ES10.06.12 Spray Deposition of Insulating Layers at the Rear Side of Silicon Solar Cells to Enhance their Internal Reflectance**

**George M. Spruill; Mechanical Engineering, Alabama A&M University, Memphis, Tennessee, United States.**

The solar industry has recently transitioned to manufacturing passivated emitter rear contact (PERC) cells, which are also more efficient than Al back-surface field (BSF) cells because they provide rear-side surface passivation. The goal of this experiment was to enhance the short-circuit current of PERC solar cells by inserting a low-refractive index dielectric layer between the rear passivation layer and screen-printed aluminum paste, which parasitically absorbs near-infrared light, stealing current from the cell. We used a low-cost deposition method, based on an open-air sprayer, to deposit these coatings from solution. We coated the front side of textured silicon wafers with silicon nitride (SiNx), which is used for commercial cells, and then deposited aluminum oxide (Al2O3) onto the back of some these wafers to test against reference cells with standard atomic layer deposited (ALD) Al2O3. We then deposited silicon dioxide (SiO2) on top of the sprayed Al2O3 to test if the lower refractive index of SiO2 would enhance the reflectance of our spray deposited cells. The experiment showed that samples with 10 nm ALD Al2O3 were optically equivalent to samples with 84 nm spray deposited Al2O3, and by depositing SiO2 on top of Al2O3 we were able to get a higher reflectance at longer wavelengths than with Al2O3 alone.

**ES10.06.13 Highly Efficient MIL-100(Fe)/TiO2 Composite Photocatalysts for Environmental Remediation**

**Xiang He and Wei-Ning Wang; Virginia Commonwealth University, Richmond, Virginia, United States.**

Semiconductors, such as TiO2, BiVO4, and C60, are the most widely used photocatalysts for environmental remediation due to their outstanding photocatalytic ability and low cost. However, semiconductor-based photocatalysts have two major inherent drawbacks: limited light absorption and fast electron/hole recombination. The most widely used method to solve the issues is to create semiconductor heterojunctions, with which not only the light absorption can be expanded but also the electron/hole separation can be efficiently promoted. As reported in this study, the $\text{MIL-100(Fe)}$ on $\text{TiO2}$ surface, the composite photocatalysts exhibited enhanced photocatalytic efficiency towards both tetracycline degradation and Cr(VI) reduction. The enhanced photocatalytic performance was attributable to promoted charge separation, which arose from the unique structure at the interface between $\text{MIL-100(Fe)}$ and TiO2. More specifically, during the in-situ growth of MIL-100(Fe), defect energy levels were created in the electronic structure of the composite photocatalyst, as demonstrated with the density functional theory (DFT) simulation. The defect energy levels served as sinks to capture excited charge carriers and thus retarded the recombination process, which eventually led to increased charge carrier density and enhanced photocatalytic efficiency. This work not only presents the rationally designed MOF/semiconductor composite structures for environmental remediation, but also provides mechanistic insights into the photocatalytic pathways.

**ES10.06.14 Wet Etching Mechanism of Epitaxial Er2O3 on Si for Integration to Semiconductor Technology**

**Tomas Grimova1, Tomas Dronga1 and Rytis Dargis2; 1 Institute of Photonics and Nanotechnology, Vilnius University, Vilnius, Lithuania; 2 IQE, Inc., Greensboro, North Carolina, United States.**

The rare earth oxide Er2O3 is of its exceptional and diverse properties, which can benefit in the various fields of semiconductor technology. In particular, erbium oxide is characterized by a high dielectric constant (14) and a wide bandgap (5.6 eV). It is distinguished as a high thermal resistant and chemical stable compound. Erbium oxide grown on silicon substrates reacts poorly with Si and retains its properties unchanged up to 900°C, which makes it one of the most stable compound compared to other rare earth metal oxides. Additionally, erbium oxide is noted for its high conduction band offset relative to silicon. All of these mentioned above properties are favorable for an application as a high-k gate dielectric in complementary-metal-oxide-semiconductor (CMOS) technology. Due to its stability erbium oxide can serve as a buffer layer for III-group nitrides such as GaN, InGaN, InN epitaxial growth on silicon. Furthermore, because of a large difference in refractive index between Si(n=3.5) and Er2O3(n=1.8) the stacks of Si/Er2O3 can serve as distributed Bragg reflectors for the optoelectronic devices.

The unique properties and a wide range of applications leads to necessity to investigate the patterning of erbium oxide. The easiest way to perform patterning is through the wet chemical etching. Till now, the comprehensive research have not yet been proceeded on patterning of erbium oxide. Therefore, we report on the wet etching mechanism of erbium oxide in sulphuric acid solution. After detailed analysis of wet etching kinetics, the parameters were optimized to achieve well defined structures. The etching experiments were performed on 300 nm thick Er2O3 thin films prepared on Si substrate by molecular beam epitaxy (MBE). The surface morphology studies revealed that etching mechanism was different for Er2O3(111) on Si(111) compared to Er2O3(110) on Si(100) orientation samples. Finally, GaN epitaxial growth results by metal organic chemical vapour deposition
Highly Dispersed Doped Semiconducting Nanocrystal for Efficient Opto-Electronics Application  

Talinya Gunawansa, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, Portsmouth, Virginia, United States.

Due to their unique opto-electronic properties, luminescent quantum dots (QDs) have been enhancing renewable energy efficient devices, i.e. solar cells. Although quantum dot-based organic solar cells exhibit lower efficiencies, their advantages of being lightweight, cost effective, variable materials processing, and easily tunable optical energy gaps, make them an appealing alternative to inorganic solar cells. In order to enhance the opto-electrical properties, we doped rare earth and novel metals into the semiconductors nanocrystals. Cadmium telluride (CdTe) QDs is a direct band gap materials with band gap energy of 1.52 eV and emits electromagnetic radiation in the visible region by tuning the quantum confinement of charge carriers. One pot microwave irradiation technique is an efficient, highly favored, quicker and more cost-effective synthesis route of core type CdTe nanocrystals. Cadmium telluride (CdTe) QDs is a direct band gap materials with band gap energy of 1.52 eV and emits electromagnetic radiation in the visible region by tuning the quantum confinement of charge carriers. One pot microwave irradiation technique is an efficient, highly favored, quicker and more cost-effective synthesis route of core type CdTe nanocrystals. The electromagnetic wave absorption properties of the FeNi/rGO nanocomposites exhibit enhanced properties and wide absorption bandwidth with compared with that of FeNi alloys. The minimum reflection loss of FeNi/rGO nanocomposites with a thickness of 3.0 mm can reach ~39.86 dB at 11.12 GHz, and the absorption bandwidth is up to 4 GHz. It is believed that the FeNi/rGO nanocomposites can be a best candidate for efficient electromagnetic wave-absorbing materials and widely used in practice.

ES10.06.16  
Modeling Current-Potential Responses of Homogeneous-Heterogeneous Photocatalysts  
Brian L. Wadsworth, Anna M. Beiler, Diana Khusnutdinova and Gary F. Moore; School of Molecular Sciences, Arizona State University, Tempe, Arizona, United States.

Chemical modification of semiconductor surfaces with metal electrocatalysts provides a strategy for developing homogeneous-heterogeneous materials capable of converting sunlight to fuels and other value-added products, but their development is hampered by an incomplete understanding of the factors limiting their performance. Although SEM has been separately developed to describe photoelectrochemical or homogeneous electrocatalytic reactions, related modeling for molecular-modified hybrid photocathodes has not been as extensively elaborated. This presentation addresses the interplay between light absorption, charge transfer, and catalytic activity during photoelectrosynthetic transformations at a molecular-modified semiconductor. The analysis provides opportunities to better understand the principles governing these hierarchical constructs and develop improved photocatalytic assemblies.

ES10.06.17  
The Distinctly Enhanced Electromagnetic Wave Absorption Properties of FeNi/rGO Nanocomposites Compared with Pure FeNi Alloys  
Dong An; North University of China, Taiyuan, China.

FeNi/rGO nanocomposites were successfully synthesized by a facile one-pot method and demonstrated via powder X-ray diffraction, Raman spectra, X-ray photoelectron spectroscopy, and the scanning electron microscope. The electromagnetic wave absorption properties of the FeNi/rGO nanocomposites exhibit enhanced properties and wide absorption bandwidth with compared with that of FeNi alloys. The minimum reflection loss of FeNi/rGO nanocomposites with a thickness of 3.0 mm can reach ~39.86 dB at 11.12 GHz, and the absorption bandwidth is up to 4 GHz. It is believed that the FeNi/rGO nanocomposites can be a best candidate for efficient electromagnetic wave-absorbing materials and widely used in practice.

ES10.06.18  
Density Functional Theory Calculations of Nanopyramidal ZnO—Crystal Growth and Improved Performance in Water Splitting  
Seong Ho Park and Dong Hyun Lee; Dankook University, Gyeonggi-do, Korea (the Republic of).

In this study, we introduce a simple and effective method to induce directed self-assembly (DSA) of symmetric block copolymers (BCPs) on large area using soft grating patterns. By physically rubbing poly(tetrafluoro ethylene) (PTFE) at various temperatures near its melting point, the horizontally aligned PTFE grating patterns with ~20nm in amplitude and ~200nm in pitch distance are produced on flat Si substrates due to its low friction coefficient and high wear rate. Then thin films of symmetric polystyrene-block-poly(methyl methacrylate) copolymers (PS-b-PMMA) form on the patterned substrates as spin-coated at 2000 rpm. To induce BCP self-assembly on the patterned surface, the thin films are solvent-annealed in vapor of organic solvents like acetone, tetrahydrofuran, toluene. Even though initial morphology of the as-spun BCP thin films is irregular, the parallel orientation of lamellar nanostuctures of PS-b-PMMA is generated after solvent-annealing process. Interestingly, it is observed that those lamellar nanostructures are aligned along the pitch of underlying PTFE grating patterns and their ordering behavior are surprisingly improved by the grating patterns as compared to the BCP morphology on flat substrates. As the BCP patterns are used as templates for metal (Au, Ag, Pt) deposition process, extremely aligned metal nano-wires can be produced on the Si substrates. The ordering behavior of BCP thin films on the patterned surface is characterized by using atomic force microscopy (AFM) and scanning electron microscopy (SEM).

ES10.06.19  
Impact of Average, Local and Electronic Structure on Visible Light Photocatalysis in Novel B4REW05 (RE = Eu & Tb) Nanomaterials  
Pradeep P. Shabangu1, 2, Rajamani Raghunathan1, Mikhail Feygenson1, Joerg Neugebauer1 and Nalini G. Sundaram; 1Poornaprajna Institute of Scientific Research, Bengaluru, India; 2Manipal Academy of Higher Education, Manipal, India; *UGC-DAE Consortium for Scientific Research, Indore, India; †Forschungszentrum Jülich, Jülich, Germany; ‡Chemical and Engineering Materials Division, Oak Ridge National Laboratory, Oak Ridge, Oak Ridge, Tennessee, United States.

B1W5O19, the simplest member of Aurivillius phase (n = 1) crystallizes in orthorhombic phase (P21a)[1]. It is found to be a potential material for visible light photocatalysis since it is a wide band gap semiconductor (Eg = 2.8 eV) with a visible light harvesting capacity at around 440 nm, and its valence band is largely dispersed due to the hybridization of O 2p and Bi 6s orbitals and conduction band is composed of W 5d orbitals[2]. To improve the light absorption capacity to the broader spectrum of visible light for efficient photoexcitation, kinetic models have been separately developed to describe photoelectrochemical or homogeneous electrocatalytic reactions, related modeling for molecular-modified hybrid photocathodes has not been as extensively elaborated. This presentation addresses the interplay between light absorption, charge transfer, and catalytic activity during photoelectrosynthetic transformations at a molecular-modified semiconductor. The analysis provides opportunities to better understand the principles governing these hierarchical constructs and develop improved photocatalytic assemblies.
photocatalysis, chemical modification of Bi$_2$WO$_6$ using transition or rare earth and p-block elements are employed[3]. It is known that doping alters the band gap and electronic structure of the material. Particularly, rare earth (RE) ions with 4f electronic configuration can absorb light from UV, Visible and IR which are associated with the f-f transitions[4], thus possibility of tuning material for wide spectrum responsive photocatalyst. In this context we have synthesized the nanostructured Rare earth (Eu & Tb) substituted Bi$_2$WO$_6$ nanoparticles by facile hydrothermal method; material crystallized in isorstruclural to monoclinic (A2/m) phase of Bi$_2$WO$_6$ having predominantly rod type morphology. Combined Rietveld refinement of synchrotron and neutron data using ordered and disordered strustures the average structure yields similar fit leading to the uncertainty in choosing the model. Further model validation is carried out through local structure probing using high Q neutron data in the short and medium range r concludes that ordered model is suitable for these nanomaterials. Rare earth substituted materials are found to be photocatalytically active for Congo-red dye degradation under visible light irradiation, the parent orthorhombic Bi$_2$WO$_6$ remained photocatalytically inactive. The increased photocatalytic activity of BiTbWO$_6$ over BiEuWO$_6$ is attributed to the enhanced charge separation as evidenced by photoelectrochemical and time resolved fluorescence study and higher mobility of excited electrons due to the nearly linear W-O-W bond angle compared to the latter. In addition our DFT calculations show that a combination of enhanced electron mobility due to large curvatures of the CB and efficient e-h separation process due to the inherent nature of electronic structure in the Tb compound is the key for improved photocatalytic activity of BiTbWO$_6$ compared to the BiEuWO$_6$ nanomaterial.

ESI10.06.21 Noncovalent Self-Assembly and Formation of Active Porphyrin Nanostructures Gavin Heanne1, Charles Fan1, Ashley Bowman2, Jasmine Quianbao2, Casey Karler1 and Hongyou Fan1,2; 1Albuquerque Academy, Albuquerque, New Mexico, United States; 2The University of New Mexico, Albuquerque, New Mexico, United States; 3Sandia National Laboratories, Albuquerque, New Mexico, United States.

Porphyrins are a class of optically active biomacromolecular compounds that play critical roles in many biological processes including photosynthesis, and also serve as color pigments covering a wide range of the visible spectrum. As an effort to utilize these versatile porphyrins in advanced materials development, organized porphyrin nanostructures with photoactive properties have been obtained through a surfactant-assisted non-covalent self-assembly method through the cooperative interactions of the porphyrin building block zinc meso-tetra(4-pyridyl)porphine. Electron microscopic characterizations in combination with X-ray diffraction confirm that self-assembly of optically active porphyrin building blocks leads to formation of ordered nanostructures including nanorods, nanowires, nanocylinders, nanoctahedron. Investigations of variable parameters influencing the growth process show that the final product morphology is determined by reaction conditions including pH, reaction time, precursor concentration, and surfactant types. Optical characterizations using UV-vis spectroscopy and fluorescence imaging and spectroscopy show enhanced collective optical properties over the individual porphyrins, favorable for exciton formation and transport. With active and responsive optical properties, these porphyrin nanostructures are promising components for a wide range of practical applications including solar cells, photoelectrochemistry, and phototherapy. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.

ESI10.06.22 Nanomaterial-Dependent Electrowetting Phenomena of Nanofluids Urvice Tohyahl1,2 and Nicholas Godman1; 1Azimuth Corporation, Beavercreek Township, Ohio, United States; 2Materials and Manufacturing Directorate, Air Force Research Laboratory, Wright-Patterson Air Force Base, Ohio, United States.

Electrowetting as a droplet actuation principle is used in many applications including digital microfluidics and reflective display devices.1 The manipulation of fluids on surfaces via electrowetting offers several advantages such as lower power consumption, high mobility of fluids and flexibility in the design of the substrates. Electrowetting on dielectric is very attractive due to large changes in contact angle between the liquid droplet and the substrate. Nanofluids (fluids containing nanoparticles) are of great interest due to reported enhanced wetting characteristics on surfaces2. Nanoparticles possess tunable optical, electrical and dielectric properties as well as varying chemical stability. They also cover a wide range of technological applications from infrared detectors, solar cells, displays to photoresponsive materials. We have evaluated the electrowetting properties of nanofluids comprised of visible II-VI (CdSe), III-V (InP) and near infrared IV-VI (PbS) and mid-wave infrared (Ag) semiconductor nanomaterials as well as ferroelectric nanomaterials (BaTiO$_3$). We will present our results on the influence of surface chemistry (different hydrophilic ligands on nanoparticles) and nanomaterial type on the electrowetting phenomena of aqueous droplets of nanofluids. We observed pronounced differences in the wetting behavior of nanofluids for all the nanomaterials studied. The study underscores the material-dependence of the wetting properties of nanofluids and the potential exploration of the optical properties of these materials in electrowetting-based platforms as well as optofluidics.

ESI10.06.23 Application of Low-Energy Photoelectron Spectroscopies to Probe the Energetics in Organic Tin Halide Perovskites and the Influence of Interfacial Energetics on Photovoltaic Performance Alex M. Boehm and Kenneth R. Graham; University of Kentucky, Lexington, Kentucky, United States.

Hybrid organic-inorganic metal halide perovskites have generated tremendous interest as low-cost semiconductors for optoelectronic applications such as photovoltaics. The rapid success of hybrid organic-inorganic perovskites has thus far been centered around the lead-based perovskite derivatives; however, in recent years a sub-field has developed that seeks to substitute lead with a less toxic and more environmentally friendly alternative. Here, the clear front runner is tin, which has successfully been used in photovoltaics to achieve over 95% power conversion efficiency. In conjunction with the active layer properties the performance of optoelectronic devices is also dependent on the energetic alignment between adjacent layers. To select or design appropriate transporting materials for use in tin hybrid perovskites based optoelectronics the energetics of the active layer must be understood. Herein lies an issue where current literature regarding the valence and conduction band energies cannot reach consensus, and for a material as studied in our low energy ultraviolet and inverse photoelectron spectroscopy systems, which allow for us to minimize sample degradation, and apply them to the study of some the aforementioned factors that may contribute to the variation in reported energetics for formamidinium tin iodide. We find that air exposure has little effect on the measured energetics whereas the addition of tin(II) fluoride, which is used nearly universally in tin perovskite photovoltaics, can have great influence. Further, a series of fullerene derivatives with varying electron affinities were investigated to probe how the energetic alignment between the perovskite and electron transport layer influences photovoltaic performance.

ESI10.06.24 Exotic Magneto-Caloric Effect and Quadrupolar Interaction in Ho-Dy:Bi$_2$WO$_6$ Beomuki Cho1, Gwang-Hee Kim2 and Songhee Han1; 1Materials Science and Engineering, Gwangju Institute of Science and Technology (GIST), Gwangju, Korea (the Republic of); 2Physics, Sejong Univ., Seoul, Korea (the Republic of); 3Division of Navigation Science, Mokpo Maritime National Univ., Mokpo, Korea (the Republic of).

Recently, the coupled systems of the degree of freedom among spin, lattice, charge and orbital have been suggested as a breakthrough to improve conventional magnetoaloric
effect (CMCE) for magnetic refrigeration application [1]. We have investigated the MCE of rare earth tetraboride, RB₄ (R = Dy, Ho). These compounds show complex magnetic phase transition with highly degenerated system due to the interplay between magnetic and quadrupolar ordering. After the orbital degeneracy is lifted, the quadrupolar moments are geometrically frustrated through quadrupolar fluctuation. The network of quadrupolar moments forms the Shastry-Sutherland lattice (SSL) and the direction and angle of magnetic moments are limited from simple antiferromagnetic state by the strong spin-orbit coupling. Giant inverse MCE (IMCE) is observed at quadrupolar ordering temperature, which is strongly-coupled with the magnetic ground state. The exotic IMCE exhibits maximum values of 19.6 J/kgK, 19.0 J/kgK and 22.7 J/kgK at the critical applied magnetic fields of 5 T, 4 T, and 2.5 T for DyB₄, Dy₂HoB₄, and HoB₄, respectively. In particular, the exotic IMCE, which is enhanced under the critical field, decreases above the critical fields, due to the disappearance of quadrupolar ordering. These results offer new insight into the mechanism of exotic giant MCEs and magnetic cooling applications.

ES10.06.25

Rationally Designed Metal Heterostructures for Plasmon-Enhanced Photocatalysis

Han Zhang, Jianhua Yang and Jianfang Wang; The Chinese University of Hong Kong, Hong Kong, China.

Photocatalysis is a powerful way for tackling the increasingly severe environmental and energy concerns. Owing to their intriguing localized surface plasmon resonances, noble metal nanocrystals and nanostructures have shown a great potential for enhancing the photocatalytic efficiency and thereby have attracted rapidly growing interests recently. Au and Ag nanocrystals typically exhibit strong plasmonic resonances, while Pt and Pd nanoparticles typically function as versatile catalysts for various chemical reactions. In order to employ plasmon to enhance photocatalysis, much effort has been devoted to the synthesis of metal heterostructures by integrating plasmonic Au and/or Ag nanocrystals with catalytically active Pt and/or Pd nanoparticles. Such heterostructures usually exhibit enhanced catalytic performances in comparison with their monometallic counterparts due to a concerted action between the different components. However, many reported metal heterostructures are often in core@shell configurations, which can suppress the plasmonic and/or catalytic performances of the inner components. Moreover, plasmonic nanocrystals have been well known to possess hot spots, where light energy is strongly squeezed. A few studies have shown that catalytic nanoparticles deposited at the hot spots can optimize the plasmonic enhancement effect and at the same time minimize the use of expensive Pt and Pd. In this regard, we have recently performed systematic studies on the site-selective deposition of catalytic metals on pre-grown plasmonic metal nanocrystals and on their plasmon-enhanced photocatalysis behaviors.

We have recently develop a synthetic method for the site-selective overgrowth of catalytic metals on Au nanorods (NRs) and Au nanobipyramids (NBPs) (Angew. Chem. Int. Ed. 2013, 52, 10344 and Adv. Funct. Mater. 2017, 27, 1700016). Silica is first selectively deposited at the two ends of Au NRs or Au NBPs owing to the higher curvature, or deposited on the side surface when the ends are blocked by thiol-terminated methoxy poly(ethylene glycol). The pre-deposited silica component on the Au nanocrystals guides the subsequent selective overgrowth of a second metal on the exposed Au surface. Au NBP-end Pd and Au NBPside Pd heterostructures have been prepared for exploring the effect of the local electric field enhancement on the photocatalytic activity. Suzuki coupling reaction has been chosen as a model reaction to evaluate the photocatalytic performances of the different Au/Pd heterostructures. The results indicate that the photocatalytic activity is highly dependent on the site of the Pd nanoparticles, and that the plasmonic hot spots play an important role in hot-electron-driven plasmonic photocatalysis.

We have recently synthesized highly asymmetric Au nanocups, which possess a strong magnetic plasmon mode (Adv. Mater. 2016, 28, 6322). The electromagnetic field at the edge of the cup and in the opening region is strongly enhanced. We have therefore deposited Pt or Pd nanoparticles selectively at the opening region or inside the cavity of the Au nanocups and studied their photocatalytic performances. Taken together, our results offer a new insight into the rational design of highly anisotropic metal heterostructures out of two or more functional metals for various plasmon-enhanced applications, including photocatalysis, optics and biomedicine.

ES10.06.26

Formation of Novel HCSs/NbO:F Heterostructured Materials with Enhanced Carrier Separation Efficiency and Carrier Transfer

Fei Huang¹,², Zhen Li¹ and Aihua Yan¹; ¹Low Carbon Energy Institute, China University of Mining and Technology, Xuzhou, China; ²College of Technology, Arizona State University, Tempe, Arizona, United States.

As a kind of novel optoelectronic materials, niobium oxyfluoride (NbO:F) has recently attracted wide attention because of its stable crystalline phase, TiO₂-like electronic & band structure, excellent light-corrosion resistance and weak carrier recombination. However, due to its wide bandgap (3.12 eV) and low carrier separation efficiency, NbO:F is hard to be activated under visible-light irradiation to get high photocatalytic efficiency. Here, hollow carbon spheres (HCSs)-decorated NbO:F hierarchical nanostructures were successfully synthesized by a two-step hydrothermal method. The final products were characterized by a series of testing methods, such as XRD, FESEM, Raman, XPS, UV-vis spectroscopy, photocatalytic system, etc. The mechanism of carrier generation, separation, transfer and recombination for HCSs/NbO:F samples was investigated. Comparatively, NbO:F/HCSs nanostructures exhibited higher photodegradation efficiency and faster photodegradation rate in the solution of rhodamine B (RhB) under visible-light irradiation. 1.5 at.% HCSs/NbO:F samples could achieve final 97.9% RhB degradation in 50 min, while pure NbO:F samples only got 67.3% in the same time. UV-Vis spectra showed that HCSs not only enhanced optical absorption in the range of 400-1000 nm, but also extended the absorption edge, as well as tended to narrow the bandgap of NbO:F photocatalyst. That is, the enhanced photocatalytic performance can be attributed to higher spectrum absorption and faster carrier transfer from HCSs. The results here may inspire more engineering, new design and facile fabrication of novel photocatalysts with highly photocatalytic activity.

ES10.06.27

The Fabrication and Characterization of Co-Co₃(PO₄)₂-Core/Shell/Au Barcode Nanowires

Jun Hwan Moon, Yoo Sang Jeon, EunMin Yoo and Young Keun Kim; Materials Science and Engineering, Korea University, Seoul, Korea (the Republic of).

In recent years, ceramic and noble metals have been utilized as photocatalysts [1]. In the case of catalyst, the size, shape and electrical state of the catalyst is important for obtaining sufficient catalytic activity. Especially, the unique phenomena caused by ceramic materials supported by noble metal have been researched [2]. In this prospect, the composite of ceramic and metal in the shape of multi-layer structure with varying length could provide new possibilities in catalyst area. Meanwhile, a view point of material, amorphous cobalt phosphate is an promising candidate by effectively promoting water degradation by sunlight [3]. Furthermore, it is well known that Co is an excellent electrical conductor and absorbs light of different wavelengths depending on their shape, size and interdistance of each other [4]. In this study, we propose a relatively facile and economical synthesis process fabricating 1D heterostructures, that is, core-shell/barcode nanowires (BNWs) of which each segment’s length, diameter and the thickness of shell can be easily tuned. First, we synthesized CoAu BNWs by pulsed electrodeposition method using anodic aluminum oxide (AAO) template. After that, AAO was removed with chromium phosphate and phosphoric acid. At the same time, BNWs with a core shell - noble metal structure were formed by selectively reacting only with Co layers. Scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray diffraction (XRD), energy-dispersive spectrometer (EDS), X-ray photoelectron microscopy (XPS), Inductively coupled plasma atomic emission spectroscopy (ICP-AES), Ultraviolet-visible spectroscopy (UV-vis) and vibrating-sample magnetometer (VSM) were employed to observe the shape and microstructure of core-shell/BNNWs. The length of each part of nanowires were successfully adjusted by the applied current densities, duration time, and phosphorus containing solution. As the face centered cubic (FCC) Au nanowires of subsequent layers, the transition of Co layers was observed from FCC to stable hexagonal closed packed (HCP) structures. Moreover, the Co phosphate shell was characterized as amorphous structures and if the reaction time is enough, Co layers are completely reacted by intruding phosphorus changing into a perfect ceramic-noble metal nanowire. X-ray based measurement system and ICP-AES let us understand the diffusion of phosphorus. In addition, UV-vis provides optical property of synthesized nanowires. Finally, we verified the catalytic properties depending on the dimension of each part.

Electronic Textiles Based on Aligned Electrospun Belt-Like Cellulose Acetate Nanofibers and Graphene Sheets—Portable, Scalable and Eco-Friendly Strain Sensor

Xu WanLin, Fu WanLin and Dai Yunqian; Southeast University, NanJing, China.

Electronic Textiles based on aligned electrospun belt-like cellulose acetate nanofibers and graphene sheets are portable, scalable and eco-friendly strain sensors. Aligned electrospun belt-like cellulose acetate nanofibers were synthesized through single-nozzle electrospinning. Graphene sheets were subsequently deposited on the nanofibers to obtain the conductive sensor. The strain sensitivity of the developed sensors is around 260 Ω% for a strain range of 10%. The fabricated sensors were used to detect the strain of a human finger. The results show that the developed sensors provide a high sensitivity and good reversibility. The fabrication process is simple and scalable and can be extended to the production of other flexible electronic devices.
Recently there is strong interest in flexible, and wearable electronics to meet the technological demands of modern society. Environmental-friendly and scalable electronic textile is a key area that is still significantly underdeveloped. Here, we describe a novel strain sensor composed of aligned cellulose acetate (CA) nanofibers with belt-like morphology and reduced graphene oxide (RGO) layer. The unique spatial alignment, microstructure and wettability of CA nanofibrous membrane facilitate their close contact with deposited GO colloids. After a portable and fast hot-press process within 700 s at 150 °C, the GO on CA membrane can be facile reduced to conductive RGO layer. Moreover, the connection among contiguous CA nanofibers and the interaction between GO and CA substrate were both highly enhanced, and thus a superior mechanical strength with Young’s modulus of 1.3 GPa and small sheet resistance lower than 10 KΩ. Therefore, the conductive RGO/CA membrane was successfully utilized as a strain sensor in a broad deformation range and versatile deformation types. Moreover, the distinctive mechanical strength under different stretch angles endowed the well-aligned RGO/CA film with intriguing sensitivity against stress direction. Such a cost-effective and environmentally-friendly method can be easily extended to scalable production of graphene based flexible electronic textiles.

ES10.06.29
Nanomaterials for Mesoscopic Perovskite Solar Cells Zheqin Zhang; Guilin University of Electronic Technology, Guilin, China.

To meet requirements of low cost, fully printable mesoscopic perovskite solar cells (MPSCs) based on carbon counter electrode are investigated. Devices with excellent long-term stability and a certified PCE of 12.8% are successfully fabricated by mixing MAPbI3 with an additive of 5-ammoniumvaleric acid iodide (5-AVAI). In the presentation, a simple and effective way is developed for enhancing the performance and long-term stability of hole-transporting MPSCs, by incorporating an additive of iodide benzylamine (BAI) into the methyl ammonium iodide. BA-MAPbI3 based fully printable MPSCs achieves a PCE of 12.69%, in comparison with 6.43% of the controlled MPSCs. The introduction of BAI induces better pore filling in the perovskite TI2O3 scaffold, reduces defect concentration in perovskite films, and induces better contact with TI2O3 scaffold. All the factors result longer excitation lifetime and higher quantum efficiency in BA-MAPbI3 MPSCs. Furthermore, BA-MAPbI3 MPSCs show excellent stability, the devices could keep 80% of origin power conversion efficiency for over 500 hours in ambient air under continuous light.

Spray Deposited ZnO/Bi2O3 Thin-Film Heterojunctions with Enhanced Visible Photocatalytic Activity Juliette Reyes Arrango and Monserrat Bizarro; Instituto de Investigaciones en Materiales, UNAM, Mexico, Mexico.

The wide interest of finding new photocatalysts that can efficiently use the solar energy as activating source has led to the development of different strategies. The most common one is the introduction of dopants into a semiconductor’s matrix, in order to decrease its bandgap. However, the bandgap diminution entails also a decrease in the oxidation and reduction power of the photocatalyst, reducing its final efficiency. By contrast, the coupling of two different semiconductors seems to be a better alternative, as the best characteristics of each other can be exploited. In this work, we developed heterostructures based on the coupling of two semiconductors, zinc oxide (ZnO) and bismuth oxide (Bi2O3), using the pneumatic spray pyrolysis technique. The ZnO/Bi2O3 heterostructures were obtained on glass substrates with the help of aluminum masks with different configurations. The configuration of the masks was optimized based on the exposed area of each semiconductor, in order to maximize their coupling. The structural, morphological, optical and electronic properties of the samples were characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM), UV-Vis diffuse reflectance spectroscopy and photoluminescence (PL). Finally, the photocatalytic activity for the degradation of indigo carmine (IC) dye was evaluated under visible light using UV-Vis spectrophotometry technique. ZnO films present a nano-flake morphology with nano spikes that provide high surface area, while Bi2O3 coatings appear as dense clusters or agglomerates. The results show that the heterostructures are effectively activated under visible light showing an enhanced photocatalytic response compared to the independent ZnO and Bi2O3 films. This synergistic effect is achieved due to the visible light excitation of the Bi2O3 film and the subsequent charge transfer to the ZnO film.

ES10.06.31
Highly Transparent Catalysts for Solar Fuels Applications via Mesoscale Photonic Design Wen-Hui Cheng, Matthias H. Richter, Sisir Yalamanchili, Phillip Jahelka, Pin Chieh Wu and Harry Atwater; California Institute of Technology, Pasadena, California, United States.

Direct solar-to-fuel generation using a photocathode-based photoelectrochemical cell requires a light absorber which can provide the photovoltage necessary to overcome the thermodynamic potential (1.23V for H2/O2, 1.33V for CO2/O2) as well as the catalyst overpotentials for both cathode and anode reactions. To realize high solar-to-fuel efficiency, it is necessary to maintain a catalytic current density close to the light limiting photocurrent density for a solar-driven light absorber, which can be fulfilled when catalyst ensembles are highly transparent. Recently, we reported a record solar-to-hydrogen efficiency using a tandem III-V semiconductor photoelectrode based solar photoelectrochemical cell with an optically transparent catalyst comprised of a dense array of Rh metal nanoparticles1. For CO2 reduction, a different approach is required, given the opaque nature and limited activity of most CO2R catalysts. Here, we report and demonstrate two light trapping photoredox strategies to create highly active and effectively transparent catalyst structures for photocathodic CO2 reduction: i) an effectively transparent catalyst consisting of arrays of micron-scale triangular cross-sectional silver grid fingers, which is capable of redirecting the incoming light to the open areas of the PEC cell without shadow loss, and ii) arrays of mesophotonic dielectric cone structures that are made as tapered waveguide light coupler to efficiently guide incident light through apertures in an opaque catalyst into the light absorber. To validate these designs, numerical calculations using full wave electromagnetic simulations were used to investigate the optical response. We find that a mesoscale silver grid array with triangular cross-section lines and metal coverage of ~ 50% exhibits negligible additional reflection loss. For the nanostructure dielectric cone light couplers, <10% reflection (>90% transmission) is achieved experimentally for metal (Cu) coverage as high as 70%. Both catalyst designs will be described in detail, including simulations and fabrication methods, as a guide to efficient catalyst design for photoelectrochemical solar fuels generation.

Secondary Emissive Coatings from ALD—Metal Oxides and Fluorides Maximilian Gebhard1, Mark Popecki2, Till Cremer1, Michael Minot1, Anil Mane1 and Jeffrey Elam1; 1Argonne National Laboratory, Lemont, Illinois, United States; 2R&D, Incom Inc., Charlton, Massachusetts, United States.

An important building block for detector devices are signal amplifiers, such as microchannel plates (MCPs). Due to the electron cascade produced within the high voltage-biased MCP pores, incident electrons, photons, or ions can be amplified by 10^6, making MCPs highly efficient in photon-counting devices. Moreover, since the MCP comprises millions of parallel pores, these devices are ideal for imaging applications astronomy, high-energy physics, medicine, etc. Recently, MCPs have been fabricated by functionalizing capillary array glass using atomic layer deposition (ALD) coatings to impart the necessary electrical resistance and secondary electron emissive (SEE) properties. Considering the complex geometry of the MCPs, ALD is ideal for depositing these functional coatings with high precision and conformity. Thus far, a limited number of ALD materials (i.e. Al2O3 and MgO) have been evaluated as SEE layers in MCPs. While these materials show great performance in real-life MCP applications, chemical reactions between these SEE materials and the underlying resistive coatings are a possible limitation to their ultimate performance. In addition, the reaction of MgO SEE layers with ambient H2O and CO2 changes the surface chemistry and causes a drop in the SEE value. These issues motivate the study of alternative ALD materials to function as SEE layers in MCPs.

We present here the development and evaluation of ALD metal fluoride and mixed metal oxy-fluoride coatings as potential SEE layers in MCPs. We also investigated the
influence of H$_2$O and CO$_2$ exposure on the SEE surfaces to understand the effect of these ambient compounds on the properties of the coatings. The ALD mechanism was studied using in-situ quartz-crystal microbalance (QCM), quadrupole mass-spectrometry (QMS), and Fourier transform infrared spectroscopy (FTIR) measurements. The materials were analyzed to determine their structure and composition using X-ray photoelectron spectroscopy (XPS), X-ray diffraction (XRD) and X-ray reflectivity (XRR). The ALD SEE layers were deposited on commercial MCP substrates to evaluate the electronic properties and to measure the gain and stability during operation.

**Novel Method of Transferring CNT Forest to Any Substrates**

Chi P. Haynh, Masa Ito and Raquel Ovalle; Nano science and nano technology, Lintec of America, Richardson, Texas, United States.

Carbon nanotubes (CNTs) have many attractive properties, and show promise in a wide variety of applications. Demonstrated is a light absorption material, EMI shielding and or sound absorption material utilizing CNT materials in the form of a vertically aligned CNT forest. The CNT forest is grown via chemical vapor deposition and requires catalyst, carbon source, inert gas and hydrogen. Hard substrates such as quartz, silicon wafer, stainless steel or aluminum are generally used as these can withstand the high temperatures required for CNT growth. Such hard substrates make it difficult to use the CNT forest in applications, particularly those requiring complex geometric configurations or flexibility.

The fragility of the CNT forests makes it a challenge to transfer them from their inflexible growth substrate onto a target substrate. In this work we report a novel method of transferring CNT forests onto an arbitrary substrate, including common polymer films such as PET. The developed technique is also able to alter the alignment angle of the CNT forest relative to the substrate: 90 degree (high angle), 45 degree (mid angle) and 25 degree (low angle). Typically, an adhesive is used to transfer the CNT forest, but in some cases the adhesive is replaced with a non-adhesive material.

**An In Situ Room Temperature Route to CuBils Based Bulk-Heterojunction Perovskite-Like Solar Cells**

Zhi Zheng and Yan Lei; Xuchang University, Xuchang, China.

Both bismuth and copper are toxic and relative low-abundant elements suitable for lead-free halide perovskite-like photovoltaic devices. Here, we report a highly facile route for in-situ producing copper-bismuth-iodide (CuBiI$_3$) thin films directly on ITO substrate at room temperature, by utilizing a Bi-Cu alloy layer as precursor. X-ray diffraction and TEM results verified the formation of well crystalized CuBiI$_3$ thin films with (222) facet orientation. The transient photovoltage (TPV) analysis revealed that the CuBiI$_3$ is an n-type semiconductor with preferable photoelectric conversion character comparing with CH$_3$NH$_3$PbI$_3$ perovskite. A suitable band gap of ~1.81 eV for solar absorption and photovoltaic was illustrated by UV-Vis, PL and IPCE spectra in its experiments. It is very interesting to note that the subsequent spin-coating process of the classical Spiro-MeOTAD organic solution with TBP and acetonitrile resulted in a completely mixed, dense, and smooth CuBiI$_3$: Spiro-MeOTAD bulk-heterojunction film. The preliminarily fabricated simple sandwich structures of ITO/ CuBiI$_3$: Spiro-MeOTAD: Au hybrid solar cell devices displayed efficient photovoltaic performance with the PCE up to 1.119% of the best sample. The current room temperature direct metal surface elemental reaction (DSMER) method may provide a new insight for future all-inorganic lead free perovskite-like A$_n$B$_m$X$_p$ compounds and high performance photovoltaic devices.

**Hierarchical Zinc Oxide Nanostructures for the Photochemical Reduction of Bicarbonate to Solar Fuels**

Hanging Pan and Michael Heagy; New Mexico Institute of Mining and Technology, Socorro, New Mexico, United States.

Zinc oxide (ZnO) is an earth abundant, non-toxic, and low-cost material that has been used widely for photocatalytic water splitting, gas sensing, and dye degradation. In this study, several ZnO structures were synthesized, characterized, and tested for the photocatalytic reduction of bicarbonate to formic acid, an intermediate to methanol, a high-octane-number fuel. The different ZnO morphologies studied include micron- and nano-particle ZnO, rods, wires, belts, and flowers. ZnO was also synthesized from the direct calcination of zinc acetate, which provided a cheap and large-scale synthesis method to produce ZnO. The photocatalytic efficiency of the synthesized ZnO was compared to TiO$_2$ alone. The enhancement is predicted to be due to the plasmon-induced excited charge transfer from TiO$_2$ to the conduction band of TiO$_2$: TiN. The enhancement is predicted to be due to the plasmon-induced excited charge transfer from TiN to the conduction band of TiO$_2$: TiN. The enhancement is predicted to be due to the plasmon-induced excited charge transfer from TiN to the conduction band of TiO$_2$: TiN.

**Plasmon-Enhanced Photocatalytic Reaction on Titanium Nitride Nanoparticles-Combined Experimental and Theoretical Study**

Alyssa Beierle$^1$, Paul Gieri$^2$, Alejandro Manjavacas$^3$ and Sanchari Chowdhury$^4$; $^1$New Mexico Tech, Socorro, New Mexico, United States; $^2$Physics and Astronomy, The University of New Mexico, Albuquerque, New Mexico, United States.

Plasmon-enhanced photocatalytic reaction on TiO$_2$ under solar light using alternative plasmonic titanium nitride(TiN) nanoparticles is studied. The excellent chemical stability at elevated temperatures and higher integrated absorption efficiency under a solar light in comparison to conventional plasmonic nanomaterials (silver and gold) make TiN a promising candidate for this application. We observed an efficient production of formic acid through simultaneous photoreduction of bicarbonate and oxidation of glycerol in the presence of TiO$_2$/TiN composite nanocatalysts in an isothermal condition. The photocatalytic productivity of formate with TiO$_2$/TiN composite is significantly (6 times) higher than TiO$_2$ alone. The enhancement is predicted to be due to the plasmon-induced excited charge transfer from TiN to the conduction band of TiO$_2$: <div>Interestingly, under solar light TiN alone can photo catalyze the reaction more efficiently than TiO$_2$ nanocatalyst (Degussa, P-25). The enhanced performance of TiN is attributed to the efficient hot electron transfer from TiN nanoparticle core to native thin (1-2 nm) amorphous titanium oxide shell, where the reaction takes place. The characterization of TiN nanoparticles after the reaction confirmed that TiN nanoparticles could remain stable under reaction conditions for extended periods of solar light exposure (8 hours). Comprehensive theoretical analyses
including fully numerical solutions of Maxwell equations to understand the optical properties of the nanostructures are done to support the experimental observation.</div>

Design Strategies for Novel Catalyst for (Photo)Electrocatalytic CO₂ Reduction Reaction Francesco Maria Tongi; Lawrence Berkeley National Laboratory, Berkeley, California, United States.

( Photo)electrocatalytic reduction of carbon dioxide offers an efficient strategy to reduce the presence of greenhouse gases in the atmosphere while concurrently producing valuable carbon-based products. However, existing ( photo)electrocatalysts for this process are insufficiently active or selective for attractive energy dense products, particularly in the face of the competing hydrogen evolution reaction ( HER ). Here, we present design strategies for the synthesis of novel ( photo)electrocatalysts for CO₂ reduction. We provide different examples of catalytic systems that can reveal design principles that enable development of active and selective catalysts and provide further insights into the reaction mechanism.

Functionalizing Si with WO₃ or BiVO₄ for Photoelectrochemical Applications Guido Mui¹, Alexander Milbrat², Bastian Mei², Jurriaan Huskens² and Ronald Jong²; IPCS Group, MESA+ Institute for Nanotechnology, University of Twente, Enschede, Netherlands; University of Twente, Enschede, Netherlands.

In this presentation recent efforts to create Si based photoanodes for photoelectrochemical applications will be discussed. Particular attention will be paid to WO₃ films, using an ITO interface. WO₃ on ITO/Si was found to rapidly lose performance in acidic media, which we assume to be due to the formation of adsorbed hydroperoxo species. When nanometer thin Pt was used to interface WO₃ with Si, stability and enhanced performance could be induced by deposition of TiO₂, prior to deposition of IrO₂. The effect of the height and spacing of microwires of Si on the photoelectrochemical performance of deposited BiVO₄ will also be addressed. Microwire substrates with BiVO₄ underperformed compared to BiVO₄ on flat surfaces. We predominantly attribute this to detrimental diffusion limitations of the redox species within the internal volume of the microwire arrays, in agreement with existing literature and observations regarding the electrodeposition of BiO, used as precursor for BiVO₄. Our results assist in developing high-efficiency PEC devices.

11:30 AM ES10.08.03
Solar-Driven Photocatalytic CO₂ Reduction in Water Utilizing a Ru Complex Catalyst on p-Type Fe₂O₃ with a Multiheterojunction Keita Sekizawa, Shunsuke Sato, Takeo Arai and Takeshi Morikawa; Toyota Central R&D Laboratories, Inc., Nagakute, Aichi, Japan.

To accomplish a practical CO₂ reduction system aimed at artificial photosynthesis, a hybrid system composed of a metal complex catalyst and a semiconductor photosensitizer has become a feasible approach, and the conversion efficiencies of such systems have been improving. However, there is still little research focusing on material cost and operation in water. Hematite (α-Fe₂O₃) is one of the most abundant and low-cost semiconductor materials, and can absorb a substantial amount of solar light (Bandgap: 2.1 eV). Although a usual α-Fe₂O₃ exhibit n-type conductivity, doping with ions such as Mg²⁺ and Zn²⁺, and N⁺ into α-Fe₂O₃ induce p-type conduction. We have reported that N,Zn-codoped α-Fe₂O₃ (N,Zn-Fe₂O₃) exhibited high cathodic photocurrent for O₂ reduction.[1] However, there are two issues with p-type Fe₂O₃; in that the charge separation property is inefficient and it easily corroded due to the self-reduction reaction under the reducing conditions in the CO₂ saturated aqueous electrolyte. To overcome the issues, a TiO₂ layer was introduced onto the surface of p-type N,Zn–Fe₂O₃ to passive surface defects. In addition, to ensure efficient electron transfer, a thin Cr₂O₃ layer was also inserted between N,Zn–Fe₂O₃ and a bottom side conductive oxide layer to generate a favorable band alignment for hole transfer. To optimize a metal complex – semiconductor hybrid photoelectrode, a Ru complex polymer with a low CO₂ reduction potential and an electron network with polypyrrole chains was determined to be the best combination with TiO₂/N,Zn–Fe₂O₃/Cr₂O₃.[2] We have successfully accomplished stable CO₂ reduction reaction coupled with H₂O oxidation in the absence of an external electrical bias by constructing a tandem cell reactor with an n-type SrTiO₃ photoanode.

Consciously Constructing Z-Scheme Photocatalysis via Photo-Deposition Method for Improving Photocatalytic Activity Wenshuai Jiang and Zaicheng Sun; Beijing University of Technology, Beijing, China.

Heterojunction and direct Z-scheme nanostructures are two typical representatives of an efficient photocatalyst, which is composed of two semiconductors. However, it is a great challenge to construct each of them on purpose. Photo-deposition technique can be a potentially powerful tool to regulate the electron flow direction for constructing these nanostructures. So, can we refer to the controllability of photo-deposition on the direction of charge flow to achieve a direct Z-scheme nanojunction construction? Based on the above discussion, we synthesized Fe₃O₄/g-C₃N₄ and TiO₂/CdS composites by photocatalytic oxidation deposition and photocatalytic reduction deposition, respectively. In order to verify both systems are the Z-scheme type junction, charge-tracking experiments were performed on both of them. The charge tracking experiments of Fe₃O₄/g-C₃N₄ composites obtained by oxidative deposition of Fe₃O₄ on g-C₃N₄ substrates show that the oxidation sites of the composites are located in Fe₃O₄ which is the same as the expected results. At the same time, TiO₂/CdS composite material is obtained by using TiO₂ nanorods reduction deposition of CdS, the charge tracking results showed that the reduction site of the composite was located in CdS, which proved that direct Z-scheme was reached through photo-deposition.
Innovations in photoelectrode architecture can continuously increase surface area, enhance light absorption and improve charge transport, and thereby increase overall power conversion efficiency. In the past, nanostructures of varying complexities, from one-dimensional nanotubes, nanowires and nanorods, to two-dimensional films and nanonets, and three-dimensional (3-D) porous structures, were reported with superior performance. In this presentation, branched 3-D nanostructured materials, especially ZnO, were discussed. To elevate the spatial occupancy of one-dimensional ZnO nanostructures and explore new structures as efficient electrodes for industry-level photoelectrochemical (PEC) water splitting into usable H2 fuel, we have developed procedures to fabricate nanoforest and “caterpillar-like” ZnO nanostructured network (CZN) for PEC applications. Moreover, by fine-tuning the synthesis procedure and manipulating their growth process, the dependence of their PEC properties on geometry factors of the unique branched nanostructures was controlled. As a result, the branched ZnO array nanostructures of tunable surface-to-volume ratio and roughness have been investigated. They offer mechanically and electrically robust interconnected networks with open micrometer-scale structures and short hole diffusion length. The preferential light-material interaction and charge separation to maximize the photo-to-hydrogen conversion efficiency were further studied. When used as photoanode, our branched nanostructures not only favor sunlight harvesting with multireflection ability, but also suppress the recombination of photogenerated charge. To sum, these novel branched nanostructures represent a new generation of photoelectrodes for high-efficiency solar energy harvesting and conversion to clean chemical fuels and hold bright potential for a wide range of practical applications in renewable energy.

Size-Dependent Photoresponse of Plasmonic Aluminum Nanoparticles
Yan Cheng, Kenneth J. Smith, Ebsuka S. Arintze, Tina Gao, Arthur E. Bragg and Susanna M. Thon; Johns Hopkins University, Baltimore, Maryland, United States.

Aluminum has attracted a great deal of attention as a plasmonic material in recent years due to its high abundance and low toxicity. Compared to frequently used gold and silver, it exhibits relatively high free carrier density, and the localized surface plasmon resonances (LSPRs) of aluminum nanoparticles can be tuned from the ultraviolet to the visible wavelength regime by controlling the nanoparticle size and shape. Aluminum nanostructures have been successfully used as sensitizers in photocatalysis for absorption.
enhancement and higher photocatalytic efficiency and selectivity. Since this process relies on hot carrier injection into the semiconductor photocatalyst, investigations on carrier relaxation dynamics in aluminum nanoparticle systems are critical in order to develop optimal architectures for efficient carrier injection. In an early study, we synthesized aluminum nanoparticles with diameters of approximately 100 nm in the solution phase and characterized used high-resolution transmission electron microscopy to show that these particles contain a 3.7 nm thick self-limiting surface oxide layer. Using transient absorption spectroscopy (TAS), we demonstrated that these large nanocrystals show a decreased transmission in the visible and near infrared regions while displaying a bleach in the wavelength that corresponds to the aluminum interband transition. These large particles show fast energy transfer to the solvent, on a timescale of approximately 250 ps, which is mediated by the thin oxide shell according to an extended two interface model for thermal transport. Here, we prepare aluminum nanoparticles with tunable sizes in the range of 70 nm to 130 nm in diameter with dipolar LSPRs ranging from 350 nm to 580 nm in wavelength. TAS is employed to study the size-dependent thermal relaxation dynamics. We show that the frequency of phonon oscillation is inversely proportional to the size of the particles which is consistent with acoustic modeling results. Furthermore, we find that the energy relaxation timescale decreases with decreasing nanoparticle diameter. For all particle sizes, the oxide shell mediates a faster energy exchange process than that predicted for metal-only particles. These energy dissipation studies are crucial for designing nanostructures with optimized sizes and surface profiles that will be favorable for utilizing local temperature variations and charge transfer to enhance photocatalytic rates in heterogeneous systems.

Photocatalytic System with Built-In Light Supply Based on Optical Waveguide Effect
Min Du; Shandong University, Jinan, China.

Light propagation limitation in wastewater constrain the photocatalytic water treatment system in type of large-area with thin in depth. The industrial water treatment with photocatalytic technique was constrained by the land shortage. To realize the 3D photocatalytic system, the light propagation in deep water was overcome via the optical fiber based on the optical waveguide effect. One-dimensional TiO$_2$ array are synthesized on commercial optical quartz fiber by a one-step hydrothermal process. The light propagation in the optical fiber and export at the junction between optical fiber and TiO$_2$ nanorods. The light propagation in the TiO$_2$ nanorods would be absorbed in high efficiency, which results in a high rate of the light utilization. This built-in light supply mode can solve the light propagation in deep water. The demo device assembled by TiO$_2$ functioned optical fiber exhibits excellent photocatalytic performance implying its high potential in industrial application.

Amazing Acid-Mediated Porphyrin Self-Assembly with NIR Absorption as Highly-Efficient PTT Platform for Curing Tumors
Jinghui Wang; Key Laboratory for Special Functional Materials of the Ministry of Education, Kaifeng, China.

Exploring the synthesis of photosensitizers that not only have strong absorption in the near-infrared region but also achieve rapid temperature rise in a short period of time are required for excellent photothermal therapy. Porphyrins as a class of biological macrocyclic conjugated molecules with good biocompatibility are more and more used in biological diagnosis and treatment. However, to make ordinary porphyrin molecules achieve strong absorption in 800 nm near infrared region and enhance penetration ability in PTT is still unresolved. Here we report a proton acid doping porphyrin self-assembly method to construct strong NIR absorbance near 1000 nm photothermal conversion agents using 5,10,15,20-tetrakis (4-aminophenyl) porphyrin (TAPP) as optical active precursor. A series of morphologies including nanosheets (NSs) and nanorods (NRs) as amorphous nanoparticles (NPs) are synthesized with controlled size and dimension. The morphology and absorption spectra can be regulated by adjusting the types of surfactant micelles and the addition amount of protonic acid though adjusting the weak interaction forces between the assembled molecules. Owing to the inner core protonated of the TAPP in NPs effectively improved NIR-absorption and complete quenching of fluorescence. Ultimately obtaining a morphologically dependent NPs capable of efficiently utilizing NIR light energy to thermal energy conversion is obtained. The NPs connected with ERGD have been used in the treatment of tumor-bearing mouse models to achieve excellent therapeutic effects. This method of adjusting the spectral changes by adjusting the weak interaction between the assembly elements has a good extension value.

Controllable Self-Assembly of Porphyrin with Photocatalytic Water Splitting Under Visible Light
Ronghui Cao; Key Laboratory for Special Functional Materials of the Ministry of Education, Henan University, Kaifeng, China.

Photocatalytic hydrogen production from water splitting is considered as one of the promising ways to provide clean fuels that can convert solar energy into chemical energy. In the past years, researchers have made great efforts to develop various inorganic and organic materials systems as photocatalysts for water splitting. Photocatalytic water splitting includes three steps: (i) photocatalyst absorbs light; (ii) photogenerated charge separation; (iii) surface chemical reaction. Only by enhancing the efficiency of each step can the efficiency of photocatalytic water splitting be improved. Directional separation of photogenerated charge is more studied in inorganic semiconductor photocatalysis, but little research has been done on organic photocatalysis. Here, we reported an emulsifier-assisted co-solvent method to fabricate porphyrin nanomaterials using Pd meso-tetra-(4-carboxylphenyl) porphyrin as building blocks. The specific arrangement of aggregates were spontaneously constructed driven by confined noncovalent interactions of hydrogen bonds, π-π stacking, hydrophilic-hydrophobic. The four carboxyl groups and center metal Pd within the PdTCPP molecular endowed strong hydrogen bonding and axial coordination between porphyrin and emulsifier. These assemblies had a wide absorption spectrum at 400-700 nm, which was good for absorbing visible light. These assemblies were used for photocatalytic hydrogen production under visible light and the result exhibited the outstanding hydrogen evolution rate of 9.38 mmol/g/h in the absence of Pt particles as cocatalyst in our work. The rate of photohydrogen production increases to 138.94 mmol/g/h after photocatalytic deposition of Pt nanoparticles. What's interesting is that the Pd nanoparticles are mainly on the edge of the assemblies. This indicated that the edge of the assemblies was the electron transport channel. The hole transport channel remained to be studied.
Currently over 95% of hydrogen is made from fossil fuels through natural gas reforming or coal gasification. A major part of reducing carbon emissions must therefore include sources of renewable hydrogen. In addition, capture of existing carbon dioxide sources and subsequent conversion to higher value chemicals also requires a hydrogen source. Using hydrogen from traditional sources for this purpose does not make environmental sense, since the net effect is just shifting where the carbon dioxide is emitted geographically. Large scale, cost competitive sources of renewable hydrogen are critical in moving to more sustainable processes worldwide.

Low temperature electrolysis has decreased significantly in cost while increasing in scale over the last several years, and there continue to be large opportunities for additional cost reduction and performance improvements. With the advent of low cost renewable electricity, particularly in times of excess capacity when storage is most needed, electrolysis is reaching the production and cost scale to provide a viable solution. However, as research activities have increased, differences in testing conditions, reporting comparisons, cell designs, and other factors convolute data interpretation and can lead to misleading conclusions. In addition, insufficiently controlled procedures can mask effects. This talk will describe some of the complex interactions that need to be considered, and current efforts in developing community-wide tests ranging from ex-situ material screening protocols to realistic device testing. This work is part of an ongoing program across all of the major advanced water splitting technologies, the subject of this symposium and the parallel high temperature water splitting symposium.

10:45 AM ES11.01.02/ES12.01.02
**Development of Protocols and Standards for Photoelectrochemical Water-Splitting**  
Chengxiang Xiang; California Institute of Technology, Pasadena, California, United States.

Cost competitive hydrogen generation at scale using sunlight and water can play a significant role in decarbonization of our society. In recent years, photoelectrochemical (PEC) water splitting has made significant progress in materials discovery, mechanistic understanding, as well as in achieving un-precedent solar to hydrogen conversion efficiencies in the laboratory scale. To further advance this technology and reach the bench scale (0.1 kg/day) and sub-scale (2 kg/day) operational platforms, development of standard protocols and best practices for benchmarking materials and devices as a community is critical. Standardized methodologies and best practices also provide significant benefit in accelerated RD&D of advanced materials and cross-cutting efforts.

In this presentation, I will talk about recent community-based efforts in defining targets, best practices and gaps in PEC hydrogen production in HydroGEN Energy Material Network (EMN) consortium. Specific challenges related to PEC will be discussed including scale up challenges, integration challenges at the component level, lack of performance data and test protocols for photoelectrodes under real-world operating conditions and lack of fundamental understanding of photoelectrode corrosion mechanisms and accelerated test protocols. In addition, I will also present a brief summary and status reports on lab EMN nodes/capabilities for PEC water-splitting. Key takeaways from a recent HydroGEN Benchmarking&Protocols Workshop and DOE PEC Working Group Meeting will also be discussed.

11:00 AM ES11.01.03/ES12.01.03
**Framework and Test Protocols for High Temperature Electrolysis**  
Olga Marina; Pacific Northwest National Laboratory, Richland, Washington, United States.

Hydrogen production via water electrolysis is considered to be an efficient way to smoothen the fluctuating power output of renewable energy sources and avoid oversupplies. This presentation will provide the status of the standards and protocols development for high temperature electrolysis (HTE) technology within the US DOE HydroGEN Energy Materials Network Consortium. The current material standards, advanced characterization techniques, best practices and testing protocols from screening of fundamental material properties to device level benchmarking will be discussed to address key challenges and leverage technical advancements across the different water splitting technologies.

11:15 AM ES11.01.04/ES12.01.04
**Framework and Test Protocols for Solar Thermochemical Water Splitting**  
Ellen B. Stechel; LightWorks and School of Molecular Sciences, Arizona State University, Tempe, Arizona, United States.

This presentation will provide the status of standards and protocol development within the US DOE HydroGEN Energy Materials Network (EMN) Consortium for advanced water splitting using concentrated solar thermochemical redox cycles, generally referred to as STCH, solar thermochemical hydrogen. Cost competitive water splitting to produce hydrogen at scale using concentrated sunlight can contribute significantly to a net CO₂ neutral society. In recent years, STCH has made significant progress. Working as a community will further advance STCH technology with a goal of reaching demonstration scales of multiple kilowatts with promising redox active materials. The development of standard protocols, definitions, metrics, best practices, and roadmaps for benchmarking materials and reactor designs is critical to accelerate progress and lower barriers for new researchers.

In this presentation, we will discuss recent HydroGEN EMN community-based efforts in defining metrics, best practices, and gaps in STCH. In addition, we will present a brief summary of EMN nodes/capabilities as well as key conclusions from a recent questionnaire and from a recent HydroGEN Benchmarking & Protocols Workshop specifically for STCH.

11:30 AM PANEL DISCUSSION
This work presents a detailed PL spectroscopy investigation on thin nanostructured TiO\textsubscript{2} films prepared by Pulsed Laser Deposition. To selectively discern the luminescent traps, the effects of different degrees of defectivity, related to oxidizing (air) and reducing (Ar/H\textsubscript{2}) treatments, on the PL properties is considered. With both UV and green excitation, the PL emission is quenched and that of the other films exhibits a blueshift, compatible with the effect of reducing thermal treatments and the comparison between different excitation wavelengths (i.e. above and below the bandgap energy) are very limited.

The present findings confirm how PL spectroscopy can efficiently probe defect states in reduced TiO\textsubscript{2} systems, allowing a deeper understanding on the relationship between defects and photoactivity, yielding to higher performance; in this way, defects such as oxygen vacancies and Ti\textsuperscript{3+} ions are quenched and that of the other films exhibits a blueshift, compatible with the effect of reducing thermal treatments and the comparison between different excitation wavelengths (i.e. above and below the bandgap energy) are very limited.

**Nanotechnological Spinel Ferrite Photoanodes for Photoelectrochemical Water Splitting**

Kristin Kirchberg\textsuperscript{1}, Stefanie Waitz\textsuperscript{2}, Songcan Wang\textsuperscript{3}, Christian Suchomski\textsuperscript{1}, Torsten Brezesinski\textsuperscript{1}, Lianzhu Wang\textsuperscript{4} and Roland Marschall\textsuperscript{5,6}; \textsuperscript{1}Justus-Liebig-University Giessen, Giessen, Germany; \textsuperscript{2}University of Bayreuth, Bayreuth, Germany; \textsuperscript{3}Georg-August-University Göttingen, Göttingen, Germany; \textsuperscript{4}The University of Queensland, Brisbane, Queensland, Australia; \textsuperscript{5}Karlsruhe Institute of Technology, Eggenstein-Leopoldshafen, Germany.

Mesoporous ZnFe\textsubscript{2}O\textsubscript{4} and LiFe\textsubscript{2}O\textsubscript{4} thin film photoanodes were fabricated by sol-gel synthesis\textsuperscript{[1,2]} using a polymer-templating approach. By means of different amphiphilic diblock- and triblock copolymers, large and partly ordered mesopores are obtained after dip-coating by evaporation-induced self-assembly followed by heat treatment. Scanning electron microscopy (SEM) confirms the porous morphology, and Raman spectroscopy and XRD Rietveld analysis revealed phase pure spinel ferrite photoanodes.

Furthermore, photocurrent and Mott-Schottky measurements were performed at different pH values to determine the flat band potential and photocurrent density of the thin film photoanodes calcined at various temperatures. By varying the block-copolymers, altered pore structures of the photoanodes and their influence on photoelectrochemical performance will be discussed.

**Excitation Wavelength- and Medium-Dependent Photoluminescence of Reduced Hierarchical TiO\textsubscript{2} Films**

Luca Mascaretti\textsuperscript{1,2}, Valeria Russo\textsuperscript{1,2}, Giorgio Zoppellaro\textsuperscript{1,2}, Andrea Lucotti\textsuperscript{1}, Carlo S. Casari\textsuperscript{1,3}, Stephan Knerr\textsuperscript{4}, Alberto Naldoni\textsuperscript{5} and Andrea Li Bassi\textsuperscript{5}; \textsuperscript{1}Department of Energy, Politecnico di Milano, Milano, Italy; \textsuperscript{2}Regional Centre of Advanced Technologies and Materials, Palacky University Olomouc, Olomouc, Czechia; \textsuperscript{3}Center for Nanoscience and Technology - IIT@Polimi, Istituto Italiano di Tecnologia, Milano, Italy; \textsuperscript{4}Department of Chemistry, Materials and Chemical Engineering "Giauho Natta", Politecnico di Milano, Milano, Italy.

Nanostructured forms of TiO\textsubscript{2} have been extensively investigated as photoactive materials for energy-related applications, such as dye-sensitized solar cells, photocatalysis and water splitting. Annealing in reducing atmospheres has been frequently employed as an approach to increase TiO\textsubscript{2} performance; in this way, defects such as oxygen vacancies and Ti\textsuperscript{3+} sites are introduced, leading to increased light absorption, higher \emph{n}-type conductivity, and new catalytic sites with enhanced reactivity\textsuperscript{[1]}. These defects often induce a series of discrete electronic states in the bandgap with similar energies and their characterization is of pivotal importance for a deep understanding of their role in the enhancement of the material performance; this aspect is still an open topic in the current research. A powerful tool to probe such defect states is photoluminescence (PL) spectroscopy. For anatase TiO\textsubscript{2}, in particular, a broad visible emission is observed, with two main components in the green (\emph{green PL}) and in the red (\emph{red PL}) regions associated with holes and electrons in deep traps, respectively\textsuperscript{[2]}.

However, a definitive framework is still lacking: PL properties depend on the material porosity/morphology and detailed investigations concerning the effect of reducing thermal treatments and the comparison between different excitation wavelengths (i.e. above and below the bandgap energy) are very limited.

The development of an efficient, stable photoanode to provide protons and electrons to the (photo)electrode remains a primary materials challenge in the establishment of a scalable technology for artificial photosynthesis. However, the absolute and relative stability and performance of different OER catalysts varies with proton density with pH. The operational conditions for the solar fuels generator is often dictated by the pH stability range of the light absorber, not the conditions optimal for OER catalysts. We have evaluated the activity and stability against corrosion of over 10,000 multi-metal oxide compositions from pH 1-13 using high-throughput electrochemical methods. The experimental and data processing methods and characteristic results are described. The Mn-Sb-O system contained compositions and structures with high acid stability and OER catalytic performance. The characterization of performance and structure of the Mn-rich alloys in the rutile oxide structure will be described. The typical photoanode architecture consists of a semiconductor light absorber coated with a metal oxide that serves a combination of functions, including corrosion protection, electrolysis, light trapping, hole transport, and elimination of deleterious surface recombination sites. We describe a high throughput investigation of the variation in performance and photo-response of individual photoanodes consisting of BiVO$_4$ coated with a sputter deposited Fe-Ce oxide film as a function of composition and adjacent metal(ll) content.

Photocatalytic water splitting is one of the potential approaches for the generation of hydrogen which can fulfill the global energy requirement [1]. But BiVO$_4$ photoanode show poor photo conversion efficiency due to poor charge transport, fast surface charge recombination and sluggish water oxidation kinetics [3]. To overcome the poor charge transport, we report formation of composite of BiVO$_4$ with modified and unmodified graphite carbon nitride (C$_3$N$_4$). In current study photocatalyst electrochemical properties of BiVO$_4$, C$_3$N$_4$ and electronic properties of Tungsten (W) metal were utilized to make a composite with enhanced Photocatalytic properties. BiVO$_4$, BiVO$_4$-C$_3$N$_4$ and BiVO$_4$-C$_3$N$_4$-W composite photo anode was prepared using facile dip coating technique. The BiVO$_4$-C$_3$N$_4$-W electrode has shown much improved photocatalytic water splitting performance at 1.23 V vs RHE, under one sun illumination on both from front and backside of electrode. In particular, the photocatalytic current density (1.2 mA.cm$^{-2}$) shown by BiVO$_4$-C$_3$N$_4$-W was about twenty times higher than pristine BiVO$_4$(0.06 mA.cm$^{-2}$). The microscopic, XRD and XPS analysis showed that BiVO$_4$ grain interaction with C$_3$N$_4$ led to formation of composite system which can efficiently suppress hole-electron pair recombination. The electrochemical impedance and cyclic voltametry measurements showed that the composite formation can lowered the interface resistance, charge transfer resistance and increased the charge donor/surface state density. Further PEC performance was corroborated with changes in band gap, crystal lattice, surface grain morphology occurred in BiVO$_4$-C$_3$N$_4$-W composite.

**Study of Enhancement in Photocatalytic Water Oxidation Performance of Monoclinic BiVO$_4$ with Systematic Doping with Yttrium**

Umesh Prasad, Jyoti Prakash, Bruno Azeredo and AM Kannan; The Polytechnic School, Ira A. Fulton Schools of Engineering, Arizona State University, Mesa, Arizona, United States.

Photocatalytic (PEC) water splitting is one of the potential approaches for the generation of hydrogen which can fulfill the global energy requirement [1]. In developing economical and efficient photo-catalysts for water oxidation, n-type monoclinic BiVO$_4$ has been widely reported due to its favorable band gap [2]. But the photo conversion efficiency of BiVO$_4$ catalyst is relatively low due to poor charge transport, fast surface charge recombination and sluggish water oxidation kinetics [3]. In current report, BiVO$_4$ photocatalyst doped with yttrium(Y) was prepared by ultrasonic spray coating technique to overcome poor charge transport. Various percentage of Y (1,2,3,4,5 wt %) is doped in pristine BiVO$_4$ to optimize the PEC performance. The 4wt% Y doped BiVO$_4$ photo-anode has shown highest PEC photocurrent 2.20 mA.cm$^{-2}$ at 1.23 V RHE and 4.5 mA/cm$^2$ at 2 V RHE under simulated one sunlight illumination in K$_2$HPO$_4$ electrolyte. However, the photocatalytic activity of the other Y: BiVO$_4$ photo anodes were suppressed as the Y doping level decreased or increased, which could be attributed to the formation of photogenerated charge carrier recombination centers at the Y substituting sites. Here, Y$^{3+}$ dopant replaces Bi$^{3+}$ sites in BiVO$_4$ lattice to provide expanded light absorption wavelength region from 400-600nm. Further, Y: BiVO$_4$ photoanode were investigated by XRD, XPS and SEM. It was observed from Y: BiVO$_4$ that Y-doping didn't generate any impurity phases in pristine BiVO$_4$. XPS analysis showed the Y-peaks 3d$_{3/2}$ and 3d$_{5/2}$ at the binding energies 165eV and 160eV respectively, which confirm the oxidation state of Y as +3. The microscopic, XRD and XPS analysis showed that BiVO$_4$ grain interaction with C$_3$N$_4$ led to formation of composite system which can efficiently suppress hole-electron pair recombination. The electrochemical impedance and cyclic voltametry measurements showed that the composite formation can lowered the interface resistance, charge transfer resistance and increased the charge donor/surface state density. Further PEC performance was corroborated with changes in band gap, crystal lattice, surface grain morphology occurred due to Y doping in BiVO$_4$.

Behavior of Electrochemically Generated Hydrogen Bubbles on Silicon Microwire Arrays Paul A. Kempler1, Robert H. Coridan2, Yikai Chen3 and Nathan S. Lewis1, 2; California Institute of Technology, Pasadena, California, United States; 3Chemistry, University of Arkansas–Fayetteville, Fayetteville, Arkansas, United States.

Electrochemical generation of hydrogen and oxygen during photoelectrochemical water splitting leads to the formation of gas bubbles when the concentration of dissolved gases exceeds a critical concentration in solution. Gas bubbles inhibit the performance of solar-to-fuels devices by reflecting incident sunlight and restricting mass transfer to and from catalysts. Membrane embedded microwire arrays provide a path to fully integrated solar-to-fuels devices, but the removal of gas bubbles from the underside of the device is challenging, as gravity will direct bubbles towards the photoelectrode surface. Studies on silicon-based cathodes in a variety of orientations relative to the gravitational vector will aid in understanding the opportunities and challenges associated with unassisted photoelectrochemical water-splitting at scale.

Arrays of silicon microwires were formed via photolithographic patterning and reactive ion etching and then coated with a sputtered platinum electrocatalyst layer to form cathodes which were stable in acidic media and operated at low catalytic overpotentials for hydrogen evolution. Devices were characterized via electrochemical measurements in 0.5 M H2SO4 (aq) coupled with high speed photography. The effects of the wire diameter and packing fraction on the nucleation density and break-off diameter of hydrogen bubbles as a function of current density have been characterized. All electrode designs were found to exhibit significant hydrogen bubble coverage at current densities in excess of 75 mA cm-2, but at current densities expected for solar-to-fuels devices driven by unconcentrated sunlight—less than 30 mA cm-2—bubble coverage could be suppressed by appropriate microwire array designs. The operational overpotentials of large area cathodes have been compared as a function of tilt in a downward facing orientation to assess the ability of microwire arrays to remove bubbles without assistance under operating conditions.

4:45 PM ES11.03.06

Photo-electrochemical water splitting systems at present show low performance compared to theoretical predictions. One of the reasons for this low performance is the inefficiency of oxygen evolution reaction (OER), which occurs at the semiconductor (photoanode)-electrolyte interface. Hence, for improving the performance of such water splitting systems, we need to improve the performance of the semiconductor-electrolyte interface. However, it is still unclear, what the performance limiting processes are at the interface. We present a new approach for those systems that allows for simulating - from an atomistic model - the same electrochemical data that is measured experimentally. [1] We develop a micro kinetic model for the OER by combining density functional theory (DFT) and state-space modeling. By comparing theory and experiments, the performance limiting processes at the interface can be identified.

In literature, micro kinetic modeling has been successfully used for metallic electrodes, using Butler-Volmer theory for calculation of reaction rates. [2] However, Butler-Volmer theory is only valid for metal-electrolyte interface and does not describe the charge transfer reactions at the semiconductor-electrolyte interface during water splitting process. [3] We therefore use the Gerischer theory for semiconductors in this study. Hematite (Fe2O3) – water interface is the model system used here. We choose the four step OER mechanism proposed by Rossmail et al. [4] as the electrochemical model. Based on this mechanism, mass conservation and charge balance equations are formulated. The resulting set of differential equations are represented as a state-space model (SSM); the applied potential is the input and the current density is the output. The energy of formation of the four OER intermediates at hematite surface are calculated by DFT [5] and are used to calculate the reaction rates. With this input and hematite specific parameters from the literature, electrochemical data such as current-voltage plots and electrochemical impedance spectra are simulated from the state-space model. We can also simulate the surface coverages of all intermediate species as a function of applied potential. This data is experimentally not available, but is of utmost importance for experimental studies on identification of OER intermediates. The simulated impedance from the electrochemical reactions are compared to measured impedance data from in-house experiments [1]. The simulation results are in close agreement with the experimental measurements and capture the dynamics well. Identification of performance limiting processes by comparison with experiments will be discussed. The model is generic and can be extended to study other materials and other interfaces. From a multi-scale modeling perspective, the developed model is a continuum model, which connects first principle calculations and experimental data for semiconductor-electrolyte interfaces. Further, predicting the effect of doping and cocatalyst loading on the surface of the semiconductor electrode using the model will also be discussed.

GaAs Nanomembranes for Solar Water Splitting Haneol Lim1, Yukun Sun2, Minjoo Lee3 and Jongseung Yoon1, 2; 1Mork Family Department of Chemical Engineering and Materials Science, University of Southern California, Los Angeles, California, United States; 2Department of Electrical and Computer Engineering, University of Illinois at Urbana Champaign, Urbana, Illinois, United States; 3Ming Hsieh Department of Electrical Engineering, University of Southern California, Los Angeles, California, United States.

Despite their outstanding photovoltaic performance and record-high solar-to-hydrogen efficiency, the high production cost and limited photoelectrochemical stability of III-V compound semiconductors prohibit their practical application in solar-driven photoelectrochemical water splitting. Here we present a novel strategy for III-V photoelectrodes that can overcome these obstacles via printing-based assemblies of surface-engineered, epitaxially-grown nanomembranes. Ultrathin (i.e. emitter + base = 300 nm) GaAs photocathodes having a buried pn-junction are released from the growth wafer and printed onto a non-native, transparent substrate to form integrated bifacial photocathodes for the hydrogen evolution half-reaction of solar water splitting. Hexagonally periodic TiO2 nanoposts are incorporated into the light-absorbing interface of ultrathin GaAs to maximize the light absorption, while the n-type ohmic metal, protection layer, and co-catalyst are deposited on the reactive interface to optimize the catalytic efficiency and stability. The resulting bifacial GaAs photocathodes with nanoplanar light management exhibit significantly enhanced saturated current density (from -11.7 mA cm-2 to -16.3 mA cm-2) and diagnostic electrode efficiency (from -8.6% to -11.3%) compared to the bare GaAs photocathodes without TiO2 nanoposts, under AM1.5G solar illumination in aqueous sulfuric acid (0.5 M H2SO4).

ES11.04.02
Piezoelectric-Photoelectrochemical Characteristics of ZnO Nanopyramids for Sono-Assisted Water Splitting Yaqiong Li1, 2, Taehoon Lim2, Kichang Jung3, 4 and Alfredo A. Martinez-Morales4; 1Materials & Science Research, University of California, Riverside, Riverside, California, United States; 2College of Engineering - Center for Environmental Research and Technology, University of California, Riverside, Riverside, California, United States; 3Department of Chemical and Environmental Engineering, University of California, Riverside, Riverside, California, United States.

To date, there has been intense research in zinc oxide (ZnO) nanostructures in terms of the variety of morphologies that can be achieved and the availability of low-cost synthesis methods. ZnO is a versatile photo-responsive material which can be used as photocatalyst and photoelectrode for solar cells (e.g. perovskite solar cells). The photocatalytic activity of ZnO can be further enhanced by the extra polarization from the piezoelectric operation under external mechanical forces. Due to their low stability against mechanical stress.
one-dimensional ZnO such as nanowires and nanorods have inherent limitations for sono-assisted water splitting applications. In this work, we investigate pyramidal ZnO structures for piezoelectric-photocatalytic devices by utilizing their higher mechanical stability and photocatalytic activity. The surface of pyramidal ZnO with (112) crystal plane has higher surface energy and photocatalytic activity.

To achieve the ZnO nanopyramid we utilize a modified crystal growth method by adjusting the reaction kinetics and fluid dynamics during chemical vapor deposition (CVD). Synthesis under different experimental parameters such as reaction temperature, reactor design, reaction pressure, and gas ratio are carried out. The morphology is controlled by adjusting experimental parameter and the effects of crystal growth conditions on the piezoelectric-photocatalytic properties are also investigated. The morphology, crystal structure, and optical/electrical properties of synthesized ZnO are characterized by the scanning electron microscopy, X-ray diffraction analysis, and optical spectroscopies, respectively. The piezoelectric and photocatalytic properties are characterized by piezoelectric force microscopy and potentiostat measurements, respectively. The enhanced performance of photocatalytic water splitting is tested under the presence of mechanical forces in the form of ultrasonic waves.

Low and High -Temperature Electrolysis, Solar and thermochemical Water Splitting Materials Characterization and Development at Berkely Lab Under the HydroGEN Consortium Nemania Danilovic, Frances Houle, Ahmet Kusoglu, Francesca Maria Toma, Mike Tucker, Lin-Wang Wang and Adam Weber; Lawrence Berkeley National Laboratory, Berkeley, California, United States.

The HydroGEN consortium brings together unique National Laboratory experts and tools (nodes) with researchers developing advanced water splitting materials in a variety of technologies: Low and High -Temperature Electrolysis (LTE/HTE), Photoelectrochemical (PEC) and Solar-Thermochemical (STCH) Water Splitting. Lawrence Berkekey National Laboratory is a HydroGEN partner lab and has participated in 9 projects since 2018. This poster will highlight -Berkley Lab capabilities and expertise available to researchers in LTE, HTE, PEC and STCH fields -Our collaborative work performed with our partners in LTE, HTE and PEC in the last year -Benchmarking LTE, PEC and HTE materials performance -Tackling big scale problems in LTE, PEC and HTE through multi-node, multi-institution projects "supermodes"

ES11.04.04
CuGaSe2/Zn1−xMgO Photocathodes for Photocatalytic Water Splitting Impar S. Khan¹, Karen Heinseleman¹, Christopher Muzzillo¹, James L. Young², Todd G. Deutsch³, Andriy Zakutayev⁴ and Nicolas Gaillard⁵; National Renewable Energy Laboratory, Golden, Colorado, United States; ¹University of Hawaii, Honolulu, Hawaii, United States.

CuGaSe₂ is a promising absorber material for photocatalytic (PEC) water splitting due to its suitable wide band gap and durability in electrolyte solution. Zn₁₋ₓMgO is a potential buffer layer for the CuGaSe₂ absorber, because of its tunable conduction band offset as a function of Mg concentration. Zn₁₋ₓMgO thin film is deposited on the evaporated CuGaSe₂ absorber using combinatorial RF sputtering. Prior to the buffer layer deposition, the absorber is treated in Ca²⁺ containing solution. The quality of the CuGaSe₂/Zn₁₋ₓMgO interfaces as a function of varying Mg is studied based on solid state photovoltaic device performance. PEC performance of the device is characterized in three electrode configuration with SiO₂/Mo/CuGaSe₂/Zn₁₋ₓMgO as the photocathode, Pt counter electrode, and a reference electrode. To quantify the device performance in relation to the Mg content in the buffer, chopped-light current–voltage (CLIV) measurement is performed using a scanning droplet cell measurement system. The results of these experiments facilitate the understanding of the CuGaSe₂/Zn₁₋ₓMgO photocathode interfaces, and application of CuGaSe₂ absorbers for PEC water splitting. This work was performed as part of the HydroGEN EMN between National Renewable Energy Laboratory (NREL) and University of Hawaii, with support from the Combinatorial (A. Zakutayev), Chalcopyrite (C. Muzzillo), and PEC (T. Deutsch) nodes at NREL.

ES11.04.05
Measurement of the IPCE of Photocatalytic Electrodes Using a Pump-and-Probe Method Martin Velazquez-Rizo², Jan Diego Trelles-Molina²,¹, Liang Zhang¹, Leticia Castrejon Barron¹, Daisuke Iida¹ and Kazuhiro Okawa¹; ¹Computer, Electrical and Mathematical Science and Engineering (CEMSE) Division, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; ²Monterey Institute of Technology and Higher Education, Monterey, Mexico.

We demonstrated that a pump-and-probe method to measure the incident photon-to-current efficiency (IPCE) is reliable. We confirmed that the photocurrent of a catalytic photocathode is better described through the IPCE obtained using this method than with the IPCE obtained using only monochromatic irradiation. Commonly, the IPCE is measured through its conventional method, where the photoabsorption device is irradiated with monochromatic light and the photocurrent generated is recorded [Hwang, et al. Nanotechnology, 24, 055401 (2013)]. Then, the IPCE is derived from the response current, the applied optical power and the wavelength of the monochromatic light. The IPCE spectra obtained with this method is expected to diverge from realistic values, fundamentally because of the changes in the band diagram of photocathodes when they are excited. During the water photoelectrolysis reaction, photocathodes are irradiated with a considerable amount of optical power. Such excitation takes them to a non-equilibrium thermodynamic state, modifying not only their band structure but their carrier dynamics as well. Therefore, the method we utilized finds out the IPCE of a photocatalytic cell once its photocathode is already at a given excited state. To show the scope of this method, we characterized the IPCE of a photocatalytic cell with a SiO₂/CuGaN photocathode [Hayashi, Okawa, et al. J. Appl. Phys. 51, 112601 (2012)]. It was irradiated with a power density of 100 mW/cm² using a Xe lamp, which is the same power density used for the photoelectrochemical H₂/O₂ production. The IPCE values were calculated from the additional photocurrent induced by the monochromatic probe light. The IPCE spectrum was measured in different locations of the photocathode, and the total photocurrent was obtained by integrating the convolution of the Xe lamp radiation spectrum and the IPCE over the photoabsorption range and the geometrical area of the photocathode. The base photocurrent of the photocathode was L × 0.45 mA/cm². Using the IPCE obtained through the conventional method, the photocurrent calculated was as large as 3.01 mA/cm² (≈6.69 L). On the other hand, the value calculated using the IPCE from the pump-and-probe method was as good as 0.57 mA/cm² (≈1.27 L). Thus, using the pump-and-probe method, we obtained a calculated photocurrent value almost equal to the base photocurrent. This result indicates that the IPCE values obtained using the pump-and-probe method drastically improved the description of the photocurrent behavior of photocathodes. This measuring technique will help to characterize photocatalytic cells more reliably, and it also gives an insight into the differences in the band structure of semiconductors when they are in a non-equilibrium state.

ES11.04.06
Improvement in Performance of CuO Photocathode for Hydrogen Evolution in Solar Water Splitting Kichang Jung¹,², Taehoon Lim³, Hyojung Bae³, Jun-Seok Ha¹,⁴ and Alfredo A. Martinez-Morales¹,⁵, ¹Chemical and Environmental Engineering, University of California, Riverside, Riverside, California, United States; ²College of Engineering Center for Research & Technology, University of California, Riverside, California, United States; ³Optoelectronics Convergence Research Center, Chonnam National University, Gwangju, Korea (the Republic of); ⁴School of Chemical Engineering, Chonnam National University, Gwangju, Korea (the Republic of); ⁵Materials Science and Engineering Program, University of California, Riverside, Riverside, California, United States.

In this work, we study the performance of CuₐO as a photocathode for photoelectrochemical water splitting. The morphology of the CuO is engineered to improve the hydrogen generation efficiency through the enlargement of the surface area and increased light absorbance. The nanostructured CuO is synthesized by a two-step method. First, a Cu layer is deposited by e-beam evaporator onto FTO. Second, the CuO nanostructure film is obtained via a solution and thermal oxidation method under nitrogen environment. Due to the p-type semiconductor properties of CuO, the synthesis film can be used as a catalyst for the reduction reaction. This research shows improvement in the photoelectrochemical efficiency of CuO photocathodes by preventing the formation of unreduced Cu layer between CuO and conductive substrate (FTO). Specifically, the effect of unreduced Cu layer is investigated. CuO samples are synthesized with the same surface morphology, but exhibit different unreduced Cu layer thickness between CuO and FTO. The fully reacted CuO photocathode shows an enhanced photocurrent density and improved efficiency in hydrogen evolution compared to CuO with unreduced Cu. The enhanced photocatalytic performance of the photocathode without a trace of unreduced Cu layer is attributed to the reduction in charge recombination resulting from the full oxidation of the Cu layer. Experimentally, it is confirmed that unreduced Cu significantly reduces carrier lifetime and negatively affects the photoelectrochemical performance of the photocathode. The elimination of the unreduced Cu layer leads to higher photocurrent density. Morphology of CuO is characterized by scanning electron microscopy. Crystallinity of the samples is analyzed by X-ray diffraction. Absorbance is measured by ultraviolet-visible-near infrared spectrophotometry. The electrochemical properties of the synthesized materials in the electrolyte are analyzed by measuring current density versus voltage and electrochemical impedance spectroscopy.
Photoelectrochemical Characterization of Cuprous Oxide (Cu₂O) Thin Films Deposited by Chemical Bath Deposition (CBD)

Cuprous oxide (Cu₂O) is a p-type semiconductor with a direct band gap of about 2.0-2.7 eV and high absorption coefficient. Due to its outstanding photoelectronic properties, natural abundance, non-toxic nature, and simple preparation procedures, Cu₂O has generated interest in various applications, such as the conversion of solar energy into electrical or chemical energy, photochemical decomposition of water into O₂ and H₂ under visible-light irradiation, photocatalyst for degradation of organic contaminants, as hole transporting material in device photovoltaic technology, for gas sensing and magnetic storage. Cu₂O thin films are commonly deposited by thermal oxidation of copper thin films, which previously are deposited by sputtering or evaporation. Thermal oxidation is an expensive technique because of high temperatures and consequently the wasting of energy. In the other hand CBD is an economic, easy and scalable deposition technique, which is not well studied for Cu₂O thin films deposition.

We report an easy and direct CBD method for Cu₂O thin films. We have studied the effect of thickness on the optical, structural, morphological, electrical and photoelectrochemical properties. The thin films were analyzed by X-ray diffraction (XRD), Scanning Electron Microscopy (SEM), energy dispersive spectroscopy (EDS), UV-vis spectroscopy, electrically and photoelectrochemical characterized by Electrochemical impedance spectroscopy. The combined PV-PEC cell can benefit not only from the high oxidation potential of ZnO NRs but also from the visible range light absorption of Cu₂O to smoothen the p-n junction interface. We for the first time produced p-n homojunction Cu₂O Z-Scheme PV-PEC Cells for the Low Bias Photoelectrochemical Water Splitting Enabled by NiFe-Layered Double Hydroxide Co-Catalyst. Scientific Reports, 6., 1.=-Qi, H., Wolfe, J., Fichou, D., & Chen, Z. (2016). Cu₂O Photocathode for water splitting—a critical review. Energy & Environmental Science, 8(3), 751-759.

Enhanced Photoelectrochemical Responses of ZnO NR/p-n Cu₂O Z-Scheme PV-PEC Cells

One proposed integrated solar water splitting device involves two ion-exchange membrane-embedded, semiconducting micro-/nanowire arrays electrically connected as a tandem. Such an electrical connection must be optically transparent, ion permeable, and adhere to each membrane-embedded array. A composite Naftion-Poly(3,4-ethylenedioxythiophene)-polyethylene sulfonate (PEDOT:PSS) film possesses excellent adhesion and charge transport properties while being more transparent than PEDOT:PSS alone. Understanding the phase-separation behavior between conductive and non-conductive domains via PeakForce Tunneling Atomic Force Microscopy (PF-TUNA) enables insight towards the Naftion-PEDOT interactions that explain bulk electrical properties. A percolative network of conductive PEDOT domains held by a Naftion:PSS bulk enable electron conduction while maintaining the mechanical stability and proton conducting properties of Naftion. Addition of DMSO reduces these domain sizes from μm to nm scale, producing a dramatic >10⁴-fold increase in lateral conductivity. Nanoscale current-voltage sweeps probe the spatial variations of ionic behavior that lead to macro-scale contact resistance at composite/p-Si interfaces. The measured composite properties are input into a sensitivity analysis that guides device design via load-line analysis of a model tandem water splitting device.

Synthesis of Graphene-Carbon Nanotube Composites Functionalized with TiO₂

Hybrid organic photoelectrochemical (HOPEC) water splitting is gaining momentum in the field of solar conversion technologies. It bridges solar-powered hydrogen production with convenient and scalable fabrication techniques through earth-abundant materials and promising performances. Mirroring the development of Organic Photovoltaics, devices based on organic semiconductors require a careful understanding of their working mechanisms as well as dedicated material research. Hybrid photoelectrodes have been able so far to deliver either high photocurrent performances or long operational lifetime. The goal is to combine these results in a single high-performing and long-lasting architecture. The performance of the device relies on the dynamics occurring across various interfaces, starting from charge separation within the bulk heterojunction (BHJ) up to hydrogen evolution in contact with the electrolyte. As demonstrated, selective contacts play a major role in maximizing the result and represent the key factor to combine stability and efficiency. At these interfaces a delicate balance of energetic, morphologic and optical properties is needed to promote lossless charge extraction. Herein materials belonging to the classes of metal oxides, organic compounds and transition metal chalcogenides are tested in the role of hole selective layers (HSL). Their performances are tuned acting on their morphology at the nanoscale to optimize the interaction with the organic BHJ and the back contact. Several deposition techniques are employed to obtain thin films exerting high control on their properties. To further increase the performances, with remarkable gain in photovoltaic, we moved toward high performing organic semiconductors, aiming to replace the state-of-the-art P3HT:PCBM BHJ. Among these, photoelectrodes employing PCDTBT:PC70BM delivered excellent performances, with a noteworthy photocurrent onset potential of 0.85 V vs RHE, surpassing the actual 0.6 V vs RHE benchmark achieved with P3HT:PCBM. With the aid of AFM-Kelvin Probe, we collected work function data to have an estimate of the energetic structure of the HSL and of the HSL/BHJ coupling. UV-Vis spectra have been acquired to assess the high transparency of HSL and to integrate them the BHJ. Finally, we carry out the photoelectrochemical characterization of hybrid photoelectrodes employing the most promising hole selective layer candidates and novel BHJ. These architectures deliver photocurrents higher than 3.5 mA/cm² over several hours of continuous operation. Furthermore, taking advantage of the properties of PCDTBT:PC70BM, we successfully realized photocathodes which do not require any post-fabrication thermal treatment. With this work we set the development of low temperature, stable and high-performing hydrogen evolving photocathodes as near-future goal.

Synthesis of Graphene-Carbon Nanotube Composites Functionalized with TiO₂

Recently, there have been intense efforts in the exploration of innovative solar cell structures with high performance and cost-effective manufacturing methods. One of the alternatives is the use of carbon nanotubes in photoelectrochemical cells, as an effective strategy to increase the efficiency of the devices. For this purpose, this work aims to use functionalized multiwalled carbon nanotubes (mwcnt) with titanium dioxide nanoparticles (TiO2) by a mechanical-thermal process, and then with a spray method to obtain a hybrid material of bilayer graphene and mwcnt functionalized with TiO2 characterizing the structural, chemical and optical properties of the resulting composites. In a first stage a sintering process is applied, varying the temperatures, with the aim of introducing vacancies in the outer layer of the carbon nanotubes. The mwcnt are subjected to a mechanical process adding TiO2 and finally by the method of spraying of bilayer graphene and mwcnt functionalized with TiO2 obtain a complex material.

Strategies for Minimizing Reflection by Electro catalysts Integrated on Silicon Microwire Array Photocathodes
Paul A. Kempler, Sisir Yalamanchili, Kimberly Papadantonakis and Nathan S. Lewis; California Institute of Technology, Pasadena, California, United States.

High aspect ratio, microstructured photocathodes allow for the integration of reflective and opaque electro catalysts with semiconducting light absorbers, while avoiding losses to the maximum photocurrent density. Microwire and microarray arrays have been fabricated from p-type Si and decorated with thick films of electrochemically deposited CoP or sputtered Pt to prepare photocathodes for the generation of H2 from 0.5 M H2SO4 (aq). P-Si-CoP microwire and microcane arrays produced photocurrent densities of ~10 mA cm–2 at potentials that were ~130 mV more positive than optimized planar p-Si/CoP devices. Champion p-Si/CoP microwire array devices exhibited ideal regenerative cell solar-to-hydrogen efficiencies > 3%, and were primarily limited by the photovoltage of the p-Si/CoP junction. Thick (~16 nm) layers of Pt or CoP deposited onto n- p-Si microcane arrays yielded light-limited photocurrent densities of ~ ~32 mA cm2, constituting a reduction in light-limited photocurrent density of 6% relative to bare Si µ-cone-array photocathodes, while maintaining high fill factors and low overpotentials for H2 production.

ESI1.04.14
Efficient Solar to Hydrogen Conversion Using Morphology-Controlled Sb2Se3 Light Absorbers in Neutral Electrolytes
Jaemin Park, Woo seok Yang, Yujung Oh, Ji eawn Tan, Hyungs oo Lee, Ramireddy Boppella and Jooho Moon; Yonsei University, Seoul, Korea (the Republic of).

For practical hydrogen production via photoelectrochemical (PEC) water splitting, low-cost photocathodes that can efficiently operate in neutral electrolytes should be developed. Herein, we present novel solution-based synthesis method enabling the morphology variation of Sb2Se3 light absorber, which are nontoxic, low bandgap and earth-abundant materials. The morphology of Sb2Se3 films varies from dense particulate planar film to 1-dimensional nanowire-stacked film upon modifying the Sb and Se molar ratio in the precursor ink. The resulting Sb2Se3 films have identical composition and bandgap value regardless of initial precursor ratios. The formation mechanism was elucidated by analyzing Se-Sb precursor ink using liquid Raman spectroscopy. The effects of morphology and crystallographic orientation on the electrical and consequently the charge transport properties of Sb2Se3 photocathodes are investigated by conductive atomic force microscopy. Sequential deposition of CdS as a buffer layer with TiO2 and Pt on the morphology controlled Sb2Se3 film enables us to reduce a band offset between the Sb2Se3 and TiO2, achieving an enhanced onset potential. An onset potential of 0.55 V versus reversible hydrogen (RHE) electrode was obtained with 11 mA cm–2 at 0 V versus RHE under 1.5 global illumination in a neutral electrolyte (pH 6.5). Furthermore, stable hydrogen production over ~3 h was observed during the course of photocurrent generation by gas chromatography, demonstrating the promising potential of the proposed Sb2Se3 photocathodes as efficient PEC water-splitting devices.

Development of Catalytic Coatings for H2-Producing Photocathodes in Solar Water-Splitting
Thomas Jaramillo1,2,3, Chemical Engineering Dept., Stanford University, Stanford, California, United States; 2Photon Sciences, SLAC National Accelerator Laboratory, Menlo Park, California, United States; 3SUNCAT Center for Interface Science and Catalysis, Stanford and SLAC, Stanford, California, United States.

The vast majority of fuels and chemicals that are produced and consumed across the globe today are derived from fossil fuels: oil, coal, and natural gas. This is true of H2 as well, with annual production rate of over 60 billion kg/year, predominantly used in petroleum refining and in fertilizer production. Developing new, sustainable routes to H2 production using renewable resources (e.g. wind and solar) could play an important role in decarbonizing energy, and motivate new uses of H2 as a fuel itself and/or reducing agent for lower-carbon footprint processes. Solar-based water-splitting is a promising route to sustainable H2. This talk will focus on photoelectrochemical (PEC) water-splitting processes, with a focus on photocathodes. To achieve a cost-effective process, ambitious targets involving efficiency, durability, and low-cost must be reached. This talk will describe efforts to develop catalyst materials and associated coatings capable of providing high activity and extended durability to photovoltaic-grade solar-absorbing materials, including silicon, chalcogenide semiconductors, and III-V materials.

8:45 AM *ESI1.05.02
Photovoltaic-Photoelectrochemical Tandem Systems for High-Efficiency Stand-Alone Solar Hydrogen Generation
Siva Karuturi, Australian National Univ, Canberra, Australian Capital Territory, Australia.

Achieving efficient hydrogen evolution in water using solar light in a stand-alone system without any external bias is a highly desirable but difficult target. Ever since the first report of sunlight induced water splitting using a TiO2 electrode four decades ago, photoelectrochemical (PEC) water splitting has been intensely investigated using various semiconductor photocathodes. However, the main requirement for a photocathode in a PEC cell to induce spontaneous hydrogen evolution is the availability of a semiconductor with an appropriate bandgap of approximately 2.5 eV, having a conduction band that is sufficiently negative for H2 evolution and a valence band that is sufficiently positive for O2 evolution. Unfortunately, devices capable of spontaneous gas evolution are inefficient because the photocathodes with a bandgap of around 2.5 eV absorb only a limited portion of the solar spectrum and require an additional bias for overcoming overpotentials.4 One approach to solve this problem of single semiconductor PEC cells is the use of a tandem configuration. In particular, a photocathode combined with an appropriate photovoltaic (PV) cell with complementary absorption ability can harvest a broad part of the solar spectrum and deliver a high solar to hydrogen conversion efficiency.5

After introducing the PV-PEC approach for unbiased hydrogen evolution, I will present our work on perovskite solar cell assisted CdS photoanode. The tandem PV-PEC device consisting CdS/TiO2 photoanode as a top absorber and encapsulated perovskite solar cell as a bottom absorber was developed on a double-side conducting glass using a facile and integrated fabrication process. The fabrication of the integrated device has been achieved by using a combination of solution processing and atomic layer deposition techniques. A remarkable highest photocurrent density of 8.2 mA/cm2 was obtained for unassisted solar hydrogen generation under AM1.5 G illumination using 0.25 M Na2S and 0.35 M Na2SO3 as an electrolyte.4 Next, I will present our recent work on tandem perovskite assisted silicon photoanodes. Highly efficient buried junction n-Si based photocathodes were developed by decoupling light harvesting and hydrogen evolution reactions and breaking the tradeoff between light harvesting and light blocking catalysts. Highly efficient transparent perovskite cathodes with appropriate bandgap were developed as a top absorber. The proposed device satisfies the critical requirement of an efficient tandem configuration by providing complementary light absorption with high optical transparency to long wavelength photons and strong PEC conversion from short wavelength photons. Using this configuration, we achieved an unprecedented ~17% solar-to-hydrogen conversion efficiency for unbiased solar water splitting.5

References:
Recently, a ternary protective coating of manganese-alloyed titanium oxide, (Ti,Mn)O, into an otherwise insulating TiO$_2$ sites help stabilize key intermediates and reduce barrier for O-O coupling for water oxidation; and ii) local electron accumulation at the buried interfaces boosted hydrogen separation and activity improvement. Two new phenomena were observed at the interfaces of few-nm ALD oxides and their coated electrocatalysts: i) three dimensional active microscopy and spectroscopy. On the other hand, the intermediate band induced electronic interactions at the nano-interface with underlying (photo-)electrodes, for charge mobility and have resulted in some of the highest efficiency photoelectrodes. However, these materials are generally very susceptible to corrosion as photoanodes in strong acidic media. Intermediate-band oxides with tunable transport energy levels can serve as chemically-stable, transparent conductive protective layers for photoelectrochemical water splitting at scale. They have shown to promote charge separation and/or charge transport to surface-attached co-catalysts or intermediates at specific electrochemical potentials, practically interfacing the otherwise unstable light absorbers with strong acid or base and protecting them against corrosion. The initial re-discovery of “leaky” TiO$_2$ films to protect Si PEC electrodes for fuel generation. However, a wide variety of performances have been obtained from ALD TiO$_2$ coated with metal oxide protection layers. Finally, we present solid-state techniques and theoretical modeling used by our team to identify possible pitfalls in these material systems and discuss potential paths for improvement.

Investigation of the Photocorrosion of GaP and GaSbP III-V Photoanodes in Acid with In Situ UV/vis Spectroscopy Sahar Pishgar1, Gautam Gupta2, Gianmini Sumanasekera1 and Joshua M. Spurgeon1; 1Conn Center for Renewable Energy, University of Louisville, Louisville, Kentucky, United States; 2University of Louisville, Louisville, Kentucky, United States.

Semiconductors perform a critical role in photoelectrochemical processes for the conversion of solar energy into fuels. The III-V semiconductors, such as GaP, typically have high mobilities and have resulted in some of the highest efficiency photoelectrodes. However, these materials are generally very susceptible to corrosion as photoanodes in strong acidic or alkaline solutions under illumination or at applied bias. Herein, we investigate and quantify corrosion of n-GaP and a related novel ternary alloy, GaSbP, at applied bias and under illumination in strong acidic electrolyte. In situ UV/vis spectroscopy measurements, along with inductively coupled plasma mass spectroscopy (ICP-MS) were utilized to detect the dissolved semiconductor species at various operating conditions and quantify the faradaic efficiency of the corrosion reaction. Ultimately, surface protection strategies like atomic layer deposition of TiO$_2$, will be applied to probe their consequences on the semiconductor corrosion as a function of the deposition parameters.

Metastable Intermediates in Amorphous Titanium Oxide—A Hidden Role Leading to Ultra-Stable Photoanode Protection Lazarus N. German1, Ynanho Yu1,2, and Xuong Wang1, 1University of Wisconsin-Madison, Madison, Wisconsin, United States; 2Harvard University, Cambridge, Massachusetts, United States.

Among many functional materials, amorphous metal oxides, particularly the thin-film morphology synthesized by atomic layer deposition (ALD), are critical components in many modern energy systems, such as batteries,[1–2] catalysts,[3–9] solar cells,[10–13] and photoelectrochemical (PEC) electrodes.[14–16] One representative example is the use of ALD amorphous TiO$_2$ films to protect Si PEC electrodes for fuel generation. However, a wide variety of performances have been obtained from ALD TiO$_2$ by varying the Ti precursor, growth
temperature, and thickness despite a longstanding, yet likely overlooked expectation that ALD films are homogeneous.\cite{10} Our recent observations have shown structural homogeneities in amorphous ALD TiO$_2$ films identified as metastable intermediates: kinetically trapped structures between the metastable amorphous phase and the equilibrium crystalline phase.\cite{11,12} These intermediates enable new and enhanced properties by which their presence significantly change the performance of the overall film. Metastable intermediates represent a nonequilibrium state of matter that impose profound impacts to materials properties beyond our understandings of monolithic and equilibrium systems. We have discovered and hidden metastable intermediates in amorphous TiO$_2$ thin films and their critical role in electrochemical damage. These intermediates have a non-bulk crystal-like structure and exhibit significantly higher electrical conductivity than both the amorphous and the crystalline phases. When these TiO$_2$ films are applied to protect Si PEC photoanodes, the intermediates can induce localized high electrochemical currents that largely accelerate the etching of the TiO$_2$ film and the Si electrode underneath. The intermediates can be effectively suppressed by raising their nucleation barrier via reducing the film thickness from 24 to 2.5 nm. The homogeneous amorphous TiO$_2$-film-coated Si photoanodes achieved more than 500 h of PEC water oxidation at a steady photocurrent density of over 30 mA/cm$^2$.

These results reveal an additional pathway for optimizing the performance of amorphous oxides grown by ALD: controlling the phase composition of the amorphous and intermediate phases is crucial for optimizing the performance of oxide protected electrodes. In addition to thickness, manipulating other deposition parameters such as temperature, precursor choice, pulse and purge times, and doping offer multiple avenues for achieving greater protection performance by impeding the formation of intermediates.

11:30 AM ES11.06.05 Photoelectrochemical Hydrogen Generation from Water Using GaN with Fe$_3$O$_4$ as Cocatalyst Martin Velazquez-Rizzo, Fumio Ito, Daisuke Iida and Kazuhiro Ohkawa, Electrical and Computer and Mathematical Science and Engineering (CEMSE) Division, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; Faculty of Science, Tokyo University of Science, Tokyo, Japan.

We report for the first time the fabrication of a photoelectrode using a thin film GaN homostructure loaded with Fe$_3$O$_4$ as a cocatalyst and its successful photoelectrochemical (PEC) hydrogen gas generation from water. For the PEC characterization of the Fe$_3$O$_4$/GaN photoelectrode, it was irradiated using a Xe arc lamp with a power density of 100 mW/cm$^2$ for three hours. After this characterization, the photoelectrode did not show signals of photo-corrosion or degradation. A photoelectrode with the same GaN homostructure but using NiO as cocatalyst [Hayashi, Ohkawa, et al., Jpn. J. Appl. Phys. 51, 112601 (2012)] was also characterized under the same conditions to compare the PEC performance of both structures. The Fe$_3$O$_4$/GaN photoelectrode exhibited a stable H$_2$ generation rate of 40.6 μmol/(cm$^2$·h) and a light-to-hydrogen energy conversion efficiency of 2.6%, which is higher than the value of 2.3% found for the NiO/GaN photoelectrode. In addition, the surface of the Fe$_3$O$_4$/GaN photoelectrode was characterized using electron microscopy and energy-dispersive X-ray spectroscopy (EDS).

The thin film GaN homostructure was grown on a c-plane patterned sapphire substrate by metalorganic vapor phase epitaxy and consisted of (top to bottom) unintentionally doped (undoped)-GaN (100 nm)/n-GaN (Si-doped, n=3x10$^{18}$ cm$^{-3}$), 3 µm)/GaN (2 µm). The Fe$_3$O$_4$ cocatalyst was deposited through the spin coating of a metalorganic decomposition solution containing 3 wt% of Fe$_3$O$_4$. The PEC characterization of the photoelectrode was performed using a Pt wire as a cathode, with both electrodes immersed in 1 M NaOH solution and without applying any external electrical bias between the electrodes. The gas volume generated at the cathode and the photocurrent between the electrodes were recorded during the PEC characterization. The gas was characterized using gas chromatography to verify its H$_2$ content.

The observations performed through scanning electron microscopy allowed us to identify the presence of circular structures on the Fe$_3$O$_4$/GaN surface with diameters between 400 to 600 nm. Utilizing transmission electron microscopy and EDS we confirmed that the Fe$_3$O$_4$ deposition formed particles with a “shrub” shape, not a thin film. The results of this work represent another step towards the efficient generation of H$_2$ using nitride-based photocatalysts. We demonstrated that Fe$_3$O$_4$ improves the photocatalytic energy conversion efficiency and prevents the photocorrosion of GaN thin film structures when they are used as photocathodes in alkaline solutions. Thus, Fe$_3$O$_4$ can be added to the list of GaN photocatalysts, which expands the technological applications possibilities of nitride-based semiconductors.

11:45 AM ES11.06.06 Energy Band Alignment and Photonic Design to Enable Photoelectrochemical Water Splitting with >19% Efficiency Wen-Hui Cheng, Matthias H. Richter, Matthias M. May, Jens Ohmann, David Lackner, Frank Dimroth, Thomas Hannappel, Harry Atwater and Hans-Joachim Lewerenz, California Institute of Technology, Pasadena, California, United States; Institute for Solar Fuels, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Berlin, Germany; Fraunhofer Institute for Solar Energy Systems ISE, Freiburg, Germany; Department of Physics, Technical University Ilmenau, Ilmenau, Germany.

In photoelectrochemical (PEC) systems, realization of near-limiting photocurrent densities at the thermodynamic potential for water splitting demands careful design of the optical and electronic properties of the surfaces films exposed to the electrolyte. We report unassisted water splitting in a photocathode device utilizing tandem heterojunction III-V semiconductor photocathodes with absorber bandgaps of 1.78 and 1.26 eV. An initial solar-to-hydrogen efficiency of 19.3 % was obtained in acid electrolytes and an efficiency of 18.5 % was achieved at neutral pH conditions under simulated sunlight. Our device approaches 85% of the theoretical limit of realistic water splitting for the light absorber materials. The PEC characterization of the photoelectrode was performed using electron microscopy and energy-dispersive X-ray spectroscopy (EDS).

The thin film GaN homostructure was grown on a c-plane patterned sapphire substrate by metalorganic vapor phase epitaxy and consisted of (top to bottom) unintentionally doped (undoped)-GaN (100 nm)/n-GaN (Si-doped, n=3x10$^{18}$ cm$^{-3}$), 3 µm)/GaN (2 µm). The Fe$_3$O$_4$ cocatalyst was deposited through the spin coating of a metalorganic decomposition solution containing 3 wt% of Fe$_3$O$_4$. The PEC characterization of the photoelectrode was performed using a Pt wire as a cathode, with both electrodes immersed in 1 M NaOH solution and without applying any external electrical bias between the electrodes. The gas volume generated at the cathode and the photocurrent between the electrodes were recorded during the PEC characterization. The gas was characterized using gas chromatography to verify its H$_2$ content.

The observations performed through scanning electron microscopy allowed us to identify the presence of circular structures on the Fe$_3$O$_4$/GaN surface with diameters between 400 to 600 nm. Utilizing transmission electron microscopy and EDS we confirmed that the Fe$_3$O$_4$ deposition formed particles with a “shrub” shape, not a thin film. The results of this work represent another step towards the efficient generation of H$_2$ using nitride-based photocatalysts. We demonstrated that Fe$_3$O$_4$ improves the photocatalytic energy conversion efficiency and prevents the photocorrosion of GaN thin film structures when they are used as photocathodes in alkaline solutions. Thus, Fe$_3$O$_4$ can be added to the list of GaN photocatalysts, which expands the technological applications possibilities of nitride-based semiconductors.

SESSION ES11.07: PEC Benchmarking and Protocols Session Chairs: Todd Deutsch and Chengxiang Xiang Wednesday Afternoon, April 24, 2019 PCC North, 100 Level, Room 121 C
Direct photoelectrochemical (PEC) hydrogen production aims to provide a clean and cost-effective solar fuel. Solar-to-hydrogen (STH) conversion efficiency is central to evaluating and comparing research results, and it largely establishes the prospect for successfully introducing commercial solar water-splitting systems. Present measurement practices do not follow well-defined standards, and common methods potentially impact research results and their implications. We demonstrate underestimated influence factors and experimental strategies for improved accuracy [1].

Our focus is tandem devices that have the prospect for greater STH efficiency [2], but increased complexity that requires more careful consideration of characterization practices. We perform measurements on an advanced version of the classical GaP/GaAs design [3] while considering (i) calibration and adjustment of the illumination light-source; (ii) confirmation of the consistency of results by incident photon-to-current efficiency (IPCE); and (iii) definition and confinement of the active area of the device.

We propose applying the following standards for future PEC performance reporting: (i) traceable disclosure of the illumination-source configuration (lamp, filters, optics, PEC configuration) and/or its measured spectral distribution; (ii) thorough device-area definition including confinement of the illumination area and avoidance of indirect light paths; (iii) complementary IPCE confirmation of the solar-generation potential; and (iv) proper consideration of faradaic efficiency. We will also give a brief overview of the PEC measurements and capabilities available at NREL to support academic and industry research.

1:45 PM ES11.07.02

Measurements of photoelectrode durability in three-electrode (half-cell) configurations are typically not representative of the results obtained for nominally the same electrodes/materials when tested in a two-electrode (full-cell) configuration. While full-cell measurements are the best proxy to predict performance in a deployed photoelectrochemical water-splitting system, there are few materials that can drive both the water reduction and oxidation half-reactions. Component-level or half-cell testing is the only option for materials unable to perform unassisted water splitting. During this talk the results of multiple durability tests, some with and some without a reference electrode, will be used to evaluate key differences between the two types of testing in an effort to elucidate what leads to the incoherency between half- and full-cell measurements. It is anticipated that with this understanding, the photoelectrochemical water-splitting community can begin to move towards an accepted protocol for long-term durability testing that will have more predictive relevance to realistic device configurations.

Operando Synchrotron Characterization of Electrochemical Interfaces Walter Drisdell1, Alan Landers2 and Maryam Farmand1; Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Stanford University, Stanford, California, United States.

Electrochemical interfaces are central to water splitting technologies. Knowledge of the chemical mechanisms occurring at these interfaces is invaluable for materials discovery efforts, guiding synthesis for improved catalytic performance or resistance to corrosion. But accurately characterizing these complex buried interfaces under operating conditions is a significant challenge. The high penetration depth and elemental selectivity of synchrotron X-ray methods are ideal for accessing electrochemical interfaces without significantly limiting the chemistry. In this talk I provide an overview of strategies for operando synchrotron characterization of electrochemical interfaces, covering established techniques as well as new capabilities. These include X-ray absorption spectroscopy (XAS), ambient pressure X-ray photoelectron spectroscopy (AP-XPS), and a recently developed system for grazing incidence XAS and X-ray diffraction (XRD) to probe catalyst surfaces under high current conditions. I include examples of these methods applied to water splitting catalysis as part of the Joint Center for Artificial Photosynthesis (JCAP), and discuss potential applications for future studies as well as areas where further capability development is still needed.

2:15 PM ES11.07.04
Anodic Stripping Voltammetry for Detection of Catalyst Corrosion In Situ at Intermediate Current Densities Burton H. Simpson and Chengxiang Xiang; California Institute of Technology, Pasadena, California, United States.

Degradation of catalysts and light absorbers during photoelectrochemical (PEC) water splitting is becoming a critical limitation of PEC devices as efficiencies improve. Inductively coupled plasma mass spectrometry (ICP-MS) is currently the gold standard for detection of corrosion products in such systems, but limits throughput and offers little mechanistic information due to its high sampling time. Here, we demonstrate the use of in situ anodic stripping voltammetry using mercury ultramicroelectrode to detect corrosion products of transition metal catalysts for water splitting. Mercury ultramicroelectrodes can be easily fabricated in any electrochemistry lab and offer faster sampling rates than ICP-MS. Finally, we demonstrate that the improved temporal resolution enables rapid testing of corrosion rates at a range of intermediate current densities applicable to solar driven water splitting.

3:30 PM *ES11.08.01/ES12.06.01
HydroGEN Overview, Projects and the AWSM Node Capabilities (Huyen N. Dinh; Katie Randolph; David Peterson; Adam Weber; Anthony H. McDaniel; Tadashi Ogitsu; Richard Boardman; Donald L. Anton and Eric L. Miller; 1National Renewable Energy Lab, Lakewood, Colorado, United States; 2Fuel Cell Technologies Office, U.S. Department of Energy-EERE, Golden, Colorado, United States; 3Lawrence Berkeley National Laboratory, Berkeley, California, United States; 4SANDIA National Laboratories, Livermore, California, United States; 5Lawrence Livermore National Laboratory, Livermore, California, United States; 6Idaho National Laboratory, Idaho Falls, Idaho, United States; 7Savannah River National Laboratory, Aiken, South Carolina, United States.

HydroGEN (https://www.h2awsm.org/) EMN is a six-lab consortium, led by the National Renewable Energy Laboratory (NREL). It currently comprises six core national laboratories: NREL, SANDIA National Laboratory (SNL), Lawrence Berkeley National Laboratory (LBNL), Idaho National Laboratory (INL), Lawrence Livermore National Laboratory (LLNL), and Savannah River National Laboratory (SRNL). HydroGEN aims to accelerate the discovery and development advanced water splitting materials (AWSM) for sustainable, large-scale hydrogen production, in order to more effectively enable the widespread commercialization of hydrogen and fuel cell technologies. With the rollouts of fuel cell electric vehicles (FCEVs) by major automotive manufacturers underway, enabling AWS technologies for the widespread production of affordable, sustainable hydrogen becomes increasingly important.
The HydroGEN Consortium offers an extensive collection of materials research capabilities for addressing R&D challenges in efficiency, durability and cost. Leveraging the HydroGEN Consortium’s staff of leading technical experts and broad collection of resource capabilities is expected to advance the maturity and technology readiness levels in all the advanced water splitting technologies, including advanced electrolysis (low and high temperature), photoelectrochemical (PEC) and solar thermochemical (STCH) routes. Currently, there are 20 HydroGEN seedling projects, and one project focused on benchmarking advanced water splitting technologies. These 21 new projects utilized over 40 unique capabilities across the six HydroGEN core labs, from computational modeling to material synthesis to advanced characterization. HydroGEN is indeed a national innovation ecosystem that comprises 11 national labs, 7 companies, and 30 universities. This presentation will provide an overview of the HydroGEN EMN consortium and highlight some advanced water electrolysis and PEC projects as well as a few unique HydroGEN capability nodes that the community can leverage.

4:00 PM *ES11.08.02/ES12.06.02
European Efforts to Accelerate the Market Introduction of Renewable Hydrogen Production Martin Roeb1 and Christian Sattler1, 2, 3
1 Institute of Solar Research, German Aerospace Center (DLR), Koeln, Germany; 2 Faculty of Mechanical Science and Engineering, Institute of Power Engineering, Professorship of Solar Fuel Production, TU Dresden, Dresden, Germany.

Converting solar energy efficiently into hydrogen is a key element to develop a sustainable and affordable hydrogen economy. The presentation will give an insight in how concentrated solar radiation can be coupled into hydrogen production processes. It will discuss the benefits and challenges of using the sunlight directly instead of converting it into other energy vectors.

The main focus will be on technologies with the perspective of large scale production at very high temperatures. Therefore solar tower systems for such production processes will be presented. Also the different components like concentrator, receiver, and reactor of the solar production plants will be described, possible locations will be discussed, and synergies with other R&D efforts on using high temperature heat will be shown. Hybrid solutions e.g. from the sulfur industry will demonstrate how concentrated solar radiation can contribute even today to actual industrial business models.

As many of the addressed processes have to be operated continuously high temperature heat storage will also be introduced. Especially thermochemical heat storage has the potential for being the ideal technology for heat storage in high temperature production processes.

The European Union is supporting the development in its research framework programs since the 1980s. However until 2002 only a few projects were carried out. Since then a continuous improvement took place which was accelerated by the implementation of the European Fuel Cell and Hydrogen Joint Undertaking in 2008. This private-public partnership lead by industry is in charge to bring technologies faster into the market than research programs lead by the European Commission would. The presentation will give an overview of the actions carried out so far and the perspective of the European efforts.

4:30 PM *ES11.08.03/ES12.06.03
Benchmarking Water-Splitting Materials at the Intersection of Electrocatalysis and Photoelectrochemistry Tobias Kistler1, Shaun Alia2, Peter Agbo1, Adam Weber3 and Nemanja Danilovic4; 1 Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2 National Renewable Energy Laboratory, Golden, Colorado, United States.

Widespread adoption of inexpensive renewable-electricity sources brings with it many exciting challenges and opportunities, the most significant being an overabundance of low-cost electricity from renewables as well as cheap photovoltaics. Thus, there is an opportunity to use virtually free electrons and photovoltaics to produce fuels and chemicals using electrochemical and photoelectrochemical devices, respectively with water as a reactant. Electrochemical hydrogen production using water electrolysis is a commercial technology, barriers remain in terms of cost and efficiency improvements for its widespread adoption; while alternative water-splitting technologies that have the long-term potential to produce inexpensive hydrogen include photoelectrochemical (PEC) approaches, are still in their infancy. In either case materials development, interface development and cell design are critical in advancing the efficiency and cost of water splitting devices. Benchmarking protocols help to identify promising materials, facilitate translation of materials from one technology readiness level to another, and can provide clear technology crosscutting opportunities. This talk will cover benchmarking activities performed within the HydroGEN Energy Materials Network on: low temperature electrolysis (LTE) electrocatalysts, development of benchmarking cells for photoelectrochemical (PEC) water splitting devices, and crosscutting opportunities between LTE and PEC with respect to the hydrogen evolution and oxygen evolution catalysts activity and durability.

SESSION ES11.09: Poster Session II: Low Temperature Water Splitting via Electrochemistry and Photoelectrochemistry
Session Chairs: Katherine Ayers and Changfeng Yan
Wednesday Afternoon, April 24, 2019

ES11.09.01
HydroGEN Supernode—Linking Low Temperature Electrolysis (LTE)/Hybrid Materials to Electrode Properties to Performance Guido Bender1, Shaun Alia1, Michael Ulsh1, Scott Mauger1, Bryan Pivovar1, Huyen N. Din1, Adam Weber3, Nemanja Danilovic2, Ahmet Kusoglu2 and Hector Colon-Mercado2; 1 National Renewable Energy Laboratory, Lakewood, Colorado, United States; 2 Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3 Savannah River National Laboratory, Aiken, South Carolina, United States.

The energy materials network HydroGEN consists of six laboratories that have core capabilities related to hydrogen generation in four technology areas: Photoelectrochemical (PEC), Solar Thermochemical (STCH), High- and Low-Temperature Electrolysis (HTE & LTE). The core capabilities are described as nodes and are available to support projects selected by means of a competitive process through personnel, equipment, expertise, capability, materials, and data exchange and sharing platforms. Starting in the current funding period supernodes were created that combine the unique abilities of the HydroGEN nodes to perform relevant and ground-breaking research outside of the funded projects.

To date, materials advances are required to improve the cost, performance, and durability of LTE and hybrid electrolysis devices. Most materials advances are screened through ex-situ testing protocols due to ease of measurement and throughput. However, properties measured ex-situ are not always relevant for device operation and can be influenced by a number of factors, including synthesis/processing parameters and operating conditions of the individual tests. The optimized integration of novel materials, and the verification that ex-situ results have merit for operating systems is an important detail for accelerating research and development in the electrolysis space.

Savannah River National Laboratory (SRNL), Lawrence Berkeley National Laboratory (LBNL) and National Renewable Energy Laboratory (NREL) have joined several nodes together to probe the connection between materials, electrode composition and processing, and device performance for low temperature electrolysis (LTE)/hybrid electrolysis. This supernode combines/integrates nodes that focus on ex-situ materials characterization, electrode processing, in-situ device characterization, and modeling, so that ex-situ characterization approaches can be validated for their applicability to device performance and durability.

Initial results of the supernode will be presented on typical LTE materials sets that are supposed withstand for example high oxidation potential and high differential pressure. Results may give insights into mass transport challenges and resistivity losses. The presented work is intended to lead up to linking the inherent properties of materials and their composition and processing to observed device performance and durability. These efforts directly support LTE efforts and the low temperature aspects of the combined hybrid cycle.

ES11.09.02
Electrochemical Activity and Adsorbate Effects During Hydrogen Evolution Reactions on Ni/Au Overlayers Calum A. Shelden, Andrew Siwabessy and Hadi Tavassol; Chemistry and Biochemistry, California State University, Long Beach, Long Beach, California, United States.

We report on the electrochemical activity and surface properties of Ni/Au overlayers during the hydrogen evolution reaction. Ni/Au overlayers were prepared using chronopotentiometric deposition of well-defined Ni thin films on Au (111) surfaces from dilute NiSO₄ solutions in 0.1 M H₂SO₄. Using this method, we prepared Ni overlayers with varying thicknesses from 10 nm to 500 nm on Au (111) substrates. X-ray diffraction and scanning electron microscopy analysis of films is used for characterizing the
deposited Ni films. Our electrochemical analysis of these films exhibit that the overpotential required for hydrogen evolution decreases as the thickness of the Ni overlayer increases from ca. 10 nm to 100 nm. Thicker Ni overlayers exhibit higher overpotentials (as high as ca. 150 mV). Interestingly, thicknesses greater than 50nm show additional reductive features in the ca. -50 mV to 400 mV (vs. RHE) potential range. Ni overlayers also suppress features associated with sulfate interactions with Au surfaces. Such high activity of Ni/Au overlayers are significant, especially considering the stability region of Ni in acidic media. We will present results from surface enhanced Raman spectroscopy analysis of these surfaces in electrochemical solutions, and optical in-situ surface stress measurements to probe adsorbate effects during hydrogen evolution reactions on Ni/Au overlayers.

**Advancements in High Temperature Proton-Conducting Electrolyzer Materials**

Dong Ding

Idaho National Laboratory, Idaho Falls, Idaho, United States.

Advanced in super-proton conducting materials are being made under the DOE HydroGEN Energy Material Network. The desired goal is to reduce the operating temperature of high temperature steam electrolysis to around 600°C or less to reduce degradation and fouling of the electrode/electrolyte, interconnections, and associated stack containment and gas handling materials. Four projects funded under the DOE HydroGEN program are focusing on various aspects of materials development and testing. Methods for fabricating these materials are being developed and tested by various experimental capabilities (nodes) within the designated HydroGEN core labs. Initial testing is focusing on the performance of these materials.

Myles Steiner

Francesca Maria Toma

Genevieve Saur

Judith C. Vidal

Hanna Brunig

Daniel J. Friedman

Adam Weber

Todd G. Deutsch

National Renewable Energy Laboratory, Golden, Colorado, United States;

Lawrence Berkeley National Laboratory, Berkeley, California, United States.

In this talk we will give an overview of the HydroGEN photoelectrochemical (PEC) water-splitting Supernode and present recent progress. This Supernode project is collaboration of nine PEC capability nodes that are part of the HydroGEN Advanced Water Splitting Materials consortium. These nodes are bundled to collaboratively develop an understanding of integration issues and degradation mechanisms that emerge as PEC devices move from the current research scale, typically 1 cm², to 10s of cm² and greater that are necessary to consider a PEC module or panel. Larger devices are expected to introduce new component integration challenges and pathways for degradation that this PEC Supernode project seeks to identify while suggesting routes to take that should maximize success in the upscaling process.

The PEC Supernode project is an alliance of synthesis, characterization, and modeling nodes housed at the National Renewable Energy Laboratory and Lawrence Berkeley National Laboratory whose tasks include: 1) Photoreactor chassis fabrication and baselining, 2) development, fabrication, and testing of larger area PEC devices based on tandem III-V absorbers, 3) development of in-situ morphology and corrosion analysis techniques and characterization, and 4) analysis of durability mechanisms and impacts using life cycle analysis and techno-economic analysis. We will also describe a new photoreactor chassis that has been designed to facilitate indoor and on-sun efficiency and durability benchmarking measurements. The design has been validated in a preliminary set of multi-institution round robin testing toward understanding and harmonizing measuring conditions and protocol, which will be elaborated upon here.

**ES11.09.05**

**Chemomechanical Effects During the Hydrogen Evolution Reaction on Pt-Cu Surfaces**

Andrew Siwabessy

Andrea Nelson and Hadi Tavassoli; California State University, Long Beach, Long Beach, California, United States.

We report on the surface and subsurface hydrogen evolution reactions on well-defined platinum/silver surfaces in electrochemical environments during the hydrogen evolution reaction (HER). We are particularly focused on the Pt-Cu binary system. Well-defined surfaces of Pt and Cu/PT are prepared using thermal evaporation and electrodeposition, respectively. An optical laser method is used to perform in-situ surface stress measurements to track early stages of catalyst activation through adsorbate-induced effects. Surface stress changes on Pt surfaces show a distinctive compressive feature as hydrogen is adsorbed onto the Pt surfaces. The magnitude of this compressive feature decreases with increasing scan rates, which implies fast surface activation of hydrogen. Interestingly, the magnitude and potential dependence of the hydrogen-specific surface stress changes do not change as the solution pH changes (between pH = 1, 7 and 14). However, surface stresses change significantly in the presence of H₂ gas.

Additionally, hydrogen-specific stress changes are completely suppressed in the presence of ultra-thin copper overlayers. Our analysis shows that the adsorption of active species, i.e. H⁺ at the catalyst's active sites, causes structural changes and clearly demonstrates that the early stages of adsorbate formation could describe electrocatalysis and surface/subsurface structural effects. We will further discuss surface tuning of the Cu-Pt system for improved hydrogen evolution reactivity using insight from our in-situ analysis.

**Chalcopyrite Alloy Materials for PEC H₂ Production—Development of Theoretical Synthesis Support System for HydroGEN**

Joel B. Varley

Abhishek Sharan

Anderson Janotti

Nicolas Gaillard

Alexander DeAngelis

Tadashi Ogitsu

Lawrence Livermore National Lab, Livermore, California, United States;

University of Delaware, Newark, Delaware, United States;

University of Hawaii, Honolulu, Hawaii, United States.

Chalcopyrite alloy materials class is an attractive candidate for photovoltaic (PV) and photoelectrochemical (PEC) devices due to its high bandgap tunability and presence of low cost synthesis pathways. However, these advantages are also known to be associated with challenges in the materials synthesis as well as the device assembly processes. For example, certain chalcopyrite alloys exhibit strong tendency of developing secondary phase(s) during its synthesis, which affects on the device performance in unpredictable manner: it could be beneficial or detrimental depending on the alloy composition and the synthesis condition.

In this presentation, we first review the issue of secondary phases, such as ordered vacancy compound (OVC), reported in literature as well as our recent findings on sulfur containing chalcopyrite materials synthesis, where sulfur was incorporated in order to achieve an optimal band alignment for a PEC H₂ production device. The electronic property of OVC interacts with both the photoabsorber (chalcopyrite) and the buffer, where the defect properties of these materials play crucial roles in the functionality of hetero junction (ex. charge carrier separation efficiency, open circuit voltage). In order to find the synthesis routes that would minimize the detrimental effect of OVC formation and its intrinsic defects to the performance of complex hetero-junction (absorber-OVC-buffer), we have been developing thermodynamic alloy phase diagram of candidate photoabsorber materials that includes OVCs as well as the corresponding defect property database. We will discuss how these data may be used to predict the device performance (ex. open circuit voltage) behavior, which in turn, may be used to strategize the PEC/PV device development.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory Under Contract DE-AC52-07NA27344, and is supported by the U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, Fuel Cell Technologies Office.

**Photoelectrochemical and Low Temperature Water Splitting Materials Research at Lawrence Livermore National Laboratory Under HydroGEN Consortium**

Tadashi Ogitsu

Brandon C. Wood, Tuan Anh Pham, Joel B. Varley, Jonathan Lee, Monika Biener, Chris Orme and Yong Han; Lawrence Livermore National Lab, Livermore, California, United States.

The HydroGEN consortium brings together unique DOE National Laboratory experts and tools (nodes) with researchers developing advanced water splitting materials in a variety of technologies: Low and High -Temperature Electrolysis (LTE/HTE), Photoelectrochemical (PEC) and Solar-Thermochemical (STCH) Water Splitting. Lawrence Livermore National Laboratory is a HydroGEN partner lab and has participated in 4 projects since 2018. This poster will highlight:

- Livermore Lab capabilities and expertise available to researchers in LTE, HTE, PEC and STCH fields
- Our collaborative work performed with our partners in LTE and PEC in FY18.
- Tackling big scale problems in PEC, LTE, HTE and STCH through multi-node, multi-institution projects "supernodes"
- Come and ask questions as to how we could help your water splitting research

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344, and is supported by the U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, Fuel Cell Technologies Office.
A Demonstration of Supported Iridium Oxohydroxide as the Low Noble Loading Anode in PEM Water Electrolyser

The reduction of noble loading in PEM water electrolyser is still a big challenge, especially in the anode. Using the supported catalysts can reduce the amount of Iridium in anode significantly, some reports have achieved very low loading of iridium (about 0.1mg/cm²) in anode catalyst layer. Recently, Iridium oxohydroxide has been reported as a highly active catalyst for oxygen evolution, and it has also been supported on ATO to form a supported catalyst, however, this catalyst has not been demonstrated in PEM water electrolyser. To show the advantage of such supported catalyst, Iridium oxohydroxide was supported on titanium nanosphere in this work, and membrane electrode assemblies were prepared to achieve the low noble loading in PEM water electrolyser.

Titanium nanosphere with the diameter range form 60-200 nm was chosen as the support, the Iridium oxohydroxide was supported on it by hydrolysis method reported by Strasser’s group. The mass activity of Ir was range from 800-1600 mA/g (g=0.37V), which depends on the loading percentage on the support. We found that lower loading of Ir on support can achieve higher mass activity, and this may be due to the higher dispersion of IrOx on Ti nanosphere. The MEA with only 0.24mg/cm² Ir loading achieved 1.735V cell voltage with thicker Nafion 117 membrane, and the voltage can be reduced further by using thinner membrane. We also found that higher loading percentage of catalyst is better for achieving higher performance of water electrolyser with the same Ir loading in MEA. This must be because, on one hand, the higher loading percentage of Ir in catalysts can form a thinner catalyst layer when preparing MEA, and it will facilitate the mass transport of water and oxygen. On the other hand, larger ECSA will benefit from higher loading percentage of Ir in catalysts, because more active sites can contact with membrane.

In summary, our studies exhibited the supported Iridium oxohydroxide is a good catalyst for reducing the Ir loading in PEM water electrolyser. The Ir loading can be reduced to 0.24mg/cm² with no significant performance loss for PEM water electrolyser, and the further work will focus on performance optimizing and stability of PEM water electrolyser with such new MEAs.

Alkaline Water Electrolysis at 20 A cm⁻² with a Microfibrous, Flow-Through Electrolyzer

Feichen Yang, Myung Jun Kim and Benjamin Wiley; Chemistry, Duke University, Durham, North Carolina, United States.

Improving both the efficiency and productivity of water electrolysis is necessary for making the electrochemical generation of hydrogen economically competitive. The efficiency depends on the surface area and catalytic activity of the electrode, whereas the productivity depends on the ease with which gas can be removed from the electrode surface. Flow-through electrodes are widely used to improve the efficiency and productivity of electrochemical processes, but studies of their use in alkaline water electrolysis are relatively rare. We hypothesized that the use of a flow-through electrode could enhance the rate of bubble removal from the electrode surface, thereby improving productivity, but it was not clear what length scale of the electrode would maximize the surface area available for electrolysis without hindering bubble removal. To determine how the efficiency and productivity of the flow-through electrode depends on the electrode length scale, we compared the performance of the oxygen evolution reaction with flow-through electrodes consisting of a Ni foam, Ni microfibers (Ni MFs, d = 1.2 mm), and Ni-coated Cu nanowires (NiCu NWs, d = 350 nm). Although the turnover frequency (TOF) for the Ni foam was 2.4 times higher than the Ni MF electrode and 42 times higher than the NiCu NW electrode, its surface area was more than 90 times lower than the other electrodes, resulting in the lowest overall current density. Although the NiCu NW electrode had a higher surface area than the Ni MF electrode, it had a lower overall current density because of its low TOF. We attribute the higher performance of the Ni MF electrode to the fact that the mean pore size of the Ni MF electrode (5-10 mm) is on the order of the mean bubble size (20 mm) that was measured by examining the bubbles generated from a mesh electrode under an optical microscope. The performance of the Ni MF electrode was further improved by coating it with a Ni-Fe layered double hydroxide (LDH) catalyst, resulting in an OER overpotential of 247 mV at 0.1 A cm⁻² and a Tafel slope of 26 mV dec⁻¹. These values are among the lowest reported for Ni-Fe LDH catalysts. The LDH-coated Ni MF anode was paired with a cathode coated with a Ni-Mo alloy to measure the overall productivity for water splitting. The maximum current density for water splitting was 20 A cm⁻² at 3.9 V in 30% KOH, which is 20 times greater than the highest current densities previously reported for alkaline water electrolysis. This current density and voltage could be sustained for at least 8 hours with no signs of degradation. This high current density was attributed to the ability of the flowing fluid to promote bubble removal and keep the hot electrode surface from boiling water. This work demonstrates that flow-through microfibrous electrodes can improve the efficiency and productivity of alkaline water electrolysis.

ES11.09.11

Hierarchical Porous Ni₃CoₓSnSe₄ Nanostructures on Nickel Foam as High Efficient Water Oxidation Catalyst Synthesized Through a Facile Route

Jianping Xin; State Key Laboratory of Crystal Materials, Shandong University, Jinan, China.

Electrochemical water splitting is considered as one of the most robust way to generate hydrogen gas as an alternative to traditional fossil fuels to relieve the energy crisis and environmental changes. Compared with hydrogen evolution reaction, oxygen evolution reaction involves four-electron redox processes, and generally this sluggish process determines the rate of water splitting and significantly hinders the improvement of the overall efficiency. To address this issue, a great deal of effort has been devoted to develop high performance OER electrocatalysts to facilitate the reaction kinetics. To date, noble metal based catalysts such as IrO₂ and RuO₂ are still the benchmark electrocatalysts for OER, but their scarcity and high cost immensely limit their large-scale and widespread deployment. Therefore, it is imperative to develop noble-metal-free electrocatalysts with high activity and good durability. In recent years, transition metal compounds as a class of candidates ranging from oxides, hydroxides, phosphates, nitrides to chalcogenides, have attracted significant attention due to their unique electronic and relatively high efficiency for OER. Nevertheless, the catalytic activity of the existing catalysts still falls short of expectations. For this reason, designing and synthesizing new materials is a promising way to realize the massive boost of the OER catalytic efficiency. Herein, we report the synthesis of nickel-cobalt selenite (Ni₃CoₓSnSe₄) networks on a nickel foam with promising electrocatalytic performance through a facile electrodeposition method. The networked structure built with interconnected nanosheets along with the three-dimensional backbone of nickel foam is able to provide large surface area for the reaction to take place and simultaneously offer the connected channels for charge carriers to pass through, consequently, realizing the enhancement of oxygen evolution reaction (OER) electrocatalytic activity. Importantly, the multilevel channel structure achieves vast spaces to buffer the volume change during repeated redox reactions and offers favorable channels for gas release, leading to the good electrochemical stability. The best sample with optimized composition shows superior catalytic activity with high current density of 243.6 mA cm⁻² at the overpotential of 500 mV and excellent stability.

Effect of Boron Chain in Vanadium Boride Hydrogen Evolution Reaction Electrocatatysts

Eusoom Lee and Boniface Fokwa; Chemistry, University of California, Riverside, Riverside, California, United States.

In order to generate hydrogen, which is promising fuel in the future, electrochemical water splitting through hydrogen evolution reaction (HER) have taken center stage. Although, existing catalysts for HER such as platinum group metals have been considered the best catalyst, they have problems with high cost and scarcity. Recently, transition metal boride (TMBS) has been considered potential HER electrocatalysts and various covalent networks of boron in the crystal structure have meaningful relation with electrocatalytic activity for HER. In this work, we synthesize vanadium borides which have different boron chains by arc melting; VB (zig-zag chains), V₄Bₙ (double chains), and VBₓ (flat hexagonal chains). The open circuit voltage of a conventional H₂O₂ fuel cell is limited to ~1.23 V under atmospheric pressure, which limits the efficiency of the system. Here, we reported a dual-electrolyte microfluidic fuel cell system (DEFC), which could stably deliver an open circuit voltage up to 1.76 V at room temperature under atmospheric pressure, and a peak power density of 145 mW/cm², improved by 3 times compared with that in single electrolyte mode. When operated in the reverse mode, the microfluidic cell can be used for water electrolysis, demonstrating a water split voltage of ~0.74 V and a round trip voltage efficiency of 83.5% at a current density of 100 mA/cm². The neutralization energy of the two electrolytes, which could be wasted as heat, can be directly utilized to produce electricity or split water with high efficiency. Given the DEFC’s features of high open-circuit voltage, low water splitting voltage, and room-temperature operation condition, the reported DEFCs technology presents a superior route for high-efficiency energy conversion and storage system that could revolutionize the fields of large-scale energy storage and portable power systems.
network). Electrochemical measurements show that VB$_2$ requires the lower overpotentials (-0.360 V) than that of VB (-0.430 V) and V$_3$B$_5$O$_{11.6}$ (0.416 V) in 0.5 M H$_2$SO$_4$ to achieve a current density of 100 mA/cm$^2$. Besides, the activity of VB$_2$ is remained after 5000 cyclic voltammetry measurements. These results indicate that graphene-like flat boron layers in VB$_2$ give positive effect for increasing HER activity due to its electrical conductivity and Ag$_3$ value close to 0 V.

Engineering on Ni-Co-S Bifunctional Electrocatalyst for Water-Splitting Jing Wu, Huijing Guo, Zhao Kang and Yue Zhang; State Key Laboratory for Advanced Metals and Materials, School of Materials Science and Engineering, University of Science and Technology, Beijing, China.

Ni-Co-S is a technologically important electrode material that has recently achieved remarkable performance in catalysis. Herein, Ni$_{1-x}$Co$_x$S$_2$ bifunctional catalysts with tunable stoichiometry was synthesized on Ni foams. The electronic structure engineering contributed to the significantly elevated electrocatalytic performance. As a result, overpotentials $\eta_0$ of 97 mV (vs.RHE) for hydrogen evolution reaction (HER) and 285 mV for oxygen evolution reaction (OER) in 1M KOH solution. At the same time, we study the electrocatalytic properties of the NiCo$_2$S$_4$ by using density functional theory, the Gibbs free energy changes of different active sites shows the Co top site of the (011) surface is the most active site. The excellent catalytic activities are attributed to the optimal electronic structure of catalyst surface, we found the different atomic ratios between Ni and Co have significant impact on the electronic structure by calculating the electron density difference of Ni$_{1-x}$Co$_x$S$_2$.

Leveraging Plasmas for Electrochemical Fuel Production—Synthesizing Novel Low-PGM OER Catalysts and Enhancing the Rate of Electrochemical Ammonia Production Joshua M. Spurgeon, Sudesh M. Kumari and Sahar M. Pishgar; Conn Center for Renewable Energy Research, University of Louisville, Louisville, Kentucky, United States.

Plasmas have a number of unique properties which researchers may be able to leverage to enhance desired electrocatalyst material properties and steer electrochemical reaction performance. Two examples of the recent application of plasmas for advancements in electrochemical fuel production are presented. In the first, the nonequilibrium reaction environment of an air plasma enabled the synthesis of homogeneous phases of metastable mixtures of a mixed W$_x$Ir$_{1-x}$O$_2$ alloy. For a low-platinum-group-metal (PGM) composition of only 1% Ir, plasma-synthesized W$_9$Ir$_{10}$O$_{29}$ was observed to be an acid-stable oxygen evolution reaction (OER) catalyst of competitive overpotential. Moreover, the plasma-synthesized alloy was observed to have an OER overpotential ~ 570 mV less than that of a thermally oxidized alloy of the same composition. In the second example of a plasma enhancement, a nitrogen plasma was coupled into the cathode of a proton exchange membrane electrolyzer to provide energetically activated N$_2$ species to the electrocatalyst surface and demonstrate a proof-of-concept synergistic enhancement in the rate of ammonia production. At an applied bias of ~3.5 V across the electrolyzer, plasma-assisted operation was observed to produce 47% more ammonia than the combination of plasma-without-bias and bias-without-plasma conditions.

ES11.09.15

Due to the extreme conditions encountered during typical use; solar thermochemical (STCH) water splitting materials that do not begin in a low energy state will evolve during cycling. Evolution during cycling may take many forms, including Oswald ripening of grains or slow conversion of impurity phases, all of which will have some effect on the performance of the material during cycling. Thus, creating phase pure materials with stable grain sizes is of utmost importance to evaluating STCH materials. We report on the methods of designing high quality STCH materials from the modeling stage onwards, the synthesis of phase-pure and pre-ripened materials, and characterization used to determine the stability of the material over many cycles.

ES11.09.16
Developing an Atomic Understanding of the Layered Perovskite Ba$_{2}$CeMn$_{2}$O$_{6}$ and Its Polytypes for Thermochemical Water Splitting—A HydroGEN Supernode Anthony H. McDaniel, Andrea Ambrosini, Eric Coker, Joshua Sugar, Robert T. Bell, David S. Ginley, Stephan Lany, Philip Parilla, Tadashi Ogitsu, Sabrina Wan and Brandon Wood; Sandia National Laboratories, Livermore, California, United States; Sandia National Laboratories, Albuquerque, New Mexico, United States; National Renewable Energy Laboratory, Golden, Colorado, United States; Lawrence Livermore National Laboratory, Livermore, California, United States.

Next generation perovskite-oxide based materials for thermochemical water splitting (aka STCH) are key to developing a massively scalable technology that efficiently converts solar energy to hydrogen. The challenge is to design optimal perovskites that achieve DOE performance targets, such as high efficiency operation at low thermal reduction temperature. Current research is mired in a heuristic approach to probing the enormous array of possible material compositions that manifest water splitting activity in perovskites. A comprehensive molecular-level picture of the factors that influence redox cycle behavior is missing. We report on a HydroGEN Advanced Water Splitting Materials (H2AWSM) consortium effort to develop a fundamental understanding of how the unique crystallographic structures induced by the Mn$_x$O$_{y}$ ligand bond found in layered perovskites influences properties critical to favorable material behavior. This is accomplished by examining perovskite electronic structures resulting from redox transitions using advanced spectral microscopies and, in conjunction with atomistic theory, deriving correlations between electronic configurations and thermodynamic properties that manifest water splitting material behavior.

ES11.09.17
Bifunctional Oxygen and Hydrogen Evolution Electrocatalytic Activities of P-Type Delafossite Cu$_2$Mo$_3$O$_7$ Oxides Yuanbing Mao; The University of Texas at Rio Grande Valley, Edinburg, Texas, United States.

Making easy-to-make, cost-efficient, and durable bifunctional electrocatalysts for overall water splitting to produce oxygen and hydrogen is of paramount significance for future renewable energy system but still a challenge. Herein, we explored earth-abundant and non-toxic delafossites with a CuMo$_2$-type general composition, where ‘M’ is trivalent metals of Al, Ga, Cz, Co, Fe, etc. First, we report that nanocrystalline CuGa$_2$O$_4$ hexagons showed enhanced electro-catalytic activity as compared to the sub-micron sized and micron sized particles of CuGa$_2$O$_4$ counterparts for the oxygen evolution reaction (OER) and hydrogen evolution reaction (HER) in 0.5 M KOH versus Ag/AgCl. Then, based on a widely used strategy to increase the surface area of functional materials, we synthesized delafossite CuGa$_2$O$_4$ nanoflakes. Their electrochemical (EC) and photoelectrochemical (PEC) performance in 0.5 M KOH electrolyte versus Ag/AgCl along with their stability were studied. The developed electrocatalysts are very efficient to produce H$_2$ cheaper, offers no complications in synthesis of materials and fabrication of electrolyzers, which can greatly enable the realization of clean renewable energy infrastructure.

ES11.09.18

Pacific Northwest National Laboratory’s (PNNL) experience in solid oxide electrolysis cell (SOEC) technology and related high temperature electrochemical devices extends back to 1987 and has been documented in over 150 peer-reviewed technical papers and numerous patents. PNNL’s experimental and modeling experience and capabilities in high temperature electrochemistry encompass all aspects of the technology, from materials development and characterization to design, fabrication, and testing of cells, stacks, and systems. In addition to performing work for the U.S. Department of Energy and other agencies, PNNL has collaborated successfully with a number of industrial developers. PNNL’s high temperature electrochemistry laboratories contain all the materials synthesis, processing, fabrication and testing equipment necessary to develop and test solid oxide electrolyzers, stacks, and complete power systems. The experimental work is being supported by computational modeling at the cell, stack, and system levels. PNNL also hosts a national user facility, the Environmental Molecular Sciences Laboratory, with a large suite of physical and chemical characterization tools.
With the gradual consumption of fossil fuels and rapidly increasing pressures from environmental pollution, it is important and necessary to develop and harvest clean renewable energy in large scales to fulfill the sustainable development in economy and society. Hydrogen generated from electrochemical water splitting can not only replace fossil fuels as a clean and efficient energy carrier, but also realize large-scale conversion and storage of sustainable energy-produced electricity. Generally, electrocatalytic water splitting consists of two half reactions, namely hydrogen evolution reaction (HER) and oxygen evolution reaction (OER), while an additional potential is required for the implementation because of the limitation in slow cathodic and anodic kinetics. Non-noble metal-based electrocatalysts (such as manganese, iron, cobalt, and nickel) are of huge advantages in the low cost and rich abundance as compared with noble metals, but their activity and stability are still not satisfactory for practical applications. In this regard, rational design of the structures and composites of hierarchical electrocatalysts using various strategies are widely explored to aim for reducing the overpotentials for efficient water splitting. Typical methods include controlling the morphology, employing the conductive substrates as supports, regulating the ratios of various constituent components, engineering the defects, doping with the foreign elements, as well as surface coating and decoration in order to enhance the catalytic activity and stability of electrocatalysts. Recently, more attentions are paid on regulating the catalytic activity of catalysts by incorporating with rare earth elements. Because of the stable chemical property and unique electronic structure of rare earth elements, their integration with hierarchical transition metal-based electrocatalysts is developed as a novel method to modify the structure and property of electrocatalysts. In this presentation, cerium as a typical rare earth element, is selected and introduced into the transition metal-based electrocatalysts to improve their HER and OER properties. The role of cerium-based species and their influences on the structures and properties of electrocatalysts are also investigated.

Molecular hydrogen is the most promising candidate for clean, renewable and economical energy carrier to address the every increasing demand for clean energy. However bottleneck for large scale commercialization of the water electrolyzer is the requirement of costly Pt electrocatalyst. Search for efficient and cheaper alternatives based on Earth abundant elements is limited by the slow kinetics of the Volmer step for adsorption of hydrogen and subsequent Tafel step for generation of molecular hydrogen from recombination of adsorbed H atoms. In a recent work MoNi4 electrocatalyst supported on MoO2 is synthesized from thermal reduction of NiMoO4. Very high efficiency for HER with 0 mV onset over potential tafel slope ~30 mV/decade has been reported which originated from drastically accelerated Volmer and Tafel steps. However detail understanding for microstructural evolution, alloy formation and phase separation during thermal reduction of NiMoO4 along with the role of MoO2 is required for further improvement of the catalyst. In the present work detail Transmission electron microscopic studies including in-situ heating, nanobeam diffraction and STEM-EDS is used for comprehensive understanding of the growth mechanism of the electrocatalyst. Role of each of the co components of the electrocatalyst and their stabilities are evaluated through impedance spectroscopy and array of other electro chemical techniques.
finding suggests that dissolution occurs from distinct surface sites from those that are responsible for O₂ evolution. This understanding corroborates our earlier work, which showed that surface Ir stabilises RuO₂ and surface Ti stabilises MnO₂, without compromising activity. On this basis, we propose there should be ample opportunities for engendering further improvements to the stability of oxygen evolution catalysts under acidic conditions.

The Role of Catalyst Metastability in Enhancing the Oxygen Evolution Reaction
Nathalie Vornrütii and Ulrich Aschauer; Chemistry and Biochemistry, Universität Bern, Bern, Switzerland.

While it was shown that metastability can increase a catalyst’s water-oxidation activity (1,2) it is still unclear what the underlying mechanism is. Using density functional theory calculations, we analyze the oxygen evolution reaction (OER) on (001) surfaces of three different materials chosen for their very different electronic properties. To account for the metastability, we study the OER on a large variety of different reaction sites by sampling many defective surface structures. Totally, we compute the OER overpotential on 770 symmetrically inequivalent reaction sites. For all three materials, we find a large range of overpotentials for different reaction sites including also overpotentials at the top of the activity volcano. This implies that the structural variety of reaction sites on dissolving metastable heterogeneous catalysts will, for some sites, lead to overpotentials close to the top of the activity volcano. Under the assumption that reaction sites with low overpotentials will dominate a catalyst's apparent activity, this implies that, independent of the electronic properties of the catalyst, operating a heterogeneous catalyst at the border of its stability region can lead to an increased apparent activity due to the large geometric variety of different reaction sites.

Controlled Electro-Deposition of IrO₂ Nano-Arrays with Different Length on TiO₂ Nanotube Arrays
Zhao-xin Lu, Yan Shi, Chang-qing Guo, Zhi-da Wang, Hong-yi Tan and Changfeng Yan; Hydrogen Production and Utilization Lab, Guangzhou Institute of Energy Conversion, Chinese Academy of Science, Guangzhou, China.

One-dimensional-arrays material possesses high surface area, oriented electron transfer pathway and facile mass transfer pathway, which shows prominent potential for electrocatalyst. IrO₂ nano-arrays (IrO₂ NAs) performs excellent activity in oxygen evolution reaction in electrochemical water splitting. In this work, TiO₂ nanotube arrays (TNTA) with a length of 1500 nm is applied as template to study electrodeposition of IrO₂ on conductive nanotube substrate through cyclic voltammetry (CV). By conducting different scan rate of CV and concentration of Ir precursor in electrodeposition, IrO₂ NAs, nanotubes or hollow nanowires, with different length is obtained, which is determined by the distribution of deposited IrO₂ under different applied conditions. With fixed concentration of Ir precursor, there is a positive-related linear range between scan rate and the length of IrO₂ NAs that is the depth of TNTA where deposited IrO₂ could construct constant layer on the tube wall. A possible mechanism is proposed. As the whole tube wall of TNTA is conductive, the electrodeposition of IrO₂ will take place throughout the tube. Due to the competition of the consuming of Ir precursor by depositing and supplementing through diffusion from bulk electrolyte, concentration gradient of Ir precursor would be gradually formed along the tube and leads to uneven depositing. And this phenomenon would be exacerbated with the prolongation of depositing time. In electrodepositing of CV, each cycle includes the depositing period and non-depositing period in which Ir precursor could be sufficiently diffused throughout the TNTA. And with a slower scan rate of CV the uneven depositing will be more significant. Besides, as the CV depositing goes on, a cover layer of IrO₂ on the top surface of TNTA, which would hinder the diffusion of Ir precursor form the bulk electrolyte to inner zone of TNTA, would be formed as we have reported. As the depositing rate near the mouth of TNTA will be hardly affected by the prolongation of depositing period of each cycle, the formation of cover layer is mainly determined by the total depositing time, while the deposited amount of IrO₂ in the depth of TNTA depends on the cycles of CV. Briefly, the length of obtained IrO₂ NAs is determined by the number of depositing cycles before the cover layer is formed. The deposition with different concentration of Ir precursor and fixed scan rate has been studied, too. With lower concentration, the required numbers to form cover layer increases, and results in longer IrO₂ NAs, which is consistent to our proposed mechanism.

Effects of Low Loading and Intermittency on Low Temperature Electrolysis from a Catalyst Perspective
Shaun Aila¹, Shraboni Ghoshal¹, Grace Anderson¹, Mai-Anh Ha¹, Sarah Stariha², Chilan Ngo³, Svitlana Pylypenko³, Rod Borup² and Ross Larsen¹;¹National Renewable Energy Laboratory, Lakewood, Colorado, United States; ²Los Alamos National Laboratory, Los Alamos, New Mexico, United States; ³Colorado School of Mines, Golden, Colorado, United States.

In commercial electrolysis, the cost of electricity input drives the cost of hydrogen production. Electrolysis, therefore, is typically run at high catalyst loading and constant power input over long periods of time. Lowering water-splitting hydrogen production costs to a level comparable to steam methane reforming requires: coupling electrolysis with low-cost power input (wind, solar) to reduce feedstock costs; and minimizing capital cost at lower capacity. [1,2] Part of reducing capital cost includes reducing catalyst loading and while minimal durability loss is seen with thick catalyst layers, losses become more apparent with loading reductions.[3]
Presented efforts include evaluating load-follow operation, start-stop operation, and contaminants, studying relevant mechanisms for loss in half-cell tests and how these losses are observed in single-cell tests. Electrolyzer durability was evaluated at low iridium-anode loading (0.1–0.5 mg cm⁻²) and with different power inputs (potentials, intermittency) to focus on systems aspects needed to significantly reduce hydrogen production costs. Within load-follow operation, iridium loss was driven by dissolution. Although higher potential accelerated single-cell loss, cycling (square/triangle wave) also increased the rate of performance decay since rapidly increasing input resulted in localized potential spikes within the catalyst layer. While start-stop operation accelerates loss through a variety of pathways (dry operation on membrane, pressure cycling on membrane and hydrogen crossover), these efforts focused on the effect of potential excursions on the catalyst. Simulated hard-stops were more detrimental to iridium durability than load-follow, likely due to surface and near-surface reduction increasing dissolution rates. The effect of contaminants was also evaluated based on likely metals added with water input. Contaminant effects in half-cell tests were observed but were relatively small and may have been due to the large amount of free electrolyte and desorption on iridium at high potential. Losses were more significant in single-cells and may have been exacerbated by contaminants blocking within the membrane and plating the cathode.

Several catalyst types have been tested, including metals (metal/hydroxide) and oxides with supports, high surface area, multicomponent, and alloys. These materials have been

studied in half-cells for the activity improvement mechanism and in single-cells to evaluate potential advantages/disadvantages in electrolysis performance and durability. By including different catalyst types, we are looking to establish performance/durability guidelines and perspectives on how catalyst development and system controls factor into low temperature electrolysis at low loading and with intermittency. These tests have significant implications with a shift toward low-cost hydrogen production through electrolysis coupled with renewable power inputs.

4:00 PM  *ES11.13.02  Alkaline Membrane Electrolysis—Challenges and Perspectives Hui Xu; Giner Inc., Newton, Massachusetts, United States.

The utilization of renewable energy has substantially driven more attention into electrolysis technologies. An electrolyzer can utilize “off peak” electricity from solar or wind farms to produce hydrogen or other fuels. These fuels can then be operated in a fuel cell mode to generate electricity when needed or used for other industrial applications. Further, the establishment of H2@scale consortium by DOE has presented unprecedented opportunities for renewable H2. However, current hydrogen production from electrolysis comprises only a small fraction of the global hydrogen market due to the high costs that result from expensive materials even if “free” electricity from renewable energy can be acquired.

Alkaline membrane water electrolysis enables to use non-precious metals (or oxides) as the catalysts for oxygen evolution reaction (OER) and hydrogen evolution reaction (HER). The commercial OER catalyst IrOx for proton exchange membrane (PEM) electrolysis is very expensive; more importantly, the global storage and production of iridium is very scarce, tremendously limiting the mass production and deployment of PEM electrolyzers. There have been a large number of non-precious metal based OER and HER studies. However, most of these studies have been performed on the rotating disk electrodes (RDEs) under alkaline solutions. Their applications in real alkaline membrane electrolyzers have been very limited.

This work will present the primary challenges associated with the realization of alkaline membrane electrolysis, which include catalyst durability, electrode design and alkaline membrane/ionomer development. First, many OER or HER catalysts demonstrating good activity in the RDE do not work for the real electrolyzer cell. Second, an optimal interaction between the ionomer and the catalyst in the electrode has not been established. Third, current commercial alkaline membrane and ionomer cannot meet the stability requirement, they decay rapidly under high operating voltage and high temperature. Furthermore, water transport in alkaline membrane electrolysis is much more complex compared to PEM water electrolysis.

The pursuit of alkaline membrane/ionomer with various chemistries and structures by a few researcher groups has rejuvenated alkaline membrane electrolysis. They will provide a better platform to test the OER or HER catalyst to enable alkaline membrane membrane electrolysis operation.

4:30 PM  *ES11.13.03  Recent Progress of PEM Water Electrolysis in DICEP Zhongang Shao; Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian, China.

PEM water electrolysis provides a sustainable solution for the production of hydrogen, and is well suited to couple with renewable energy sources such as wind and solar. Recently, the increasing desire for green energy has rekindled the interest on PEM water electrolysis. However, the performance, life expectancy and cost of PEM water electrolyzer are still the key problems restricting its large-scale commercial use. Dalian institute of chemistry physics (DICEP) has been devoted to the research and development of key material, component, stack and system for high-performance, long-life and low-cost PEM water electrolyzer. Research on electrocatalysts for oxygen evolution reaction (OER) with high activity, excellent durability and low cost is significantly important to increase the energy efficiency and stability of water electrolyzer. To synthesize Ir-based oxide electrocatalysts with high efficiency and low cost, we introduce the second less-expensive metal, including Ru, Sn and Co to fabricate Ir-Ru, Ir-Sn and Ir-Cr oxides with low Ir contents as OER electrocatalysts. Besides, a cost-effective nanoporous ultrathin film (NPUF) electrode based on nanoporous gold (NPG) with 3D interconnected nanoporosity structure and IrOx composite has been constructed to serve as oxygen electrode. A single cell performance of 1.728 V (@ 2 A cm^-2) has been achieved by NPUF electrode with a loading of IrOx and Au at 86.43 and 100.0 mg cm^-2 respectively. One of main challenge of PEM water electrolysis is the achievement of a long-term durability exceeding 100 khours. Accordingly, degradation mechanisms of membrane electrode assembly (MEA) and stack component of PEM electrolyzer deserve large attention. In DICEP, a 9-cell PEM water electrolysis stack has been developed and tested for 7800 h. The average degradation rate is 35.5 mV h^-1. The 4th MEA of the stack is offline investigated and characterized to investigate the degradation mechanism. The electron probe X-ray microanalyzer (EPMA) illustrates that Ca, Cu and Fe elements distribute in the membrane and catalyst layer of the catalyst-coated membrane (CCM). These metal cations occupy the ion exchange sites of the Nafion polymer electrolyte in the catalyst layer and membrane, which results in the increase in the anode and the cathode overpotentials. The metallic impurities are believed to originate mainly from the feed water and the components of the electrolysis unit. Fortunately, the degradation is reversible and can be almost recovered to the initial performance by using 0.5 M H_2SO_4. This indicates the performance degradation of the stack running 7800 h is mainly caused by a recoverable contamination. Nowadays, we have successfully developed a hydrogen production system with single stack to produce H_2 at a rate of 10m^3/h for more than 10 khours with a hydrogen purity of 99.99% and delivery pressure of 35 bar.

8:00 AM  *ES11.14.01  Monolithically Integrated InGaN/Si Tandem Photocathodes for Efficient and Stable Photoelectrochemical Water Splitting Zetian Mi and Srinivas Vanka; University of Michigan, Ann Arbor, Michigan, United States.

Recently, significant progress has been made in photoelectrochemical water splitting and solar hydrogen generation. For practical application, it is essential that the constituting semiconductor photocathodes can perform unassisted solar water splitting both efficiently and stably. To date, much of the research has been focused on metal-oxide, Si, and III-V semiconductor photocathodes. A double-junction photocathode, consisting of a top light absorber (energy bandgap ~1.7 eV) and a bottom light absorber (energy bandgap ~1.1 eV) promises a solar-to-hydrogen conversion efficiency up to 30%. While Si is ideally suited to serve as the bottom light absorber, it has remained challenging to identify a 1.7-2.0 eV top light absorber that is stable in harsh photocatalysis conditions. Recent studies suggest that metal-nitride photoelectrodes, e.g. InGaN possess excellent potential for semiconductor photoelectrodes. A double-junction photoelectrode, consisting of a top light absorber (energy bandgap ~1.7 eV) and a bottom light absorber (energy bandgap ~1.1 eV) promises a solar-to-hydrogen conversion efficiency up to 30%. While Si is ideally suited to serve as the bottom light absorber, it has remained challenging to identify a 1.7-2.0 eV top light absorber that is stable in harsh photocatalysis conditions. Recent studies suggest that metal-nitride photoelectrodes, e.g. InGaN possess excellent potential for unassisted solar water splitting. InGaN with an indium composition ~50% exhibits an energy bandgap ~1.75 eV and is thermodynamically stable in photoelectrochemical water splitting. In this context, we have performed a detailed investigation of the design, synthesis, and photoelectrochemical performance of InGaN/Si double-junction photocathodes. We have demonstrated that InGaN/Si photocathodes can perform unassisted solar water splitting with relatively high efficiency in 0.5 M sulfuric acid under AM1.5G one-sun illumination. Long-term stable operation (~1,000 hrs) has been demonstrated for GaN/Si photocathodes without using any extra surface protection. In this work, GaN and InGaN nanowires are grown directly on n+-Si wafer by plasma-assisted molecular beam epitaxy. The surfaces of InGaN nanostructures are tuned to be N-rich, not only for their top c-plane surfaces but also for their nonpolar lateral surfaces, which can effectively protect against corrosion. We have discovered that the conduction band offset between GaN and Si is essentially negligible, which enables the efficient extraction of photo-generated electrons from the underlying Si wafer. The GaN/Si...
Thermal Synergies in Photo-Electrochemical Fuel Processing Devices
Sophia Haussener; Ecole Polytechnique Federale de Lausanne, Switzerland, Lausanne, Switzerland.

Achieving high current densities while maintaining a high energy conversion efficiency is one of the main challenges for enhancing the competitiveness of solar fuel producing photo-electrochemical devices. I will discuss and show how thermal integration allows for an operational device at current densities and efficiencies which otherwise could not be supported.

Photocathodes in the hydrogen-evolution half-reaction of solar water splitting. The key aspect is to incorporate nanostructured density-gradient surface of GaInP photocathodes in conjunction with sulfur-based tailoring of surface atomic composition. The resulting surface-tailored GaInP photocathodes not only significantly suppressed reflection losses at the semiconductor/electrolyte interface with enhanced saturated current density from -13.3 mA/cm$^2$ to -15.2 mA/cm$^2$ but also provides a dramatically boosted electrochemical stability with lifetime over 124 hours in 0.5 M H$_2$SO$_4$ under simulated AM1.5G illumination.

Hybrid Perovskite Photo-Absorbers for Efficient Photoelectrochemical Water Splitting
Aditya Mohite; Department of Chemical and Biomolecular Engineering, Rice University, Houston, Texas, United States.

Solution-processed halide hybrid (inorganic-organic) perovskites have demonstrated an extraordinary potential for clean sustainable energy technologies and low-cost optoelectronic devices such as solar cells; light emitting diodes, detectors, sensors, ionic conductors etc. Single junction photovoltaic efficiencies have sky rocketed to 23.3% and attempts are being made to fabricate high efficiency perovskite-perovskite tandem cells. A unique advantage of halide hybrid perovskites over other photo-absorbers is that a surface protection. To realize double-junction photoelectrodes, p-type InGaN nanowires are integrated on n-GaN nanowire junction, which enables the transport of photocreated holes from the p-InGaN to the n-GaN/Si.

Surface-Tailored GaInP: Photocathodes for High Performance Solar Water Splitting
Haneed Lim$^1$, James L. Young$^2$, John F. Geisz$^3$, Daniel J. Friedman$^3$, Todd G. Deutsch$^3$ and Jongseung Yoon$^1$; 1 Mork Family Department of Chemical Engineering and Materials Science, University of Southern California, Los Angeles, California, United States; 2 National Renewable Energy Laboratory, Golden, Colorado, United States; 3 Ming Hsieh Department of Electrical Engineering, University of Southern California, Los Angeles, California, United States.

Solar-driven water splitting is a promising approach that can potentially realize cost-effective hydrogen production from readily available resources on earth. Among various candidate materials, gallium indium phosphide (GaInP) represents an enabling material to serve as a top-junction in monolithically grown multijunction photodevices for ultrahigh efficiency solar water splitting. In such tandem photodevice systems, GaInP has multiple roles such as light absorption, electrocatalysis, and corrosion-protection as it is in direct contact with an electrolyte, all of which are critically important to realize high performance solar water splitting. Here we present an approach to simultaneously enhance both efficiency and stability of GaInP:photocathodes in the hydrogen-evolution half-reaction of solar water splitting. The key aspect is to incorporate nanostructured density-gradient surface of GaInP photocathodes in conjunction with sulfur-based tailoring of surface atomic composition. The resulting surface-tailored GaInP photocathodes not only significantly suppressed reflection losses at the semiconductor/electrolyte interface with enhanced saturated current density from -13.3 mA/cm$^2$ to -15.2 mA/cm$^2$ but also provides a dramatically boosted electrochemical stability with lifetime over 124 hours in 0.5 M H$_2$SO$_4$ under simulated AM1.5G illumination.

Solar Water Splitting—Surface Energy Engineering of GaP Template on Si
Pedesseau Laurent$^1$, Idaucci$^2$, Simon Charbonnier$^2$, Pascal Turban$^2$, Yoan Leger$^2$, Tony Rohel$^2$, Nicolas Bertru$^1$, Antoine Letoublon$^1$, Maxime Valette$^1$, Anne Poncher$^1$, Ludovic Largeau$^2$, Gilles Patriarche$^2$ and Charles Cornet$^2$; 1 Univ Rennes, INSA Rennes, CNRS Institut FOTON - UMR 6082, Rennes, France; 2 Univ Rennes, CNRS IPR (Institut de Physique de Rennes) – UMR 6251, Rennes, France; 3 CEMES-CNRS, Université de Toulouse UPS, TOULOUSE, France; 4 Centre de Nano sciences et de Nanotechnologies, site de Marcoussis CNRS, Université Paris Sud, Université Paris Saclay, MARCOUSSIS, France.

The hydrogen production will play a major nanoscience role in this energy transition. Recent, for water splitting context [1], [2], a demonstration of the efficiency enhancement of BiVO4 photocathode in PEC devices[3] by simply a texturing of surfaces. Moreover, in the study of the semiconductor photocatalyst material[4], GaP semiconductor appears to be a good candidate for photodevice in PEC devices[5]. One strong argument is to have at least 1.73 eV photopotential requirement for water splitting and its bandgap is larger and about 2.26 eV. In this aim of water splitting applications, we propose a surface energy engineering for a large scale textured GaP template monolithically integrated on Si. Based on experimental analysis and theory, the stability of the [114] facets is scrutinized by scanning tunneling microscopy images and also supported by density functional theory calculations. We then show that change of the surface energy for experimentally promoting the GaP(114) surface texturation can be achieved through (i) destabilizing the GaP(001) surface by using a vicinal Si substrate or through (ii) favoring the [114] facets formation by changing the group-V atmosphere above the surface on a miscut-free GaP substrate.

The nanostructures as a surface protection layer, we have demonstrated that GaN/Si photocathodes can exhibit long-term stable operation (>1,000 hr) without using any other extra surface protection. To realize double-junction photodevices, p-type InGaN nanowires are integrated on n-p Si wafer through a polarization enhanced p+/n+ GaN nanowire junction, which enables the transport of photocreated holes from the p-InGaN to the n-GaN/Si. The top InGaN nanowire arrays with an island composition ~50% has an energy bandgap ~1.75 eV and is designed to absorb sunlight in the visible spectrum, whereas the rest of the photons with wavelengths <1.1 μm are absorbed by the underlying planar Si p-n junction. The double junction InGaN/Si photocathode has $V_{OC}$ of ~2.3 V vs RHE in 0.5 M sulfuric acid. A solar-to-hydrogen conversion efficiency ~5% is measured under AM1.5G one-sun illumination.

Work is currently in progress to achieve solar-to-hydrogen conversion efficiency >10%, which, together with the long-term stability analysis will be performed and reported.
Corrosion is a ubiquitous natural process that impacts all engineering systems, occurs through many mechanisms, and has been studied extensively, especially for metals and non-metals commonly used in construction, pipelines, and shipping. Corrosion is particularly challenging for photoelectrochemical (PEC) water-splitting devices which call for immersion of multiple conductive materials (semiconductors, catalysts, membranes) in electrolytes saturated with either hydrogen or oxygen. In this talk, I will compare and contrast the typical and best practices used in photoelectrochemical stability testing with those developed by corrosion engineers, to identify practices that can be beneficially adopted by the PEC water-splitting community. I will also discuss these practices with a focus on mechanistic studies, corrosion prevention, failure analysis, and lifetime predictions for materials in corrosive environments.

This work was supported by the U.S. Department of Energy at the Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Friday Morning, April 26, 2019
PCC North, 100 Level, Room 121 C
10:30 AM ES12.01.01/ES11.01.01
Development of Protocols and Standards for Low Temperature Electrolysis Katherine Ayers, Andrew Motz, Christopher Capuano and Prasanna Mani; Nel Hydrogen, Wallingford, Connecticut, United States.

Currently over 95% of hydrogen is made from fossil fuels through natural gas reforming or coal gasification. A major part of reducing carbon emissions must therefore include sources of renewable hydrogen. In addition, capture of existing carbon dioxide sources and subsequent conversion to higher value chemicals also requires a hydrogen source. Using hydrogen from traditional sources for this purpose does not make environmental sense, since the net effect is just shifting where the carbon dioxide is emitted geographically. Large scale, cost competitive sources of renewable hydrogen are critical in moving to more sustainable processes worldwide.

Low temperature electrolysis has decreased significantly in cost while increasing in scale over the last several years, and there continue to be large opportunities for additional cost reduction and performance improvements. With the advent of low cost renewable electricity, particularly in times of excess capacity when storage is most needed, electrolysis is reaching the production and cost scale to provide a viable solution. However, as research activities have increased, differences in testing conditions, reporting comparisons, cell designs, and other factors convolute data interpretation and can lead to misleading conclusions. In addition, insufficiently controlled protocols can mask effects. This talk will describe some of the complex interactions that need to be considered, and current efforts in developing community-wide tests ranging from ex-situ material screening protocols to realistic device testing. This work is part of an ongoing program across all of the major advanced water splitting technologies, the subject of this symposium and the parallel high temperature water splitting symposium.

10:45 AM ES12.01.02/ES11.01.02
Development of Protocols and Standards for Photoelectrochemical Water-Splitting Chengxiang Xiang; California Institute of Technology, Pasadena, California, United States.

Cost competitive hydrogen generation at scale using sunlight and water can play a significant role in decarbonization of our society. In recent years, photoelectrochemical (PEC) water splitting has made significant progress in materials discovery, mechanistic understanding, as well as in achieving un-precedent solar to hydrogen conversion efficiencies in the laboratory scale. To further advance this technology and reach the bench scale (0.1 kg/day) and sub-scale (2 kg/day) operational platforms, development of standard protocols and best practices for benchmarking materials and devices as a community is critical. Standardized methodologies and best practices also provide significant benefit in accelerated RD&D of advanced materials and cross-cutting efforts.

In this presentation, I will talk about recent community-based efforts in defining targets, best practices and gaps in PEC hydrogen production in HydroGEN Energy Material Network (EMN) consortium. Specific challenges related to PEC will be discussed including scale up challenges, integration challenges at the component level, lack of performance data and test protocols for photoelectrodes under real-world operating conditions and lack of fundamental understanding of photoelectrode corrosion mechanisms and accelerated test protocols. In addition, I will also present a briefly summary and status reports on lab EMN nodes/capabilities for PEC water-splitting. Key takeaways from a recent HydroGEN Benchmarking&Protocols Workshop and DOE PEC Working Group Meeting will also be discussed.

11:00 AM ES12.01.03/ES11.01.03
Framework and Test Protocols for High Temperature Electrolysis Olga Marina; Pacific Northwest National Laboratory, Richland, Washington, United States.

Hydrogen production via water electrolysis is considered to be an efficient way to smoothen the fluctuating power output of renewable energy sources and avoid oversupplies. This presentation will provide the status of the standards and protocols development for high temperature electrolysis (HTE) technology within the US DOE HydroGEN Energy Materials Network Consortium. The current material standards, advanced characterization techniques, best practices and testing protocols from screening of fundamental material properties to device level benchmarking will be discussed to address key challenges and leverage technical advancements across the different water splitting technologies.

11:15 AM ES12.01.04/ES11.01.04
Framework and Test Protocols for Solar Thermochemical Water Splitting Ellen B. Stechel; LightWorks and School of Molecular Sciences, Arizona State University, Tempe, Arizona, United States.

This presentation will provide the status of standards and protocol development within the US DOE HydroGEN Energy Materials Network (EMN) Consortium for advanced water splitting using concentrated solar thermochemical redox cycles, generally referred to as STCH, solar thermochemical hydrogen.

Cost competitive water splitting to produce hydrogen at scale using concentrated sunlight can contribute significantly to a net CO₂ neutral society. In recent years, STCH has made significant progress. Working as a community will further advance STCH technology with a goal of reaching demonstration scales of multiple kilowatts with promising redox active materials. The development of standard protocols, definitions, metrics, best practices, and roadmaps for benchmarking materials and reactor designs is critical to accelerate progress and lower barriers for new researchers.

In this presentation, we will discuss recent HydroGEN EMN community-based efforts in defining metrics, best practices, and gaps in STCH. In addition, we will present a brief summary of EMN nodes/capabilities as well as key conclusions from a recent questionnaire and from a recent HydroGEN Benchmarking & Protocols Workshop specifically for STCH.

11:30 AM PANEL DISCUSSION

SESSION ES12.02: Redox-Active Oxides I
Session Chairs: Olga Marina and Christian Sattler
Tuesday Afternoon, April 23, 2019
PCC North, 100 Level, Room 121 B
Solar thermal water splitting (STWS) is a promising renewable approach to converting water into hydrogen using concentrated sunlight. The central process in STWS is the high temperature reduction and oxidation of a metal oxide where $H_2$ is produced by reaction of $H_2O$ with the reduced material. For this process to be viable, the thermodynamics and kinetics of reduction and oxidation of the redox active material must produce sufficient $H_2$ at practical rates and at temperatures at which the active material is stable. In this talk we will present our results using ab initio and machine learned models to discover candidate perovskite STWS materials. This includes predicting the stability of these materials at the operating temperature, whether these materials form as perovskites and in what specific phase, the energy of oxygen vacancies and other defects that mediate the redox process, and finally the viability of these metal oxides as STWS redox materials. The Gibbs energy, $G$, determines the equilibrium conditions of chemical reactions and materials stability. Unfortunately, $G$ has been tabulated for only a small fraction of known inorganic compounds, thus impeding an analysis of whether materials are stable and synthesizable at operating conditions. We used a statistical learning approach to identify a simple and accurate descriptor to predict $G$ for stoichiometric inorganic compounds with ~50 meV/atom.

The ability to assess and compare the performance of solar thermochemical water splitting materials individually and against other materials and even to other advanced water splitting pathways is increasingly a critical need in the field of sustainable hydrogen production. Technical assessment and comparisons include evaluating mass loss of samples during thermal gravimetric analysis (TGA) in controlled oxidizing and reducing environments; the results from TGA measurements have evolved into a widely reported metric. However, the lack of universal reference materials and calibration protocols has made comparisons between materials developed at different institutions unmanageable. We are developing standard samples and testing protocols for the solar thermochemical water splitting community as part of HydroGEN, also applicable to carbon dioxide splitting, and to solar thermochemical energy storage. We report here on the synthesis of standard materials for high temperature (~1500°C) and intermediate temperature (~1200°C) applications, the development of standard testing protocols for TGA, and benchmarking of behaviors in high temperature XRD. We will cover plans for both standard material curation and availability.

There are well-established concepts for describing and understanding the gas phase dependence of defect concentrations in oxides (Brouwer diagrams, etc.). Accordingly, detailed knowledge on bulk defect concentrations has become available for many redox-active oxides. Much less clear is the effect of the gas phase on the rate of reactions taking place on oxide surfaces, for example the oxygen exchange reaction, which is required for establishing the bulk defect concentrations. Also the partial pressure (and overpotential) dependence of oxidation and reduction reactions in solid oxide fuel or electrolysis cells is often not truly understood. The empirical dependences of the corresponding reaction rates on experimental parameters may be monitored by tools such as impedance spectroscopy, current-voltage measurements, tracer diffusion or time dependent weight or color changes. However, mechanistic interpretation of the data is impeded by the fact that the gas phase not only affects adsorbates on oxides but also ionic and electronic defects in the oxides and thus several reactants.

In the first part of the talk this lack of mechanistic understanding of oxygen surface exchange reactions is addressed. It is discussed whether partial pressure dependences of reaction rates indicate the relevant species in the rate limiting step (atomic or molecular), and what can be concluded from an exponential or non-exponential shape of a current-voltage curve in an electrochemical cells with redox-active electrodes. Moreover, it is shown how surface exchange coefficients (k-factors) from impedance measurements (k') and from tracer diffusion experiments (k") usually differ. Further factors affecting the oxygen surface exchange reaction and its degradation are exemplified by measurements with appropriate tools such as in-situ impedance PLD or microelectrodes. The usefulness of measuring the chemical capacitance for analyzing the defect chemistry of electrode materials is shown.

Effects resulting from the exposure of an oxide to light are even less understood than the surface exchange kinetics of oxides. This is addressed in the second part of the talk. It is demonstrated why such an exposure to light with energy beyond the band gap can change the defect concentration in an oxide and examples are shown for $\text{SrTiO}_3$ upon UV exposure. Illumination by light is thus a forth option for changing the stoichiometry of an oxide, in addition to the well-known approaches by partial pressure variation, applying of a voltage in electrochemical cells, and enhancing the temperature in thermochemical cells.

Ceria is used widely as an oxygen exchange material due to its phase stability and facile oxygen release and uptake. The performance of ceria in particular applications depends on the oxygen vacancy formation energy. Ceria is often doped with $Zr$ to lower the oxygen vacancy formation energy, but with the exception of $Hf$, no other single dopant has been shown to significantly alter the reduction energy, though some dopant introduce intrinsic vacancies. This is because tetralental dopants are required to prevent intrinsic vacancy formation. Here we present the use of paired charge compensating dopants to engineer tetralental dopants from non-tetralental cations. Specifically, by co-doping $3+/5+$ cations into ceria, the $3+$ dopant behaves like a tetralental dopant, thereby expanding the oxygen vacancy formation energies. We show that this novel ceria doping strategy using both computational (density functional theory calculations) and experimental results within the context of solar thermochemical water splitting.
structures through the exsolution method as an alternative to impregnation, which was successfully demonstrated to control the catalysis e.g. for \((\text{La,Sr})(\text{Ti,Ni})\text{O}_3\) solid oxide fuel cell anodes.\(^3\) Through this work we explore suited perovskite compositions towards faster reduction rates and improved syngas selectivity for thermochemical redox cycles, and also compare to traditionally infiltration processed materials of same chemistry. The high surface affinity between the metallic nanoparticles and the perovskite backbone, in which they are anchored, offers relevant advantages in terms of microstructural stability for high temperature thermochemical fuel production.

In the first part of the talk we will cover the materials design guidelines that result in exsolved-perovskite structures with increased particle coverage and size distribution, exploring the chemical nature of the nanoparticles and interfaces of the cermet. Secondly, their performance for syngas production tested under chemical looping reforming cycles will be evaluated and benchmarked with state-of-the-art materials, revealing the improved syngas production performance of exsolution-promoted perovskites and the high stability of such materials under prolonged cycling.\(^5\) These results show great promise for exsolution cermet processing route in improving fuel production kinetics, syngas yields and materials stability, opening new avenues for materials design and process optimization.

Tunable Redox-Active Metal Oxide Frameworks Alina Schimpf; UC San Diego, La Jolla, California, United States.

Metal oxides capable of supporting excess charge-carriers play an important role in current and future advancement in energy conversion and storage technologies. Colloidal semiconductor nanocrystals offer advantages of inexpensive, scalable solution-processing and size-tunable quantum properties, but structure-property elucidation can be hindered by inherent polydispersity in such materials. Polyoxometalate clusters are molecular quantum-dot analogues that can be easily reduced to contain high electron densities. Assembly of these clusters with transition-metal linkers into doped, electronically coupled arrays thus offers the opportunity to realize well-defined solid-state metal oxide materials via inexpensive, solution-phase methods. Post-synthetic modulation of electron density and the ability to tune material properties via transition metal will be discussed.

4:15 PM *ES12.02.07
Chemical and Electrochemical Stability of Perovskite Oxide Surfaces in Energy Conversion—Mechanisms and Improvements Bilge Yildiz; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

A broad range of highly active doped ternary oxides, including perovskites, are desirable materials in electrochemical energy conversion, catalysis and information processing applications. At elevated temperatures related to synthesis or operation, however, the structure and chemistry of their surfaces can deviate from the bulk. This can give rise to large variations in the kinetics of reactions taking place at their surfaces, including oxygen reduction, oxygen evolution, and splitting of \(\text{H}_2\text{O}\) and \(\text{CO}_2\). In particular, allovalent dopants introduced for improving the electronic and ionic conductivity enrich and phase separate at the surface perovskite oxides. This gives rise to detrimental effects on surface reaction kinetics in energy conversion devices such as fuel cells, electrolyzers and thermochemical \(\text{H}_2\text{O}\) and \(\text{CO}_2\) splitting. This talk will have three parts. First, the mechanisms behind such near-surface chemical evolution will be discussed. Second, the dependence of surface chemistry on environmental conditions, including temperature, gas composition, electrochemical potential and crystal orientation will be described. Third, modifications of the surface chemistry that improve electrochemical stability and activity, designed based on the governing mechanisms, will be presented. Guidelines for enabling high performance perovskite oxides in energy conversion technologies will be presented.

SESSION ES12.03: Poster Session: Redox-Active Oxides

ES12.03.01
B-Site Doped Strontium Cobalt Oxides for Water Splitting via Thermochemical Redox Reactions George Wilson; Department of Materials, Imperial College London, London, United Kingdom.

The transition towards a carbon neutral economy requires the development of new technologies for the production of alternative fuels. Thermochemical redox reactions are one established low carbon method for producing fuels to be used in existing portable and stationary applications, such as fuel cells. Current efforts have sought new redox-active metal oxides that enhance the fuel production volumes and lower the high operating temperatures set by the state-of-the-art ceria-based materials (>1200 °C). Perovskites have gained the attention of the research community due to their ability to assimilate large changes in oxygen non-stoichiometry and the large number of possible compositions, leaving the field relatively unexplored. This work presents research conducted on a new family of perovskite materials for thermochemical water splitting at more industrially useful temperatures.

B-site doped strontium cobalt oxides are a promising perovskite family previously studied for IT-SOFC cathodes.\(^2\) Thermogravimetric results demonstrate topotactic reversible redox cycling in inert and oxidising environments at intermediate temperatures (480-900 °C) significantly lower than those of ceria. The large observed changes in oxygen non-stoichiometry demonstrate the potential for significant fuel production volumes, although preliminary water splitting results show only trace hydrogen production due to strontium segregation forming a surface blocking layer. Future analysis by low energy ion scattering will aim to study the effect of surface modification with less-reducible B-site cations.\(^7\) This work intends to stabilise the perovskite surface structure and achieve improved cyclability and production volumes at intermediate temperatures.

SESSION ES12.04: Redox-Active Oxides II
Session Chairs: Olga Marina and Ellen Stechel

8:30 AM *ES12.04.01
Tailoring Solid Oxide Cells Redox Electrode Interfaces John Irvine; School of Chemistry, University of St Andrews, St Andrews, United Kingdom.
The greatest challenge facing Solid oxide cells (SOC), in both fuel and electrolysis cell modes (i.e, SOFCs and SOECs) is to deliver high, long-lasting electrocatalytic activity while ensuring cost and time-efficient electrode manufacture. Ultimately, this can best be achieved by growing appropriate nanarchitectures under operationally relevant conditions, rather than through intricate ex situ procedures. In our approach, metal particles are grown directly from the oxide support through in situ redox exsolution. We demonstrated that by understanding and manipulating the surface chemistry of an oxide support with adequately designed bulk (non)stoichiometry, one can control the size, distribution and surface coverage of produced particles. We also revealed that the emergent particles are generally epitaxially socketed in the parent perovskite which appears to be the underlying origin of their remarkable stability, including unique resistance of Ni particles to agglomeration and to hydrocarbon coking, whilst retaining catalytic activity.

We also present the growth of a finely dispersed array of anchored metal nanoparticles via electrochemical poling on an oxide electrode, yielding a sevenfold increase in fuel cell maximum power density. Both the nannostuctures and corresponding electrochemical activity show no degradation over 150 hours of testing. These results not only prove that in operando redox treatments can yield emergent nanomaterials, which in turn deliver exceptional performance, but also provide proof of concept that electrolysis and fuel cells can be unified in a single, high performance, versatile and easily manufacturable device. This opens exciting new possibilities for simple, quasi-instantaneous production of highly active nanostructures for reinvigorating Solid oxide cells during operation.

9:00 AM ES12.04.02 In-Situ Defect Mapping of High Temperature STCH Materials in Oxidizing and Reducing Environments Robert T. Bell1, Xin Qian2, Eric Coker3, Mark Rodriguez2, Philip Parilla1, Sossina M. Haile2 and David S. Ginley1; 1National Renewable Energy Laboratory, Golden, Colorado, United States; 2Northwestern University, Evanston, Illinois, United States; 3Sandia National Laboratories, Albuquerque, New Mexico, United States.

The ultimate practicality of solar thermal chemical hydrogen production (STCH) depends on the reversibility and lifetime of the reacting materials. This necessitates an understanding of the nature of the actual defects or processes involved in these parameters. In their materials, the effective defect phase diagram encompasses a wide range of behaviors, including oxygen vacancy formation, cation site interchange, polymorphic phase transitions, and phase separation. Here we map the phase behavior of YMnO3 using high temperature in-situ XRD under a range of oxidizing and reducing environments. We will report on the observation of phase separation and change in manganese oxidation state of YMnO3 into MnO and Y2O3 at high temperatures and reducing conditions. The reversibility of this transition is evaluated during subsequent oxidizing high temperature anneals. This in-situ defect mapping is key for understanding the dynamic behavior of potential STCH materials in real thermodynamic cycling environment to establish reversibility/lifetime for STCH materials and is key early data for emerging materials.

9:15 AM ES12.04.03 The “Perovskite Playground”—Engineering Defect Chemistry in Doped Perovskite and Perovskite-Related Oxides for High Temperature Redox-Active Chemical and Electrochemical Applications Byron O’Hayre1, Michael D. Sanders1, Debora R. Barcellos1, Chuancheng Duan1, Jake Huang1, Meagan Papa1, Vladan Stevanovic1, Nitin Kumar1, Andriy Zakutayev2, Stephan Lany1, Antoine Emery3, Chris Woltverton4, Chris Borg1 and Anthony H. McDaniel1; 1Colorado School of Mines, Golden, Colorado, United States; 2Northwestern University, Evanston, Illinois, United States; 3Citrine Informatics, Palo Alto, California, United States; 4Sandia National Laboratories, Livermore, California, United States.

Perovskite oxides are of great scientific interest due to their compositional versatility and the resulting breadth of physical properties they exhibit. Perovskite oxides are widely studied for numerous applications including solid oxide fuel cells, colossal magnetoresistors, multifierroics, chemical looping, and solar thermochemical hydrogen production. Currently, there are several hundred confirmed, experimentally synthesized inorganic perovskites. However, recent density functional theory (DFT) and machine learning (ML) screening efforts suggest that there are yet hundreds more stable perovskite or perovskite-related oxides remaining to be discovered and synthesized. Furthermore, because the perovskite lattice can generally accommodate significant concentrations of various A and B-site dopants, the range of possible multi-doped, perovskite solid-solution compositions (e.g. ABO3 ~ A2A-B2B2B/O3-A and so on) is virtually limitless. With such vast degrees of compositional freedom, how can we guide the design of new perovskite compositions to target specific properties or applications of interest? In this presentation, we will discuss two application areas (solar thermochemical water splitting and intermediate temperature fuel cells) where we are combining high-throughput computation and high-throughput experiment to accelerate the search for new redox-active perovskite materials and to improve our scientific understanding of the composition-property-performance relationships that can guide future perovskite materials optimization.

For solar thermochemical hydrogen production (STCH), we have implemented a high-throughput density-functional theory (DFT) based screening strategy to identify existing and new redox-active oxides (mostly perovskite and perovskite-related) that may be promising high-temperature water-splitters based on pass/fail tests of several thermodynamic criteria. In parallel, we use high-throughput experimental screening methods to rapidly validate promising compositional spaces. Together, these techniques have enabled us to discover several promising new STCH-active oxides, including a new, previously unknown layered perovskite with remarkable water-splitting activity.

For fuel cell applications, we have recently developed a remarkable new redox-active oxide electrode based on a multi-doped perovskite, BaCo0.2Fe0.8Zr0.5Y0.5O3-δ (BCFZY4411), that catalyzes both the oxygen evolution and oxygen reduction reactions in ceramic fuel cells and electrolyzers. While this oxide exhibits excellent properties, it represents only an one point in the quaternary Co-Fe-Zr-Y space that describes the possible B-site compositions of the BCFZY system. We have begun to explore this space via high-throughput experimentation using combinatorial pulsed laser deposition coupled to high-throughput characterization tools, to allow spatially-resolved composition and property measurements of these films under various conditions. This system produces large datasets (we have already characterized more than 1,000 distinct compositions within the BCFZY system) that are particularly well-suited to an informatics approach. We have partnered with Citrine Informatics, an industry leader in materials informatics, to extract insight and construct meaningful models from these data based on a set of chemical “features” or descriptors. Initial results show that the models accurately fit and predict trends in the data, suggesting that the chemical features provide an appropriate basis set to describe these materials' behavior. We are now using these models to pinpoint the optimal composition within the BCFZY system and understand property-feature relationships.

9:45 AM ES12.04.04 Predictive Framework for Materials Synthesis Pathways—In Situ X-Ray Studies of Manganese Oxide Polymorph Formation Bor-Rong Chen1, Wenhao Sun2, Danil Kittachev1, John S. Mangum2, Vivek Thampy3, Lauren Garten3, David S. Ginley3, Brian P. Gorman4, Kevin H. Stone5, Gerhard Ceder6,7, Michael F. Toney6,8 and Laura T. Schelhas3; 1Stanford Synchrotron Radiation Lightsource, Menlo Park, California, United States; 2Materials Science Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4Sandia National Laboratories, Livermore, California, United States; 5National Renewable Energy Laboratory, Golden, Colorado, United States; 6Citrine Informatics, Palo Alto, California, United States; 7University of California, Berkeley, Berkeley, California, United States; 8Applied Energy Programs, SLAC National Accelerator Laboratory, Menlo Park, California, United States; 9Department of Materials Science and Engineering, UC Berkeley, Berkeley, California, United States.

Computational driven design of materials has provided guidelines for designing functional oxide materials with desired properties. However, the current computational approaches are not able to predict reaction pathways passing through intermediate or metastable phases, which have the potential to exhibit desired properties. Consequently, repeated iteration is usually required to find the reaction conditions needed for realizing targeted materials, thus inhibiting the materials discovery process. To address this challenge, we combine theory and experiments to establish a framework that guides the synthesis of intermediate/metastable phases, as well as validate this framework using hydrothermal synthesis of manganese oxide [1,2], which is highly active in electrochemical reactions.

This framework has the ability to predict the multistage crystallization along reaction pathways, and the influence of particle size and solution composition on polymorph stability. In the experimental demonstration, we monitored the evolution of manganese oxide clusters and polymorphs occurring during the synthesis by using a combination of in-situ X-ray absorption spectroscopy and X-ray wide-angle scattering. Synthesis pathways with varying conditions were studied, including potassium ion concentrations and pH values.

The results demonstrated that our computed size-dependent phase diagrams capture the metastable/intermediate polymorphs to appear, the order of their appearance, and their intermediate phases can be isolated from reaction pathways by quenching the reaction, stabilizing the phases at room temperature.
Overall, this combination of computational and experimental methodology offers a more rational and systematic paradigm for targeted synthesis of metal oxides. We envision that this “synthesis by design” approach is promising for general binary and ternary oxides systems, and will contribute to the discovery of redox-active oxides.

10:00 AM BREAK

10:30 AM *ES12.04.05

A large solid-state entropy of reduction increases the thermodynamic efficiency of metal oxides for two-step thermochemical water splitting (TWS). We present a high-throughput density functional theory (HT-DFT) study of more than 11,000 oxide compounds to screen for thermodynamically favorable two-step TWS materials, and identify many materials as potential new candidates for TWS applications. In addition to the configurational entropy associated with oxygen off-stoichiometry, we also examine a different source of entropy, the on-site electronic configurational entropy arising from excitations of electrons distributed over a large number of multiplet states (as in f-electron cations). We find that this electronic entropy is sizable in all lanthanides, and reaches a maximum value of ~4.7 kB per oxygen vacancy for Ce⁴⁺ / Ce⁵⁺ reduction. The unique and large positive electronic entropy in ceria contributes to its excellent water-splitting properties.

11:00 AM *ES12.04.06
The Electronic Entropy of Charged Defect Formation and Its Impact on Thermochemical Redox Cycles Stephan Lany, National Renewable Energy Laboratory, Lakewood, Colorado, United States.

The ideal material for solar thermochemical hydrogen (STCH) generation, which has yet to be discovered, must satisfy stringent conditions for the free energy of reduction, including, in particular, a sufficiently large positive contribution from the solid-state entropy. By inverting the commonly used relationship between defect formation energy and defect concentration, it is shown here that charged defect formation causes a large electronic entropy contribution manifesting itself as the temperature dependence of the Fermi level. This result is a general feature of charged defect formation and motivates new materials design principles for solar thermochemical hydrogen production [1].

Since the total entropy (electronic, configurational, vibrational) equals the temperature dependence of the O chemical potential, the electronic contribution can help substantially to narrow the temperature window between reduction and oxidation, and to increase the H₂ yield (H₂/steam ratio) in the oxidation step. The charged defect thermodynamics description is applied to CeO₂ as a model case, using first principles calculations for the defect formation energy and the electronic structure.

11:15 AM *ES12.04.07
Phase Transitions in Polycation Oxides for Thermochemical Redox Reactions in Energy Science Anu Majumdar¹,²,³, Departments of Mechanical Engineering, Materials Science and Engineering, Stanford University, Stanford, California, United States; ²SLAC National Accelerator Laboratory, Menlo Park, California, United States.

The ability to dissociate H₂O and CO₂ to produce H₂ and CO, respectively, is vitally important in energy science because H₂ and CO are among the primary feedstocks to synthesize chemicals and fuels. This would offer the promising prospects of turning CO₂ from a liability to an asset and help decarbonize our global energy system. To achieve this, one would require processes at the Gigatonne scale, i.e. at the same order of magnitude as CO₂ emissions. It is worth noting that today’s chemical infrastructure at the Gigatonne scale relies almost exclusively on thermochemical transformations. Hence, this dominance warrants research in identifying materials and creating processes for thermochemical dissociation of H₂O and CO₂, both thermodynamically uphill reactions, that are infrastructure compatible. Motivated by this purpose and building upon past research on two-step thermochemical processes, we have been exploring a relatively new class of materials - polycation oxides - whose thermodynamics of phase transitions can be uniquely tuned and leveraged for redox activity. Based on this, we have demonstrated both H₂O and CO₂ dissociation at thermodynamic capacities often 5-10 times higher than state-of-the-art materials such as doped ceria, spinel ferrites and perovskites. Some of our discoveries defy conventional wisdom regarding concentrations of redox-active cations, but can be explained via calculations of phase diagrams. Our current work is focused on reducing the temperatures of redox reactions to make them infrastructure compatible, while understanding and tuning the kinetics to increase reaction rates, both of which critical to eventually make them cost competitive with traditional approaches. This talk will provide an overview of our research in this area.

11:45 AM ES12.04.08
The Effect of Structure on Oxygen Vacancy Formation Energy in Ce-Substituted Sr-Mn Oxides Michael D. Sanders¹, Anyka Bergason-Keller¹, Nitin Kumar², Jie Pan³, Debona R. Barcellos¹, Vladan Stevanovic¹, Stephan Lany¹ and Ryan O’Hayre⁴; ¹Metallurgical and Materials Engineering, Colorado School of Mines, Golden, Colorado, United States; ²Physics, Colorado School of Mines, Golden, Colorado, United States; ³National Renewable Energy Laboratory, Golden, Colorado, United States; ⁴National Renewable Energy Laboratory, Golden, Colorado, United States.

Solar Thermochemical Hydrogen production (STCH) technologies employing two-step metal oxide water-splitting cycles are emerging as a viable approach to renewable and sustainable solar fuels. However, materials innovations that overcome thermodynamic constraints native to the current class of solar-thermal water splitting oxides are required to increase solar utilization and process efficiency. Increasingly, the search for new STCH cycle materials has turned towards perovskite-structured oxides. Perovskites have many desirable traits, including high structural tolerance for non-stoichiometry, tunable point-defect thermodynamics, good chemical stability and a long history of application in related fields that require oxygen exchange functionality (such as solid oxide fuel cells, chemical looping, and electrochemical water splitting). While research into perovskite-based STCH materials is still in its infancy, several compounds including Sr₇La₃Mn₄Al₃O₁₄ (SLMA) and La₉Ce₅Mn₄Al₂O₁₄ (LCMA) have shown promise. However, not only is the compositional space of these quaternary cation perovskites vast (the number of elemental variations that will form solid-solutions of the type AₐA'₁₋ₐ'B'B'₀, O₁₋₂ₐ₀ is thought to be in the tens of thousands), but the same cation combinations can form different structures. Such is the case for the recently reported Ce₂Sr₃MnO₇ (CSM) layered perovskite and the related simple perovskite Sr₇Ce₅MnO₇ (SCM). The former is a Ruddlesden-Popper phase (kNi₂F₂-type) where the simple perovskite layers are separated by simple oxide rock-salt SrO layers.

In this presentation, we will discuss the results of a thermodynamic study of these two structural families. Preliminary extent-of-reduction measurements hint at different reduction behavior between the two structures, even when accounting for cation and oxygen ratio differences. Specifically, the SCM family is much easier to reduce than the RP-phase CSM. Thermogravametric techniques are employed to capture the reduction thermodynamics, including defect-reaction specific enthalpy and entropy, Δh° and Δs°, as well as the 6-dependent partial molar enthalpy and entropy of oxygen, Δh°₆ and Δs°₆. Additional DFT modeling is used to make oxygen-site specific predictions of the oxygen vacancy formation energy to explore the role of the rock-salt layers in CSM reduction.

SESSION ES12.05/ES08.01: Joint Session: Future Trends in CSP Enabled by Redox-Active Oxides
Session Chairs: Andrea Ambrosini and Anthony McDaniel

1:30 PM  *ES12.05.01/ES08.01.01  
Aluminum-Doped Strontium Ferrite Perovskites for High-Purity \textsubscript{N}_2 Accomplished with \textsubscript{O}_2 Separation from Air via Two-Step Solar Thermochemical Cycles  
H. Evan Bush, Rishabh Datta and Peter G. Loutzenhiser; Georgia Institute of Technology, Atlanta, Georgia, United States.

Separation of \textsubscript{O}_2 from air to produce a high-purity stream of \textsubscript{N}_2 is considered via the aluminum-doped strontium ferrite perovskite (SrAl\textsubscript{2}Fe\textsubscript{3}O\textsubscript{7}) reduction/oxidation reactions in a two-step solar cycle. The cycle encompasses 1) the solar-driven thermal reduction of SrAl\textsubscript{2}Fe\textsubscript{3}O\textsubscript{7}; followed by 2) the re-oxidation with \textsubscript{O}_2 from air to produce high-purity \textsubscript{N}_2. SrAl\textsubscript{2}Fe\textsubscript{3}O\textsubscript{7} samples were synthesized and doped with controlled levels of aluminum on the B-site via the sol-gel method. Thermogravimetry was used to determine the non-stoichiometry at chemical equilibrium for temperatures between 673 and 1373, gas flows between 1 and 90\% \textsubscript{O}_2--\textsubscript{Ar}, and aluminum dopant levels of between 0.0 and 0.2. A thermodynamic model based on the compound energy formalism was applied to thermogravimetric measurements to predict equilibrium non-stoichiometry as a function of temperature, \textsubscript{O}_2 partial pressure, and non-labile aluminum concentration. The predictions were used to calculate partial reaction enthalpies and standard entropies as functions of nonstoichiometry and aluminum concentration. Aluminum doping consistently increased in the enthalpy of reduction and, therefore, the oxygen affinity of the perovskite for all values of non-stoichiometry. The thermodynamic characterization was used to inform a thermodynamic cycle analysis of an ideal air separation cycle. The analysis showed that, for a solar reactor operating at 1073 K, 99\% purities were possible for oxide to air molar ratios of up to 0.8 to 1 in the air separator. The cycle efficiency showed a strongly-inverse relationship with \textsubscript{N}_2 purity. However, the addition of a recuperation stage significantly mitigated this decline. These findings will be used inform the study of more complex, concurrently or sequentially reducing B-site cations and dopants, as well as the tuning of compositions with other dopants and cycle operating conditions in future air separation cycles.

2:00 PM  *ES12.05.02/ES08.01.02  
Concentrated Solar Radiation to Power High Temperature Thermochemical Heat Storage  
Christos Agrafiotis\textsuperscript{1} and Christian Sattler\textsuperscript{1, 2}; \textsuperscript{1}Institute of Solar Research, German Aerospace Center (DLR), Koeils, Germany; \textsuperscript{2}Faculty of Mechanical Science and Engineering, Institute of Power Engineering, Professorship of Solar Fuel Production, TU Dresden, Dresden, Germany.

Recent developments in solar-thermal power generation aim as well to achieve higher temperatures to increase the efficiencies of the power cycles as to store the solar energy to enable baseload power generation from a transient energy source.

Thermochemical redox processes are an option to store large amounts of solar energy in a compact storage system. The enthalpy effects of these reversible chemical reactions can be exploited. Oxides of multivalent metals in particular, capable of being reduced and oxidized under air atmosphere with significant heat effects are perfect candidates for air-operated Concentrated Solar Power plants since in this case air can be used as both the heat transfer fluid and the reactant (\textsubscript{O}_2) and therefore can come to direct contact with the storage material (oxide).

Porous ceramic structures like honeycombs and foams are favorable for heat exchange applications, the idea of employing such structures either coated with or entirely made of a redox material like manganese oxide and cobalt oxide, as a hybrid sensible- thermochemical solar energy storage system in air-operated Concentrated Solar Power plants has been set forth and tested up to a prototype scale on DLR’s solar tower in Juelich, Germany. By cascading different redox materials heat can be stored even more efficiently than by single material systems,

HydroGEN Overview, Projects and the AWSM Node Capabilities  
Huyen N. Dinh\textsuperscript{1}, Katie Randolph\textsuperscript{2}, David Peterson\textsuperscript{2}, Adam Weber\textsuperscript{1}, Anthony H. McDaniel\textsuperscript{1}, Tadashi Ogitsu\textsuperscript{1}, Richard Boardman\textsuperscript{2}, Donald L. Anton\textsuperscript{1} and Eric L. Miller\textsuperscript{1}; \textsuperscript{1}National Renewable Energy Lab, Lakewood, Colorado, United States; \textsuperscript{2}Fuel Cell Technologies Office, U.S. Department of Energy- EERE, Golden, Colorado, United States; \textsuperscript{3}Lawrence Berkeley National Laboratory, Berkeley, California, United States; \textsuperscript{4}Sandia National Laboratories, Livermore, California, United States; \textsuperscript{5}Lawrence Livermore National Laboratory, Livermore, California, United States; \textsuperscript{6}Idaho National Laboratory, Idaho Falls, Idaho, United States; \textsuperscript{7}Savannah River National Laboratory, Aiken, South Carolina, United States.

HydroGEN (https://www.h2aws.org/) EMN is a six-lab consortium, led by the National Renewable Energy Laboratory (NREL). It currently comprises six core national laboratories: NREL, Sandia National Laboratory (SNL), Lawrence Berkeley National Laboratory (LBNL), Idaho National Laboratory (INL), Lawrence Livermore National Laboratory (LLNL), and Savannah River National Laboratory (SRNL). HydroGEN aims to accelerate the discovery and development advanced water splitting materials (AWSM) for sustainable, large-scale hydrogen production, in order to more effectively enable the widespread commercialization of hydrogen and fuel cell technologies. With the rollouts of fuel cell electric vehicles (FCEVs) by major automotive manufacturers underway, enabling AWs technologies for the widespread production of affordable, sustainable hydrogen becomes increasingly important.

The HydroGEN Consortium offers an extensive collection of materials research capabilities for addressing RD&D challenges in efficiency, durability and cost. Leveraging the HydroGEN Consortium’s staff of leading technical experts and broad collection of resource capabilities is expected to advance the maturity and technology readiness levels in all the advanced water splitting technologies, including advanced electrolysists (low and high temperature), photoelectrochemical (PEC) and solar thermochemical (STCH) routes. Currently, there are 20 HydroGEN seedling projects, and one project focused on benchmarking advanced water splitting technologies. These 21 new projects utilized over 40 unique capabilities across the six HydroGEN core labs, from computational modeling to material synthesis to advanced characterization. HydroGEN is indeed a national innovation ecosystem that comprises 11 national labs, 7 companies, and 30 universities. This presentation will provide an overview of the HydroGEN EMN consortium and highlight some advanced water electrolysis and PEC projects as well as a few unique HydroGEN capability nodes that the community can leverage.

4:00 PM  *ES12.06.02/ES11.08.02  
European Efforts to Accelerate the Market Introduction of Renewable Hydrogen Production  
Martin Roeb\textsuperscript{1} and Christian Sattler\textsuperscript{1, 2}; \textsuperscript{1}Institute of Solar Research, German Aerospace Center (DLR), Koeils, Germany; \textsuperscript{2}Faculty of Mechanical Science and Engineering, Institute of Power Engineering, Professorship of Solar Fuel Production, TU Dresden, Dresden, Germany.

Converting solar energy efficiently into hydrogen is a key element to develop a sustainable and affordable hydrogen economy. The presentation will give an insight in how concentrated solar radiation can be coupled into hydrogen production processes. It will discuss the benefits and challenges of using the sunlight directly instead of converting it into other energy vectors.

The main focus will be on technologies with the perspective of large scale production at very high temperatures. Therefore solar tower systems for such production processes will be presented. Additionally the components like concentrator, receiver, and reactor of the solar production plants will be described, possible locations will be discussed, and synergies with other R&D efforts on using high temperature heat will be shown. Hybrid solutions e.g. from the sulfur industry will demonstrate how concentrated solar radiation can contribute even today to actual industrial business models.

As many of the addressed processes have to be operated continuously high temperature heat storage will also be introduced. Especially thermochemical heat storage has the potential for being the ideal technology for heat provision in high temperature production processes.

The European Union is supporting the development in its research framework programs since the 1980s. However until 2002 only a few projects were carried out. Since then a continuous improvement took place which was accelerated by the implementation of the European Fuel Cell and Hydrogen Joint Undertaking in 2008. This private public partnership lead by industry is in charge to bring technologies faster into the market than research programs lead by the European Commission would. The presentation will give an overview of the actions carried out so far and the perspective of the European efforts.
Widespread adoption of inexpensive renewable-electricity sources brings with it many exciting challenges and opportunities, the most significant being an overabundance of low-cost electricity from renewables as well as cheap photovoltaics. Thus, there is an opportunity to use virtually free electrons and photovoltaics to produce fuels and chemicals using electrochemical and photoelectrochemical devices, respectively, with water as a reactant. Electrochemical hydrogen production using water electrolysis is a commercial technology, barriers remain in terms of cost and efficiency improvements for its widespread adoption; while alternative water-splitting technologies that have the long-term potential to produce inexpensive hydrogen include photoelectrochemical (PEC) approaches, are still in their infancy. In either case materials development, interface development and cell design are critical in advancing the efficiency and cost of water splitting devices. Benchmarking protocols help to identify promising materials, facilitate translation of materials from one technology readiness level to another, and can provide clear technology crossing opportunities. This talk will cover benchmarking activities performed within the HydroGEN Energy Materials Network on: low temperature electrolysis (LTE) electrocatalysts, development of benchmarking cells for photoelectrochemical (PEC) water splitting devices, and crossing opportunities between LTE and PEC with respect to the hydrogen evolution and oxygen evolution catalysts activity and durability.

**SESSION ES12.07: Redox-Active Oxides III**

Thermochemical Trends in ABO$_2$-Type Compounds for Solar Fuel Generation

Sessina M. Haile and Xin Qian; Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States.

Solar-driven thermochemical production of chemical fuels using redox active oxides has emerged as an attractive means for storing solar energy for use on demand. In this process a reactive oxide is cyclically exposed at high temperatures to an inert gas, which induces partial reduction of the oxide, and to an oxidizing gas of either H$_2$O or CO$_2$, which reduces the oxide, releasing H$_2$ or CO. The capacity for fuel production is dictated by the thermodynamic properties of the oxide, specifically the enthalpy and entropy of reduction. Here we report the thermodynamic properties of a range of previously unexplored ABO$_2$-type compounds and identify those with promising characteristics for efficient thermochemical fuel production.

9:00 AM ES12.07.02

Stable Proton-Conducting Solid Oxide Electrolysis Cells for Pure Hydrogen Production at Intermediate Temperatures

High temperature electrolysis of water provides an economic and efficient pathway for large-scale hydrogen production that not only utilizes steam from nuclear energy but also allows using concentrated solar energy to accelerate renewable and sustainable energy utilization. In this technical contribution, a newly developed proton conducting solid oxide electrolysis cell (SOEC) offering the opportunity of producing dry, high purity and pressured hydrogen will be presented. Experimental results pertaining to the electrochemical performance of electrochemical cells containing developed electrolyte and electrode formulations will be presented and discussed. Bulk, interface and surface morphological and chemical stability, studied using scanning electron microscopy-energy dispersive spectroscopy (SEM-EDS) and focused ion beam-transmission electron microscopy (FIB-TEM) techniques, for the electrodes and electrolyte will be presented. Approaches for the minimization of cell performance degradation associated with electrode poisoning will be discussed.

9:15 AM *ES12.07.03*

Solid Oxide Electrolysis Cells for Hydrogen and Synthetic Fuel Production from Renewable Energy

Anne Hauch, Ming Chen, Henrik Frandsen, Peter Vang Hendriksen, Peyman Khajavian, Rainer Küngas, Theis Skafte, Xiaofeng Tong, Martina Trini, Dordije Tripkovic, Xiufu Sun and Mogens Bjerg Mogensen; Department of Energy Conversion and Storage, Technical University of Denmark, Roskilde, Denmark; 2Haldor Topsøe AS, Kgs. Lyngby, Denmark.

Solid oxide electrolysis cells (SOECs) can efficiently convert electrical energy (e.g. surplus wind power) to energy stored in fuels such as hydrogen or other synthetic fuels. Hydrogen can be produced via steam electrolysis and synthesis gas via co-electrolysis of steam and carbon dioxide followed by catalytic reaction to produce to synthetic fuels. Furthermore, this presentation will provide an overview of the development and improvement of SOECs over the last 15 years at Risø Nat. Lab./DTU Energy. The SOEC improvements are based on a) reduction of the ohmic resistance (including that due to oxygen electrode performance), analysis of and elimination of impurities in the feed streams, optimization of processing routes and of the Ni/YSZ based fuel electrode structure. These improvements have led to a decrease in long-term degradation rate from ~40 %/kh to ~0.4 %/kh for steam electrolysis at -1 A/cm$^2$, while the initial area specific resistance has been decreased from 0.44 Ω$\cdot$m$^2$ to 0.15 Ω$\cdot$m$^2$ at -0.5 A/cm$^2$ and 750 °C. Advanced and complementary characterization techniques have been developed during these 15 years of SOEC improvements and these will be included in the talk.

Secondly, a couple of critical degradation issues for state-of-the-art SOECs will be exemplified and discussed. This includes: 1) impurity sensitivity, where even impurities in the ppb-range can play a major role in detrimental degradation of the SOECs; 2) studies of carbon deposition and its relation to the specific operation conditions and the resulting overpotential of the SOEC; 3) segregation of phases and structural changes e.g. morphology changes and electron conducting nickel in the fuel electrode; and 4) observed Ni migration in the active fuel electrode leading to significant reduction in the percolating triple-phase-boundary length and changed properties of the remaining percolating structures.

Thirdly, the last, this talk will touch upon four selected case studies illustrating on-going SOEC research. This will include: 1) New results on improved mechanical reliability of SOEC via mechanically stronger stabilized zirconia. This is obtained through modifications (decreased yttria content or Ce-Y co-doping) of the traditional 3YSZ giving rise to a significant increased fracture strength and toughness alongside improved resistance against both high and low temperature aging. 2) Interesting results on the kinetics of LSF (lanthanum-strontium-ferrite based) electrodes will be discussed. Here tremendous performance increase has been obtained through thermal cycling – and thereby surface modifications - of model LSF electrodes. Furthermore addition of iron(III) and Zr(IV) ions to the LSF electrode surfaces have shown very promising initial performance at temperatures as low as 400 °C. 3) Recently completed thorough microstructural analysis of the Ni/YSZ electrode of a pristine and a 1-year tested SOEC stack has provided new insight into the nature of microstructural changes including Ni coarsening and mobility. In this context, phase field modelling has been used for simulating the microstructure evolution of three-dimensional complex Ni/YSZ electrodes and additional studies now reveals how critical parameters and driving forces such as contact angles and fuel electrode overpotential (pO$_2$ gradients) influences e.g. Ni morphology changes and Ni migration. 4) As the degradation of the Ni/YSZ based fuel electrode is the dominating degradation issue for S-o-A SOEC on-going research activities to overcome these degradation phenomena will also be discussed. This include results from long-term testing of SOEC with pre-reduced and infiltrated Ni/YSZ electrodes as well as more explorative work on Ni-free fuel electrodes and experiments with doping of the NiO during manufacturing the fuel electrode.

9:45 AM ES12.07.04

Durability Assessment of High Temperature Electrolysis Cells

Olga Marina, Christopher Coyle, Danny Edwards and Jeffrey Stevenson; Pacific Northwest National Laboratory, Richland, Washington, United States.
Renewable electric energy has become a significant source of the nation’s electricity. However, wind and solar power technologies are intermittent and fluctuating, and have to be balanced for electric grid stability purposes. Over-generation can lead to grid congestion or “curtailment”. Relieving the grid of excess renewable electricity can be accomplished by powering a water electrolyzer to produce hydrogen. The hydrogen can be temporarily stored and then used in filling stations, industrial applications, or converted back to electricity when shortages occur. It can also be injected into the natural gas grid either directly or after methanation as “renewable fuel”. There are a number of technologies that can be used to electrolytically split water to form hydrogen. Solid oxide cells (SOC) offer the highest overall efficiency as the high operating temperature significantly reduces the amount of electrical energy required to produce the hydrogen.

The biggest challenge for SOCs is the rapid material degradation and the limited long term stability due to their high operating temperatures. This paper will discuss the degradation processes in SOC electrodes.

Multiple button cells were tested using customary SOC materials: yttria-stabilized zirconia (YSZ) electrolyte, Ni/YSZ negative electrode, and (La, Sr)MnO\textsubscript{3} (LSM)-YSZ or (La, Sr)(Co,Fe)\textsubscript{2}O\textsubscript{4} (LSCF) positive electrodes. Long-term electrochemical performance was recorded using a multichannel potentiostat over a range of operating conditions. For each cell, loss processes associated with ohmic and electrode processes were separated using electrochemical impedance spectroscopy. Open-circuit voltage was periodically recorded to verify the quality of seals in a high steam environment as well as the consistency in steam production. Following termination of electrochemical tests, LSM/YSZ surfaces and cross-sections of individual cells were analyzed using scanning electron microscopy and energy dispersive spectroscopy (SEM/EDS).

Cells with LSM/YSZ anodes operated at higher potentials for similar H\textsubscript{2} production and degraded more rapidly when compared to cells with the LSCF electrodes. The SEM/EDS analysis revealed microstructural changes near the electrochemically active interface such as LSM/YSZ electrode delamination and embrittlement of the YSZ electrolyte. While this was consistent with the previous findings reported by other groups, our results indicate that cell failure can occur at low current densities (low oxygen flux through the electrolyte). One of the possible degradation mechanisms is the perovskite lattice expansion that leads to delamination at the oxygen evolution electrode. SOC with LSCF positive electrodes operated at 0.9 A/cm\textsuperscript{2} near or below thermoneutral voltage for over 1000 hours. Some performance degradation was observed during the initial 200 hours and was explained by an increase in polarization resistances. Subsequently, a rather stable performance (degradation rate < 0.4%/1000 hours) was observed with only a minimal increase in ohmic resistance and no changes in the electrode polarization resistances. The improved electrode stability was attributed to the presence of the ceria-based barrier layer between YSZ and LSCF that suppresses the formation of the SrZrO\textsubscript{2} phase during fabrication and is known to contribute to the anode delamination in SOC.

10:00 AM BREAK

10:30 AM *ES12.07.05 Principles of Materials Selection for Thermochemical Fuel Production Cycles Brendan Bulfin\textsuperscript{1}, Josua Vieten\textsuperscript{2}, Dorottya Guban\textsuperscript{2}, Liya Zhu\textsuperscript{2}, Patrick Huck\textsuperscript{2}, Matthew Horton\textsuperscript{2}, Martin Roeb\textsuperscript{2}, Christian Sattler\textsuperscript{3}, Kristin A. Persson\textsuperscript{2} and Aldo Steinfeld\textsuperscript{2}.

Thermochemical H\textsubscript{2} production is broken into two parts; (a) determine the redox thermodynamics of a large set of materials and add them to a database, (b) plug each materials thermodynamic properties into a simplified process model, to determine reaction conversion extents and a figure of merit such as efficiency. The performance parameters can then be used to rank the materials for a given application.

According to this methodology, a large family of perovskite solid solutions with the general composition A\textsubscript{1-x}B\textsubscript{x}M\textsubscript{y}Ni\textsubscript{1-y}O\textsubscript{2} with A = Ca, Sr and M = Ti, Mn, Fe, Co, were investigated experimentally. The redox enthalpies and entropies of these perovskites can be tuned by adjusting their composition, making them ideal for such a broad screening process. As well as an experimental screening, an even broader range of perovskites were investigated using theoretical data gathered via density functional theory (DFT) calculations. In a joint effort between the German Aerospace Center and the Lawrence Berkeley National Laboratory, the data was used to create a search engine for redox materials based upon the infrastructure of Materials Project. A thermochemical fuel production process model is also included, which can be used to rank the materials for a given set of operation parameters.

11:00 AM ES12.07.06 Perovskite-Based Thermochemical Oxygen Pumping—A Down-Stream Applicational Approach to Increase H\textsubscript{2}/CO\textsubscript{2}-Splitting Efficiency in Concentrated Solar Power Plants Mathias Pein\textsuperscript{1}, Christos Agrafiotis\textsuperscript{2}, Martin Roeb\textsuperscript{2} and Christian Sattler\textsuperscript{3}.

Thermochemical H\textsubscript{2}O and CO\textsubscript{2} splitting is a promising approach to convert and store solar energy. Further processing of the produced H\textsubscript{2} and CO via Fischer-Tropsch-Synthesis facilitates a path to renewable carbon based fuels. For efficient cycling of the active redox material (e.g. CeO\textsubscript{2}) and high solar-to-fuel efficiencies low oxygen partial pressures during reduction are a necessity. We report an approach to overcome the present energy penalties of high vacuum pumping or intensive inert-gas sweeping, using perovskite based oxides as a thermochemical oxygen pump. Our results show, that Ca-Mn-based perovskites are able to effectively increase the reduction extent of the state-of-the-art splitting material CeO\textsubscript{2} through absorption of the oxygen released by the CeO\textsubscript{2} during reduction. That offers a way to increase the efficiency of the solar-to-fuel process, while minimizing energy penalties since this application can be implemented down-stream of the main reactor in a concentrated solar power (CSP) plant. To forecast and contribute to an actual implementation of the application into a CSP plant, our work includes a study of the cyclic behavior of structural specimens offering insight to strengths, challenges and prospects concerning structural integrity of manufactured parts. This incorporates investigation on the thermal expansion, considering structural changes and expansion due to oxygen vacancy formation, and thermal stress resistance.

11:15 AM *ES12.07.07 Using SCAN+ Calculations and the Sub-Lattice Formalism to Estimate Off-Stoichiometry in Oxides Sai Gautam Gopalakrishnan and Emily A. Carter.

Using SCAN+ U calculations and the sub-lattice formalism to estimate off-stoichiometry in oxides.

Transition-metal oxides that can tolerate a large number of oxygen vacancies, specifically systems containing the redox-active Ce (CeO\textsubscript{2}), Mn (LaMnO\textsubscript{3}), and Fe (FeO\textsubscript{2}) atoms, are crucial ingredients for generating renewable fuels via two-step, oxide-based solar thermochemical (STC) reactors. However, any predictive modeling, such as using density functional theory (DFT) calculations, needs to accurately describe the energetics of redox reactions (and, subsequently, defect formation) involving transition metals, if new candidate materials are to be found. Recently, the strongly constrained and appropriately normed (SCAN) exchange-correlation (XC) functional was developed, which impressively satisfies all the 17 known constraints for the behavior of any XC functional. However, the ability of SCAN to describe redox energies involving transition metal atoms thus far has remained unexplored. Hence, in the first part of the talk, we will explore the need for a Hubbard U correction, along with SCAN, to account for some of the discrepancies in the thermodynamic and electronic properties of transition-metal and rare-earth oxides.

Importantly, theoretical models that can accurately predict the extent of off-stoichiometry, i.e., the extent of oxygen deficiency within the oxide, will be crucial in identifying promising candidates for STC applications. Thus, the second part of the talk will focus on using the sub-lattice formalism in combination with SCAN+ U calculations to accurately predict off-stoichiometries in CeO\textsubscript{2} and Zr-doped CeO\textsubscript{2}. Note that the sub-lattice formalism is a common tool used to thermodynamically assess experimental data and build
temperature-composition phase diagrams in a variety of binary, ternary, quaternary, etc. systems. Although the sub-lattice model has been primarily used to "fit" to existing experimental data, the framework is general and can be used alongside DFT-based data. Hence, we build a sub-lattice model entirely based on SCAN+U calculations and observe fair agreement between experimental and predicted oxygen off-stoichiometries in CeO$_2$ and Zr-doped CeO$_2$. Finally, we will touch upon some of the future challenges in generalizing the use of sub-lattice models across chemical systems.

Study of the Reduction Thermodynamics of Sr$_{1-x}$Ce$_x$MnO$_3$ Perovskites for Solar Thermochemical Hydrogen Production
Anyka Bergeson-Keller, Debora R. Barcellos, Michael Sanders and Ryan O'Hayre; Colorado School of Mines, Golden, Colorado, United States.

Solar Thermochemical Hydrogen Production (STCH) is an emerging technology that uses concentrated solar heat to split water and produce hydrogen. STCH leverages the ability of some transition metal oxides to reversibly change their oxygen stoichiometry with changes in temperature and oxygen partial pressure. The potential impact of this technique is significant because it enables the use of solar radiation as a carbon-free energy source to produce industrial scale quantities of hydrogen, which is widely used in steel production, ammonia synthesis for fertilizers, and as an alternative renewable fuel.

The high reduction temperatures necessary for the current state-of-the-art STCH material, CeO$_2$ (ceria), results in solar utilization and process efficiencies that are too low for practical application, leading to a broad effort to replace it. However, the thermodynamic constraints of lowering the reduction temperature while retaining a defect formation energy large enough to facilitate water splitting is challenging. The tunable point-defect thermodynamics, good chemical stability, and structural tolerance for non-stoichiometry inherent in transition-metal perovskite oxides makes them attractive candidates. The recent development of Sr$_x$La$_{1-x}$MnO$_{3-δ}$ (SLMA) and BaCe$_0.25$Mn$_0.75$O$_3$ (BCM) as active STCH oxides demonstrate the potential of the perovskite materials space for this application.

Following the success of BCM, a Sr-containing variant has been synthesized, Sr$_{1-x}$Ce$_x$MnO$_3$ (SCM). Unlike BCM, the SCM family contains Ce on the A-site and it is not a line compound, instead accommodating a wide compositional range of approximately 0-50% Ce substitution. This allows for a level of defect tunability that is not possible in BCM.

For this work, we discuss the results of a thermodynamic study of this compositional family and the effects of Ce content on thermal reduction. Thermogravimetric techniques are employed to capture the reduction thermodynamics, including defect-reaction specific enthalpy and entropy, Δh° i and Δs° i, as well as the δ-dependent partial molar enthalpy and entropy of oxygen, Δh° O and Δs° O. Extent of reduction and water-splitting hydrogen production results will also be shared.

SESSION ES12.08: Redox-Active Oxides IV

1:30 PM ES12.08.01
Development of Solid-Oxide Fuel-Cell Stacks Based on Proton-Conducting Ceramics
Long Q. Le$^1$, Hanping Ding$^1$, Liangzhu Zhu$^4$, Carolina Herradon Hernandez$^2$ and Neal P. Sullivan$^1$; $^1$Mechanical Engineering Department, Colorado School of Mines, Golden, Colorado, United States; $^2$Department of Engineering Science, Universidad Andrés Bello, Santiago, Chile; $^4$Idaho National Laboratory, Idaho Falls, Idaho, United States; $^3$Metallurgical and Materials Engineering Department, Colorado School of Mines, Golden, Colorado, United States.

In this paper, we present our efforts to scale up proton-conducting ceramic fuel cells (PCFC) into small stacks. Encouraging stack performance is observed under hydrogen and methane fuels at intermediate temperatures. The membrane-electrode assembly features a BaCe$_{0.25}$Zr$_{0.75}$Y$_{0.25}$O$_{3+δ}$ (BCZYZ) electrolyte on a Ni-BCZY26 anode support. The cathode material is BaCe$_0.25$Fe$_{0.75}$Zr$_{0.25}$O$_{3+δ}$ (BCFY), with mixed ionic-electronic conduction, enabling high performance at 550 °C. Cell active area is ~ 5 cm$^2$. The cells are packaged within ThyssenKrupp’s Crofer 22 APU ferritic-steel interconnects. A three-cell stack operating at 550 °C under internally reformed methane-steam fuel achieved 0.25 A / cm$^2$ at 11:45 AM.

Stack development brings concerns of materials compatibility, mating novel proton-conducting ceramics with high-chrome ferritic steels and glass-ceramic sealants. While lower operating temperature should reduce degradation rates, it also brings questions on scale composition, materials interactions, and other sources of performance degradation. In an effort to gain insight on root causes behind degradation in our protonic-ceramic stacks, we distribute numerous voltage taps throughout the electrical interfaces across the unit-cell stack. We trace stack degradation to an increase in electrical resistance across the cathode interconnect. Following testing, this interconnect displays a scale with high iron content, rather than the desired (Mn,Cr)$_2$O$_3$ scale. We present early results on the effectiveness of interconnect pre-oxidation in reducing degradation. We also explore stack performance when using Sandvik’s SANERGY 441 interconnect, with and without protective Ce-Co coatings.

1:45 PM ES12.08.02
Electrode Degradation in Proton-Conducting Ceramic Fuel Cells and Electrolyzers
Marcos Hernandez Rodriguez$^1$, Long Q. Le$^1$, Liangzhu Zhu$^1$, Carolina Herradon Hernandez$^2$, Max Pisciotta$^3$ and Neal P. Sullivan$^1$; $^1$Colorado School of Mines, Golden, Colorado, United States; $^2$Department of Engineering Science, Universidad Andrés Bello, Santiago, Chile.

In this paper, we present our efforts to identify, quantify and mitigate sources of degradation in proton-conducting ceramic electrochemical devices. Proton-conducting ceramic membranes present an exciting new class of electrochemical materials that are now being harnessed to address societal challenges in electricity generation, energy storage, and fuels synthesis. Many materials-compatibility questions arise as we move protonic ceramics from lab-scale, “button cell” architecture to commercial kW-scale assemblies. For the first time, we are packaging protonic ceramics within multi-cell stacks, mating novel perovskites with high-chrome ferritic-steels and advanced glass materials. The compatibility and stability of these materials within tightly packaged assemblies over thousands of hours of operation is unclear. Additionally, the unique operating conditions found with protonic ceramics differ substantially from those for which the packaging materials were initially designed. Both fuel cells and electrolyzers based on protonic-ceramics feature high water-vapor content at the air / steam electrode. Operating temperatures may be 200 °C lower than that of the oxygen-ion-conducting equivalent. While this lower-temperature operation should be beneficial for long-term operation, many questions remain.

In this talk, we present our approaches to capturing degradation effects at the protonic-ceramic air / steam electrode. We have developed precise experimental tools and fabrication protocols to accurately quantify the small performance changes that may be manifested over thousands of hours operation. We utilize symmetric cells for these experiments, where a BaCe$_{0.25}$Zr$_{0.75}$Y$_{0.25}$O$_{3+δ}$ (BCZYZb) electrolyte is sandwiched between BaCe$_{0.25}$Zr$_{0.75}$Y$_{0.25}$O$_{3+δ}$ (BCFY) air-stem electrodes, and exposed to steam-air mixtures at −550 °C. In addition to identifying stable operating conditions, we are exploring the compatibility of commercial ferritic steels, such as ThyssenKrupp’s Crofer 22 H and Sandvik’s SANERGY 441 materials, with these novel protonic-ceramic materials. Experiments are executed under continuous potentiostatic electrochemical impedance spectroscopy (EIS) through a Gamry Reference 600 instrument. While degradation is found to be high at 50% steam in air, far-lower degradation is observed at 10% steam. Preliminary results reveal...
that packaging of symmetric cells within uncoated, untreated ferritic steels can lead to substantial performance degradation. We will also present on the effectiveness of degradation-mitigation strategies to enable long device lifetime.

2:00 PM ES12.08.03
Ammonia Synthesis in Two Cyclic Steps—Basic Thermodynamic Considerations James E. Miller1, Ivan Ermanoski2, Andrea Ambrosini2 and Ellen B. Stechel1; 1Arizona State University LightWorks®, Tempe, Arizona, United States; 2Sandia National Laboratories, Albuquerque, New Mexico, United States.

The fossil fuel based production of ammonia, NH3, is essential to the modern agricultural endeavor that sustains humanity. However, a combination of kinetic and thermodynamic considerations drives the current industrial process to high pressures and moderately high temperatures. Furthermore, the process is net carbon intensive. Thus, more sustainable alternatives will be needed. Following the model of thermochemical approaches to water splitting for H2 production, one potential option is to accomplish the conversion by dividing the desired reaction into multiple steps. However, the typical understanding of thermochemical cycles does not directly map onto the ammonia production step. Typically, thermochemical cycles apply to difficult endothermic reactions, which are thermodynamically unfavorable at moderate conditions of temperature and pressure. The ammonia production from hydrogen and nitrogen is exothermic and quite thermodynamically favorable at low temperatures. The implications of this difference as well as other basic thermodynamic considerations for producing ammonia from H2 and N2 in two cyclically-repeated steps will introduced and discussed.

2:15 PM ES12.08.04

Ammonia is an important industrial precursor [1] and a promising energy carrier due to its low liquefaction pressure. In this paper, we report high electrochemical ammonia-synthesis rates using proton-conducting ceramics with nitrogen and steam feedstocks. Ammonia synthesis is enabled through use of a novel barium-calcium-aluminum oxide support with a low-loading ruthenium catalyst (Ru-B2CA) [2]. This catalyst and support have been patented by Starfire Energy, Denver, Colorado, USA, for both ammonia synthesis and ammonia cracking. The matting of protonic-ceramic electrochemical cells with advanced Ru-B2CA catalysts enables efficient, cost-effective storage of intermittent renewable electricity in the form of a commodity chemical. The cell-catalyst system is also reversible, and demonstrates high power density under ammonia fuel.

The protonic-ceramic electrochemical cells feature a BaCe0.8Zr0.2Y2O3-δ (BCZY) electrolyte on a Ni-BZY fuel-electrode-support, and BaCo0.8Fe0.2O3-δ (BCZFO) air-electrode steam. These solid-state electrochemical-synthesis processes, we achieved an ammonia production rate of \(1.0 \times 10^4\) mol.s\(^{-1}\) at ambient pressure from steam (carried by humidified air) and nitrogen feed streams. This rate is among the highest electrochemical ammonia-production rates ever reported, regardless of electrolyte type [3-6]. Other reported rates reach 1.1 \(\times 10^6\) mol.s\(^{-1}\) using Nafion electrolyte and SFCN as ammonia formation catalyst [3], and 1.0 \(\times 10^4\) mol.s\(^{-1}\) using molten NaOH-KOH as electrolyte and nano-Fe2O3 as catalyst [4]. An ammonia-production rate of 8.2 \(\times 10^4\) mol.s\(^{-1}\) has been reported using GDC electrolyte and Ag-Pd catalyst [5]. The effects of cell architecture, operating temperature and pressure on ammonia-synthesis rate will be discussed in this talk.

2:30 PM ES12.08.05

Solar-thermochromic (STC) carbon dioxide and water splitting is a pathway for the direct thermal production of solar fuels—an alternative to direct thermolysis. Currently, the most widely researched implementation is the two-step cycle. Reducing two–step cycles to practice is challenging, and there is a substantial ongoing effort to improve reactor designs, and to synthesize redox active materials that exceed the STC potential of ceria, the current state–of–the–art redox active material. We have analyzed the underlying general thermodynamic boundaries that lead to materials performance tradeoffs between heat of reduction, productivity, and yield. These boundaries apply to all nonstoichiometric oxides without phase changes during redox cycles, or where the phase changes are energetically negligible. We quantify the tradeoffs between the desirable decrease of the heat of reduction and penalties such as decreasing yields and increasing cycling temperature range, and show that operating parameters pose firm limitations on cycle performance and on the desirable materials properties space.

2:45 PM ES12.08.06
Nanostructured Ceria Based All-Oxide Electrodes as the Key to Efficient and Robust High-Temperature Energy Storage Technology Christopher Graves1, 2, 3; 1Department of Energy Conversion & Storage, Technical University of Denmark, Roskilde, Denmark; 2Noon Energy Inc., Berkeley, California, United States; 3Cyclotron Road Fellow at Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Solid oxide electrochemical cells have the potential to play a major role in our renewable energy future. They efficiently store electrical energy as synthetic chemical fuels such as H2, CO and hydrocarbons by electrolysis of H2O and/or CO2. They can also operate as fuel cells to produce electricity again from those fuels. By reversible operation between electrolysis and fuel-cell modes, they can function as rechargeable flow batteries with extremely low cost storage media.

A major obstacle to commercialization is insufficient device lifetime due to loss of electrode performance. Nearly all cells employ nickel-based fuel-electrodes, which experience gradual deactivation - mainly due to the mobility of nickel - and can even be completely destroyed by oxidation or carbon deposition. Alternative electrodes made of mixed ionic-electronic conductor (MIEC) oxides are known to avoid these issues, but at the expense of typically much lower electrochemical activity.

We have been developing nanostructured ceria-based fuel-electrodes that overcome these issues and outperform conventional nickel-based electrodes. In the H2/H20/CO/CO2 fuel environment, acceptor-doped ceria is a MIEC with a high concentration of oxygen vacancies, which provide a high density of surface reaction sites. This presentation will focus on how these electrodes achieve:
- exceptional activity: electrode polarization resistance <0.1 ohm cm\(^2\) at 650°C
- exceptional stability: inhibiting carbon deposition even during CO2 electrolysis in thermodynamic carbon deposition conditions, as well as the ability to re-activate electrode performance by periodically shifting to oxidizing conditions and back again

3:00 PM ES12.08.07
Stabilization of Brownmillerite SrCoO\(_3\) for Oxygen Enrichment Applications Aswathy M. N, Rajasekar Parasuraman and Arun M. Umarji; Indian Institute of Science, Bengaluru, India.

Mixed ionic-electronic conducting (MIEC) oxide ceramics are grabbing attention towards a variety of applications such as oxygen sensors, catalyst bed for combustion of fossil fuels, cathodes for solid oxide fuel cells, oxygen separation membranes, oxygen storage devices etc. These MIECs can transport oxide ions through their lattice when an oxygen partial pressure gradient is applied across the material\(^2\). They also have reversible oxygen storage capabilities at elevated temperatures. Transition metal Perovskite oxides (general
thermal–driven pumping approach has the potential to substantially exceed state-of-the-art pumping efficiencies, especially in the low-pressure regime, in inherently simple and potentially low-cost devices.

10:30 AM ES09.01.01
Manganese Oxides—Functional Electrochemistry and Insight into Their Redox Mechanisms Esther S. Takeuchi, Amy C. Marschilok and Kenneth Takeuchi; Stony Brook Univ, Stony Brook, New York, United States.

Manganese oxides are a structurally rich class of materials and can be prepared as layered, tunneled, or spinel structured materials. The synthetic versatility of these materials is further expanded as they are often prepared with cations as part of the structures including univalent cations such as K\(^+\), Ag\(^+\), or Na\(^+\), Rb\(^+\), or Cs\(^+\) or multivalent cations such as, Ni\(^2+\), Cu\(^2+\), Co\(^2+\), Mg\(^2+\), or Al\(^3+\). The ability to deliberately tune both the structure and the composition of the materials has led to investigation of their functional behavior for a number of applications as both the parent structure as well as the nature of the cation can be determining factors. The interest in manganese oxide materials is further enhanced by their relatively low cost and toxicity.

This presentation will explore the electrochemistry of manganese oxides in lithium, sodium and magnesium based electrolytes for possible application in electrochemical energy storage devices. Examples of layered, tunneled and spinel manganese oxide structures will be considered. Discussion will include the functional electrochemistry as well as insight into the reduction and oxidation mechanisms.

11:00 AM ES09.01.02
Toward a Low-Cost High-Voltage Sodium Aqueous Battery Kiosik Kang; Seoul National University, Seoul, Korea (the Republic of).

Highly concentrated aqueous batteries have emerged as potential candidates for large-scale energy storage applications; however, the need for high-cost organic electrolyte salts is a potential obstacle hindering their practical application. Herein, we revisited all the commonly used low-cost inorganic electrolytes and discovered that the use of low-cost super-
concentrated aqueous solution result in a high electrochemical stability window of up to 2.7 V by suppressing water dissolution and induces stable solid-electrolyte interphase (SEI) layer formation without involving the reduction of salt anions. The SEI layer, composed of Na$_2$CO$_3$ and Na–O compounds, guarantees the excellent electrochemical storage stability of the full-cell composed of a Na$_2$Fe$_3$(PO$_4$)$_2$(P$_2$O$_7$) cathode and NaTi$_2$PO$_4$ anode for over 890 hours. This new-class 2-V Na-ion battery provides remarkable cycle stability and a Coulombic efficiency of over 99% at 1C for over 200 cycles.

The Advanced Electrochemical Materials section at the U.S. Naval Research Laboratory has designed and validated a three-dimensional (3D), monolithic Zn electrode architecture that solves the limited rechargeability of Zn. We use a simple emulsion-based protocol to produce moldable, scalable, Zn “sponge” electrodes whose structural characteristics impart: (i) interconnected pathways that maintain long-range electronic conductivity within the electrode volume throughout charge-discharge; (ii) an electrified 3D interface that imparts more uniform current distribution; and (iii) confined internal void volume that controls Zn/Zn$^{2+}$ precipitation/dissolution dynamics and product redistribution.

These Zn “sponge” anodes exhibit unprecedented cyclability at high depths-of-discharge (theoretical DOD$_{max}$), increased specific capacity relative to conventional powder-bed Zn electrodes, and tens of thousands of cycles with low-DODZn pulse-power profiles, as recently demonstrated in prototype Ni–Zn cells. This breakthrough enables the entire family of alkaline Zn batteries (Ni–Zn, Ag–Zn, MnO$_2$–Zn, and Zn–air) plus neutral pH zinc-ion batteries to be reconfigured in extensively rechargeable forms, with energy and power characteristics that are competitive with Li-ion batteries. Our second-generation emulsion protocol improves the volumetric density of the sponge thereby concomitantly improving the energy density of the cell while adding mechanical ruggedness to the anode. The potential paths forward for the development and transition of this safer energy-storage technology will be discussed.

SESSION ES09.02: Water Desalination I
Session Chairs: Roland Cusick and Matthew Suss
Tuesday Afternoon, April 23, 2019
PCC North, 100 Level, Room 131 A

1:30 PM *ES09.02.01 Material Requirements for Capacitive Deionization Electrodes Michael Stadermann$^1$, Steven A. Hawks$^1$, Ashwin Ramachandran$^1$, Ali Hemmatifar$^2$, Patrick G. Campbell$^3$ and Juan G. Santiago$^4$; $^1$Lawrence Livermore National Laboratory, Livermore, California, United States; $^2$Stanford University, Palo Alto, California, United States.

Capacitive deionization (CDI) is a promising technique for water treatment. At the heart of every CDI device are the electrodes that adsorb ions from the liquid. Much of the improvement of CDI performance in the past decade has focused on increasing the sorption capacity of the electrodes.

Here, we will present our latest results on optimizing device operation, charge efficiency and thermodynamic efficiency, and the impact of these results on future electrode material and performance characterization. Specifically, we will break down the overall charge efficiency into double-layer efficiency, flow efficiency, and Coulombic efficiency and show how the choice of material, morphology, and operating conditions affects each of these efficiencies, and highlight how measured salt adsorption capacity (SAC) depends on the charge efficiency. We will demonstrate a simple way to optimize operational parameters for a specific separation and show that for a given separation the impact on SAC on performance can be limited. We will show the impact of electrode dimension on the device power consumption and thermodynamic efficiency. Our findings suggest that optimization of shape and morphology of the material play as important a role as the intrinsic capacity of the material for future CDI electrode development.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

2:00 PM *ES09.02.02 Rational Electrode Design and Device Operation for Enhanced Performance and Durability of Electrochemical Desalination Processes in Complex Waters Meagan Mauter; Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

Capacitive deionization based on carbonaceous electrodes represents an energy-efficient technology suitable for low-salinity brackish water desalination where high recovery rates are critical to economic viability. Substituting insertion compounds for carbonaceous materials in electrochemical desalination electrodes enables higher ion adsorption capacities, excellent energy efficiency in higher salinity feedwaters, and selective removal of target ions. These insertion electrode properties introduce a novel set of process applications and advantages in deploying electrochemical separations, including the selective recovery of high value byproducts from reverse osmosis concentrate and reduced energy consumption and environmental impacts associated with efficient removal of target ions of environmental concern.

Despite the promise of carbon and insertion based electrochemical desalination processes, the durability of the electrode materials when treating complex waters is a documented issue that has not been systematically investigated. This presentation will review our ongoing work to examine the impact of organic fouling on the performance of carbonaceous and insertion-based electrochemical desalination processes, identify key factors controlling the corrosion/degradation of carbonaceous and insertion-based electrodes used in electrochemical desalination, and explore and assess cost-effective strategies for improving the fouling tolerance and minimizing the corrosion or degradation of carbonaceous and insertion-based electrodes.

2:30 PM ES09.02.03 Global Sensitivity Analysis to Assess Performance and Characterize Operational Limitations Across Capacitive Deionization Technologies Steven M. Hand$^1$, Xia Shang$^2$, Jeremy Guest$^1$, Kyle Smith$^1, 3, 4$ and Roland Cusick$^1$; $^1$Civil & Environmental Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; $^2$Mechanical & Engineering Science, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; $^3$Beckman Institute for Advanced Study, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; $^4$Computational Science and Engineering Program, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Capacitive deionization (CDI) is a class of electrochemical desalination technologies which typically desalinate via ion storage in electric double-layers. CDI has received attention in recent years due to the ability to couple energy storage with salt separation. Unlike reverse osmosis (RO), a portion of the energy applied during desalination can be recovered directly as electrical energy, reducing net energy consumption. Apart from the thermodynamic minimum energy of separation, all energy applied should be recoverable.

However, in practice, ion/electronic resistances, inefficient hydraulic design, parasitic reactions, and poor selectivity limit the portion of energy recoverable. Several material additions and electrode configurations have been proposed to overcome these limitations. Two of the most prominent modifications are the addition of ion exchange membranes (IEMs), promote counter ion flux out of the desalination chamber, and utilizing flowable, carbon slurry electrodes, to increase salt removal capacity. Likewise, functionalization of carbon electrodes has been used to improve counter-ion adsorption within EDL micropores. While the incorporation of IEMs in membrane capacitive deionization (MCDI), the use of slurry electrodes in flow capacitive deionization (FCDI), and the incorporation of functionalized carbon have successfully reduced energy consumption or increased ion adsorption capacity in CDI systems, these modifications are often evaluated under limited conditions on the basis of specific performance enhancements. Further, evaluation of practical CDI performance has been limited by low reported experimental salinity reduction (the concentration difference between influent and effluent charging is typically 10 mM or less). Additional clarity is necessary to evaluate the associated performance and cost tradeoffs across the design space.

In this study, a porous electrode (M/F)CDI model was used to measure the sensitivity of CDI performance to across the design landscape of architectural, material, and operational inputs. In order to investigate the performance of FCDI, pulse-flowed electrodes of high capacity and electronic resistances were incorporated into the existing model. Similarly,
fixed charge in the anodic and cathodic micropores was studied to investigate functionalized carbon. Sensitivity for CDI, MCDI, and FCDI were evaluated by varying eight common input parameters. Sensitivity analyses were conductions using both Monte Carlo and Morris methods utilizing six common performance metrics (salt adsorption capacity [SAC], average salt adsorption rate [ASAR], energy-normalized adsorbed salt [ENAS], charge efficiency [l+ or n2+], and round-trip efficiency/energy recovery [r2+n2+], and thermodynamic efficiency [η]).

Our sensitivity analyses show that operating current density, electrode specific capacitance, and contact resistance were the parameters which most significantly dictated (M/F)CDI performance. Both CDI and FCDI were out performed by MCDI, due to relatively poor charge and round-trip efficiencies, respectively. We found that increased system performance across most metrics was associated with input parameters which increased charging cycle duration. Lastly, simulated MCDI achieved thermodynamic efficiency comparable to brackish water RO, although tradeoffs exist between water recovery and thermodynamic efficiency.

2:45 PM ES09.02.04 Cooperative Effects in Molecular Dynamics of Water Confined in Hydrophobic and Hydrophilic Nanopores Margarita Russina and Veronika Grzimek; EM-ISFM, Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany.

The molecular dynamics of confined of water is important for many areas of science and applications ranging from energy storage to transport phenomena in geology and biology. In this context, the understanding of hydrogen bonds formation in various environment and criteria governing the molecular mobility at nanoscale is of high importance. Using neutron spectrometer NEAT as a powerful magnifying glass we have investigated molecular dynamics of water in hydrophobic and hydrophilic nanocolumn in a very broad temperature range of 20-300 K. By an aimed selection of the confining systems we were able to follow the molecular behavior in pores of various sizes and shapes and in environments with variable degrees of water host interactions. Changing the amount of confined water we have studied the process of hydrogen bonds formation and were able to explain the molecular mechanism of adsorption behavior in selected hydrophobic systems. Thus in zeolite Al(PO₄)₃ with hydrophobic one-dimensional channels of about 1 nm cross section we observed non-monotonous behavior of the mean square displacement as amount of confined water increases. The cooperative interactions between water-water molecules lead to the increase of molecular mobility and the sharp rise in water intake. Guest-host interactions initiate adsorption-induced changes of the host structure, which in the case of Al(PO₄)₃ cause the anisotropic contraction of the zeolite framework. These structural changes can be the reason for a broad isotherm hysteresis observed in this system.

3:00 PM BREAK

SESSION ES09.03: Electrochemical Capacitors
Session Chairs: Majid Beidaghi and Matthew Suss
Tuesday Afternoon, April 23, 2019
PCC North, 100 Level, Room 131A

3:30 PM *ES09.03.01 Two-Dimensional Carbides and Nitrides (MXenes) for Water Purification and Electrochemical Energy Storage Samantha Buzcek,1 Ravi P. Pandey2, Abdul R. Pathath2, Khasif Rasool2, Ekaterina Pomerantseva1, Khaled A. Mahmoud2 and Yury Gogotsi1; 1Material Science & Engineering, Drexel University, Philadelphia, Pennsylvania, United States; 2Hamad Bin Khalifa University, Ar Rayyan, Qatar.

Nanomaterials have attracted significant attention by researchers over the past decade towards developing sustainable technologies. MXenes, a large family of two-dimensional (2D) transition metal carbides and nitrides, are the front runners of 2D material research due to their diverse physiochemical properties. MXenes are synthesized by wet chemical etching of an atomic layer from layered ternary carbide precursors (MAX phases), resulting in terminations (-O,-F,-OH) on the surface. Their unique combination of hydrophilicity and metallic conductivity, enable compatible solution processing of conductive MXene materials by various methods in scalable quantities. MXenes can be dispersed in aqueous and organic solvents to make colloidal, functional solutions which can be subsequently prossessed via printing, spray coating, drop casting, or vacuum filtration for the rational design of devices with different architectures. The 2D morphology, diverse transition metal chemistry, and functionality offered by MXene materials has spurred their use in a wide range of applications, specifically energy storage and water purification. The ability of MXenes to spontaneously intercalate a variety of cations and/or large organic molecules has created the platform for efficient storage or removal of guest species. Fast redox reactions at the transition metal-oxide/hydroxide-like surfaces with efficient charge transfer due to high electronic conductivity, makes MXenes a promising candidate as high rate pseudocapacitive materials for energy storage applications. Furthermore, combination of slit-like pores with electronic conductivity, qualifies MXenes as capacitive deionization (CDI) electrodes for efficient and reversible removal of ionic species/organic molecules from brackish water. In addition, membranes composed of Ti2C nanosheets have already shown potential in selectively sieving gases, such as H2 and various alkali, alkaline earth ions (Li+, Na+, K+, Mg2+, Ca2+), metals (Ni2+ and Al3+), and dye cations (MB) based on charge and size without sacrificing water flux rate. The high aspect ratio of the flakes allows for the fabrication of membranes with uniform and narrow 2D nanochannels. Systematic studies of the effect of interlayer spacing and surface functionalization on the transport of ions in confined channels can provide valuable insight to progress use of MXene in the fields of energy storage and water purification.

4:00 PM *ES09.03.02 High Performance Carbon/Carbon Electrochemical Capacitors Implementing Concentrated Aqueous Electrolytes Patryk Przygocki, Qamar Abbas, Barbara Gorska and Francois Beguin; Poznan University of Technology, Poznan, Poland.

In order to reach high voltage and high energy density, electrochemical capacitors (ECs) with activated carbon (AC) electrodes mostly implement organic electrolytes. Due to the relatively poor environment friendliness and high cost of these devices, developing ECs with alternative electrolytes is highly demanded. AC electrodes in aqueous solutions with pH close to 7 have been shown recently to display enlarged potential window compared to classical electrolytes as H2SO4 or KOH. The window is extended under negative polarization owing to water reduction and production of hydroxy groups (OH-), which leads to a pH increase inside the porosity of the AC electrode and consecutive downsfting of the Nernst di-hydrogen evolution potential. Hence, when using stainless steel current collectors and alkali sulfate solutions, practical voltage values of 1.5 V are reached. Besides, enhanced capacitance was demonstrated when hybrid AC/AC capacitors comprising a faradic positive electrode and an electrical double-layer (EDL) negative electrode are realized by implementing an aqueous solution of potassium iodide. Subsequently, bi-functional electrolytes containing Li2SO4 as negative electrode potential range extender and KI as promoter of battery-like positive electrode have been proposed to enhance cell voltage and capacitance, respectively, allowing the energy of the thereof realized hybrid EC in aqueous ChNO3 to be increased down to -40°C. Based on this success, we now propose a bi-functional electrolyte containing 5 mol kg⁻¹ LiTFSI or Li2SO4, causing advantageously a voltage extension by ca. 200 mV. Despite these advantages of water-in-liquid electrolytes, the solutions display a very low conductivity and the ECs performance quickly fades when lowering temperature down to -20°C. Recently, we have implemented a new family of concentrated (5 mol kg⁻¹) aqueous electrolytes based on choline chloride, owing to which symmetric ECs demonstrated excellent performance down to ~40°C. Based on this success, we now propose a bi-functional electrolyte containing 5 mol kg⁻¹ choline nitrate (ChNO3), as supporting neutral electrolyte providing low potential extension for the negative electrode, and 0.5 mol kg⁻¹ choline iodide (ChI), as redox active component for the positive electrode. Importantly, this electrolyte is liquid above ~40°C, as identified by differential scanning calorimetry. It shows only glass transition upon cooling, which reappears during heating and is followed by cold crystallization and melting. The hybrid EC in aqueous ChNO3-ChI exhibits a capacitance of 81 F g⁻¹ at 24°C and still 50 F g⁻¹ at ~40°C. The energy and power performance of the proposed hybrid EC and an EDLC made of the same carbon electrodes in organic electrolyte is comparable in the temperature range from 24°C to ~40°C.

4:30 PM ES09.03.03 2D MXenes as Building Blocks for Fabrication of Highly Stable Pseudocapacitive Electrodes Amin VahidMohammadi and Majid Beidaghi; Auburn University, Auburn, AL, USA; Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany.

High performance carbonaceous materials have been investigated in a wide range of applications, especially in energy storage and water purification. The ability of MXenes to spontaneously intercalate a variety of cations and/or large organic molecules has created the platform for efficient storage or removal of guest species. Fast redox reactions at the transition metal-oxide/hydroxide-like surfaces with efficient charge transfer due to high electronic conductivity, makes MXenes a promising candidate as high rate pseudocapacitive materials for energy storage applications. Furthermore, combination of slit-like pores with electronic conductivity, qualifies MXenes as capacitive deionization (CDI) electrodes for efficient and reversible removal of ionic species. However, an important cornerstone in the development of capacitors using relatively diluted aqueous solutions is the rapid fading of performance when lowering temperature. In this presentation, we show that inorganic MXenes undergo charge transport via hopping of charged species between metallic centers, which appears as an electrochemical function of 2D transition metal carbides and nitrides, supported by in-situ neutron and Raman spectroscopic studies. Importantly, we demonstrate that this unique electronic behavior can be exploited for high performance CDI at low dilutions and at low temperatures. Moreover, we demonstrate that this electronic behavior highly depends on the materials' hydrogen bonding environment. Thus, we show that highly functional MXenes are able to remove ions from aqueous solutions at a much higher rate, in the presence of common interfering ions. This work paves the way for the development of advanced MXene-based capacitive deionization systems.
Two-dimensional (2D) transition metal carbides (MXenes) are among the most promising electrode materials for pseudocapacitive energy storage. MXenes are particularly of high interest because they can store charge in the bulk of their electrodes through ultrafast intercalation of ions and fast and reversible redox reactions. To date, about 20 different MXenes with a general formula of M\textsubscript{x}M\textsubscript{y}\textsubscript{n}X\textsubscript{m}T\textsubscript{z} (M is a transition metal, X is carbon and/or nitrogen, n=1,2, and 3, and T\textsubscript{z} represents different functional groups present on their surface) are synthesized by selective etching of the A layer atoms (i.e., Al) from MAX phases (i.e., Ti\textsubscript{3}AlC\textsubscript{2}), a large group of layered ternary carbides and nitrides.\(^1\) However, from all the available MXene compositions, so far only pseudocapacitive behavior of few MXenes, such as Ti\textsubscript{3}C\textsubscript{2}T\textsubscript{x}, has been systematically studied and pseudocapacitive properties of most other MXene compositions have remained unexplored. The main reason that has hindered such investigations is instability and rapid structural degradation of delaminated (2D) form of other MXene compositions such as V\textsubscript{2}CT\textsubscript{y}. Here we demonstrate the fabrication of highly stable freestanding films of 2D vanadium carbide (V\textsubscript{2}CT\textsubscript{y}) MXene with superior pseudocapacitive properties. We show that a variety of cations including Li\textsuperscript{+}, Na\textsuperscript{+}, K\textsuperscript{+}, Mg\textsuperscript{2+}, and Al\textsuperscript{3+} can electrochemically intercalate fabricated V\textsubscript{2}CT\textsubscript{y} in aqueous electrolytes, offering capacitances of over 1300 F cm\textsuperscript{-2}. Supercapacitors fabricated using V\textsubscript{2}CT\textsubscript{y} MXene films can deliver gravimetric capacitances of over 200 F g\textsuperscript{-1} at a high rate of 100 A g\textsuperscript{-1} with a cyclic stability of over hundreds of thousands of cycles, surpassing previously reported Ti\textsubscript{3}C\textsubscript{2}T\textsubscript{x} supercapacitors. Our research describes a new approach for the design and synthesis of high performance layered electrode materials using 2D MXene building blocks.

Metastable Charge Activity in Carbon-Based Electrodes for Capacitive Deionization  
Bei Li and Steven T. Boles; The Hong Kong Polytechnic University, Hong Kong, China.

Limitations of capacitive deionization (CDI) technology and future commercialization efforts are intrinsically bound to electrode stability. In this work, the metastable behavior of salt ions and their link to stability degradation is explored. Chemical extraction studies suggest that once mobile species can become metastably trapped in the surface of aged electrodes. To qualitatively explore their impact on CDI devices, a two-electrode voltage sweep test is presented which can simultaneously monitor the active voltage window for CDI between the electrodes without the need for cell disassembly or alteration of the aqueous input feed. This voltage sweep test can be employed in conjunction with long-term operation of CDI cells. Furthermore, annealing treatments in different ambient conditions can assist to gain insights into the nature of carbon-based electrode materials and the formation of different functional groups. Preliminary investigations suggest different behavior in the anode and cathode of the CDI during continuous operation and offer insights into strategies for minimizing electrode degradation as the technology gains momentum for future commercialization.

Improving Desalination Performance of Capacitive Deionization Using Novel Operating Schemes—Use of Sinusoidal Voltage and Resonant Operation  
Ashwin Ramachandran\(^1\), Steven A. Hawks\(^2\), Michael Stadtmann\(^3\) and Juan G. Santiago\(^4\); Stanford University, Stanford, California, United States; \(^1\)Lawrence Livermore National Laboratory, Livermore, California, United States.

Capacitive deionization (CDI) performance metrics can vary widely with operating methods. To date, nearly all CDI control schemes have consisted of constant current or constant voltage operation with a constant flowrate. Such operating methods typically show benefits in either energy or salt removal performance, but not both.

In this work, first, we develop a theory around and experimentally demonstrate new operation modes for CDI which use sinusoidal forcing voltage (or sinusoidal current). We use a dynamic system modeling approach and quantify the frequency response (amplitude and phase) of CDI effluent concentration. Using a wide range of operating conditions, we show that CDI can be approximately modeled as a linear time invariant system. We validated this model with experiments and showed that a sinusoidal voltage operation can simultaneously achieve high salt removal and good energy performance. We explore the coupling between electric charge, ionic charge, and mass transport (advection) and demonstrate that sinusoidal voltage forcing functions can achieve resonance-type operation for CDI. Despite the complexities of the system, we find we can describe the resonance mode with the following simple relation: The resonance period (frequency) is proportional (inversely proportional) to the geometric mean of the flow residence time and the electrical resistance-capacitance (RC) charging time. Operation at resonance results in an optimal balance between absolute amount of salt removed (in moles) and avoidance of dilution of the feed and brine streams. The result is a maximum average concentration reduction for the desalinated water. We further developed our model to generalize the resonant frequency operation, and study and compare with the responses to square and triangular voltage waveforms as two examples. To this end, we developed a general tool that uses Fourier analysis to construct CDI effluent dynamics for arbitrary input waveforms. Using this tool, we show that most of the salt removal (~95%) for square and triangular voltage forcing waveforms is achieved by the fundamental Fourier (sinusoidal) mode. We show that the frequency content of the higher Fourier modes severely limit their flow efficiency. Hence, such high frequency modes consume additional energy while providing minimal additional salt removed. This deficiency of higher frequency modes further highlights the advantage of DC-offset sinusoidal forcing for CDI operation.

Bifunctional Cathode Configurations in Rechargeable Zn–Air Cells  
Christopher N. Chervin, Jesse S. Ko, Brandon J. Hopkins, Joseph F. Parker, Jeffrey W. Long and Debra R. Rolison; US Naval Research Laboratory, Washington, District of Columbia, United States.

Rechargeable zinc-air batteries are desirable next-generation power sources that promise to deliver high energy density (upwards of 400 Wh kg\textsuperscript{-1}) using aqueous (nonflammmable) electrolytes. We have recently addressed a long-standing problem of dendrite formation at the anode by fabricating the Zn as a 3D sponge. We now turn to another great challenge: the development of an efficient, stable, and practical air cathode that can pair with our Zn anode to deliver extended cycle life and achieve specific energies that surpass today’s Li-ion batteries. Cathode efficiency and stability are determined by the electrode architecture (e.g., porosity, hydrophobicity/hydrophilicity, and electronic & ionic transport) and to a greater extent by the incorporation of high-performance electrocatalysts that can reduce molecular oxygen (ORR) during battery discharge and evolve O\textsubscript{2} via water splitting (OER) upon charging. Our approach is to synthesize ORR and OER electrocatalysts as high surface–area aerogels and then use conventional gas diffusion–electrode fabrication techniques to incorporate these oxide nanoparticles within practical carbon architectures. We choose catalyst compositions that are highly active but only contain earthy abundant elements; namely, cryptomelane (α-MnO\textsubscript{2}) for ORR and nickel ferrite (Ni\textsubscript{Fe}\textsubscript{O}, O\textsubscript{3}) for OER or nickel ferrite alone as a bifunctional OER and ORR catalyst. We assemble Zn-air cells that comprise our Zn sponge anode and aerogel-functionalized composite cathodes and test their cycle stability and ability to deliver practical energy density and power. We will describe results for a series of cathode configurations in which we vary the placement of the ORR and OER catalyst layers and compare cathodes containing a single bifunctional catalyst with those that are made from separate OER and ORR catalysts.

Graphene Oxide/Cobalt-Based Nanohybrid Electrodes for Robust Hydrogen Generation  
Fabiola Navarro-Pardo\(^1\), \(^2\), Haiguang Zhao\(^3\), Zhiming M. Wang\(^2\) and Federico Rossetti\(^1\); \(^1\)Institute of Fundamental and Frontier Sciences, University of Electronic Science and Technology of China, Chengdu, China; \(^2\)Centre for Energy, Materials and Telecommunications, Institut national de la recherche scientifique, Varennes, Quebec, Canada; \(^3\)College of Physics and The Cultivation Base for State Key Laboratory, Qingdao University, Qingdao, China.

Generating hydrogen (H\textsubscript{2}) using photoelectrochemical (PEC) cells is a promising route towards combining a renewable source of energy with the production of a solar fuel. In this
context, considerable advances have been achieved in PEC cells based on semiconductor chalcogenides such as quantum dots (QDs). Within such devices, while QD-based photoanodes have been widely studied, the study of electrocatalysts deposited at the counter-electrode for this type of systems has been overlooked. As such, a major challenge is the development of effective electrocatalysts that possess long-term stability in strong alkaline conditions.

Several efforts have focused on identifying substitutes to enable a H2 economy without the need of Platinum, which is often considered to be the best electrocatalyst in alkaline medium and yet is rare and expensive. Different transition metals have been shown to perform adequately as state-of-the-art earth-abundant inorganic electrocatalysts. In particular, cobalt-based compounds such as cobalt oxides and cobalt chalcogenides are promising electrocatalysts for hydrogenation, due to their low energy barrier for H atom adsorption. These cobalt-based compounds have been mostly studied in alkaline conditions using a KOH aqueous electrolyte. Until now, there are no studies of their performance in a Na2S/Na2SO3 aqueous medium, which is a requirement for effective and stable operation of photocatalytic and PEC systems based in semiconductor chalcogenides.

Here we report the fabrication of cobalt-based nanohybrids (CoNHs) by directly electrospinning CoOx nanoribbons onto large-area carbon fiber paper and demonstrated their application as binder-free electrodes for solar-driven H2 generation. First, we demonstrate that the addition of graphene oxide (GO) can enhance the charge transfer and robustness of the electrode. The addition of 12wt% GO within the CoOx, can lower by ~100 mV the overpotential needed to obtain a current density (J) of ~10 mA cm−2, compared to pristine CoOx. This is corroborated by the reduced charge transfer resistance from 4.4 Ω to 2.5 Ω for p/CoNHs and the optimized GO/CoNHs, respectively. In addition, the CoNHs display outstanding electrochemical long-term stability, as the overpotential required to keep J = ~10 mA cm−2 was invariant for over 42 h. Subsequently, we show that the initial electrocatalyst nanoribbons composed of Co3O4(particles (~10 nm in size) can transform and regenerate in situ into nanosheets, leading to the formation of a mixture of cobalt sulfides (CoS/CoS2), which stabilizes the performance of these electrodes.

Finally, as proof of concept we implemented these CoNHs as counter-electrode in a QD-based PEC device using a CdSe/CdS:TiO2 photoanode in the presence of Na2S/Na2SO3 alkaline media to demonstrate the viability of these electrodes for stable H2 generation. Additionally, we confirmed the versatility of the CoNH electrodes when used as both anode and cathode and connected to a photovoltaic cell to assist solar-driven water splitting in the presence of KOH aqueous electrolyte. Our observations indicate that the GO/CoNH electrode represents a very promising application in renewable energy devices, such as PEC water splitting, electrolysis, and QD-sensitized solar cells.

Assessment and Characterization of Hybrid Mesoporous Material MCM with Titanium Dioxide for Water Treatment Jiajun Xu; Mechanical Engineering, University of the District of Columbia, Washington, District of Columbia, United States.

In the current study, a new method was developed to synthesize the hybrid mesoporous material with metallic oxides, MCM-48 with TiO2, at an improved efficiency and reduced cost. The results have shown an over 95% adsorption efficiency for trace metals for the hybrid MCM-48 with TiO2 materials, and a significantly improved maximum adsorption capacity compared to pure MCM-48. Its unique hybrid structured allows the polluted water to pass through the strong yet highly permeable structure of mesoporous material, while gives enough time for the pollutants to react with the TiO2 infused on the porous structure so that the polluted water can be treated without introducing secondary pollutants. The microstructures of the MCM-48 with and without TiO2 are characterized using SEM with EDS and Porosimeter. The effectiveness of wastewater treatment is measured using Inductively Couple Plasma-Mass Spectrometer (ICP-MS). The significant improvements observed here is likely due to the infused TiO2 to the base MCM-48 structure, which also agree with the authors' previous finding. It is noticed that, while the higher concentration of TiO2 has a positive impact on the adsorption of trace metals, the higher concentration of Ti source does not necessarily yield significantly higher concentration of TiO2 in the final product. Future study is needed to further explore this hybrid mesoporous material for other pollutants treatment, and to obtain a further understanding of its mechanisms.

Safe, Low-Cost and Sustainable High Concentrated Aqueous Sodium Battery Myeong Hwan Lee, Sung Joo Kim and Kisuk Kang; Seoul National University, Seoul, Korea (the Republic of).

Highly concentrated aqueous batteries have outperformed conventional electrolytes by forming the solid-electrolyte interphase (SEI) layer with anion decomposition and suppressing water activity, thereby expanding the electrochemical stability window. These newly proposed concentrated electrolyte systems enable high-voltage operation of aqueous batteries for a wide selection of electrodes; however, significant economic concerns have delayed the commercialization of aqueous systems, especially regarding the use of expensive inorganic salts. In the current study, we revisited all the commonly used low-cost inorganic salts and evaluated them for their use in super-concentrated aqueous electrolytes. These super-concentrated electrolytes offer a high electrochemical stability window of up to 2.7 V through suppressing water decomposition with forming a super stable SEI layer without involving the reduction of salt anions. The SEI layer exhibited the extraordinary electrochemical storage stability of the full-cell for over 890 hours. Using this new class of super-concentrated electrolyte, we successfully developed a 2-V Na-ion battery with remarkable cycle stability and a coulombic efficiency of over 99% at 1C for over 200 cycles.

ES09.04.09
Polyelectrolyte Modified Nanoporous Membranes for Selective Ion Transport in Electrodialysis Stephen Percival, Sara Russo, Ryan Hill, Amanda Peretti, Leo J. Small, Susan Rempe and Erik D. Spoerke; Sandia National Laboratories, Albuquerque, New Mexico, United States.

Ion selective nanoporous membranes are an important component for the purification of water using electrodialysis. Electrodialysis uses an applied DC electric field to actively transport dissolved ions through the membranes, purifying the water on one side of the membrane and concentrating the salt ions on the other side. This process uses a large amount of electrical energy and thus only finds limited application. In order to increase the efficiency of this process the the ionic selectivity and the ionic conductivity of the membranes must be increased. Our goal is to increase these properties of commercial nanoporous membranes by coated with an inexpensive polyelectrolyte thin films using an aqueous Layer-by-Layer (LBL) process. The polyelectrolyte coating changes the surface chemistry of the membranes leading to changes in the selectivity and conductivity. We can further tailor the properties of the membranes using various crosslinking chemistries to impact not only the chemical selectivity and conductivity but also the chemical stability of the polyelectrolyte surface modification. Polyelectrolyte film structure, such as film thickness, is shown to change the ionic selectivity of the membranes. Additionally, the addition of small functional molecules to the LBL deposition solutions will incorporate the molecules into the resulting thin film. These small molecules, upon crosslinking of the polyelectrolyte, lead to an increase in selectivity. Variations in structure and the composition of the polyelectrolyte film, polyelectrolyte deposition parameters and crosslinking chemistries are shown to controllably influence the ionic selectivity and conductivity of the nanoporous membranes as well as adhesion of the polyelectrolyte coating. Continued advances of these polyelectrolyte thin films will enable the widespread use of electrodialysis as an economical water purification technology.

ES09.04.10
Hydrophilic Carbon Nanotube-Based Thin-film Composite Membranes for Forward Osmosis Application Hsin Hua Lee, Chi-Young Lee and Nyan-Hwa Tai; Department of Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan.

Growing population, increasing water demand and rising energy use over the past few decades stimulated exploration of alternative water and energy resources [1]. For obtaining clean water from seawater by a most energy efficient method, this work proposes the fabrication of carbon nanotube-based membranes and study their application of the membranes on the forward osmosis (FO). Unlike reverse osmosis (RO), FO is an osmotically driven membrane process which can be operated without high hydraulic pressure, thus it has many potential advantages such as low energy consumption and low fouling tendency. Thin-film composite (TFC)-FO membrane separation technology can also be used in many applications, including water desalination, wastewater treatment, food processing and power generation [2]. However, most of the porous substrates for TFC-FO membranes which were made of polymer via the phase inversion method cannot withstand harsh conditions such as strongly acidic, alkaline and organic solutions. In this study, a novel carbon nanotube-based TFC (CNT-TFC) membrane with high hydrophilicity is developed, which possesses high chemical stability, thermal stability and great FO performance. These properties significantly increase the potential of application of the FO membranes in extreme conditions. Besides, the process for the CNT-TFC membrane could be easily scaled up.

The CNT-TFC membrane consists of a hydrophilic supporting layer and an ultrathin active layer. The supporting layer, designated as PET-PDA-CNT, is made of a layer containing polydopamine (PDA)-coated CNTs cast onto a polyethylene terephthalate (PET) nonwoven fabric, and the thickness of the PDA-coated CNT layer is only around 3 μm.
The active layer is an ultrathin polyamide (PA) film synthesized by interfacial polymerization (IP) of 1,3,5-benzenetricarbonyl chloride (TMC) in hexane solution and m-phenylenediamine (MPD) with sodium dodecyl sulfate (SDS) in aqueous phase. To improve the hydrophilicity of the supporting layers, PDA thin films synthesized via self-polymerization are coated on the CNT surfaces. Compared with the pristine PET-CNT supporting layer, the contact angle of the PET-PDA-CNT supporting layer drastically decreases from 77.5° (for PET-CNT) to 34.9°. Owing to the great hydrophilicity and thin thickness, the water resistance of the support layer is decreased and the overall membrane permeability is increased. On the other hand, the addition of SDS, an anionic surfactant, as co-solvent in aqueous phase during the IP process reduces the surface tension between two phases. As a result, it forms a looser PA layer than those synthesized by the conventional IP process. The looser PA layer could result in higher water flux and effectively block the reverse solute.

The results show that the TFC membrane with PET-PDA-CNT supporting layer exhibits great FO performance with the water flux of 12.58 Lm⁻²h⁻¹ and the reverse salt flux of 5.26 gm⁻²h⁻¹ when the selective layer is oriented towards the deionized water feed solution using 1 M NaCl solution as draw solution. The water flux of the membrane with PET-PDA-CNT layer is 267% higher than that of the membrane without the selective layer. The swelling extent of the PDA-CNT layer is 37% lower than that of the membrane with the pristine PET-CNT layer. Besides, it is found that the CNT-TFC membrane fabricated using 0.1 wt% SDS in the aqueous phase during IP could lead higher water flux while maintaining low reverse salt flux.

Nitrate is a common contaminant in groundwater which is a by-product of agricultural activities. Nitrate is, for example, implicated in so-called blue-baby disease. Thus, a point-of-use, reusable device to selective remove ions is crucial. Ionic exchange resins are the predominant method to selective adsorb ionic pollutants. However, the regeneration of these resins requires the disposal of significant volumes of chemicals.

Capacitive deionization (CDI) is a promising technique for water desalination. In contrast to ionic exchange resins, CDI requires no chemical to regenerate. CDI relies on electrical charges for adsorption and regeneration onto high surface area activated carbon (AC) electrodes. However, the experimental and theoretical framework for selective removal of ions with CDI is still under development.

In this work, we explored a method to enhance selectivity with a functionalized CDI system. We functionalized active carbon electrodes with ion-selective functional groups. This functionalization combines the high selectivity advantage of ionic exchange resins with the electrostatic regeneration of CDI. The active electrode was functionalized with cetyl trimethylammonium bromide (CTAB). This cationic surfactant has a quaternary ammonium moiety which acts as a nitrate selective functional group. The counter electrode was functionalized with the anionic surfactant sodium dodecylbenzenesulfonate (SDBS). In this system, the adsorption step occurs at 0 V due to the presence of chemical charge, while the regeneration step occurs at a constant (applied) voltage. We also expanded our understanding of the selective electro-adsorption process by developing and validating a well-mixed reactor model. Our model combines a Donnan treatment for electric double layers (EDL) and electrosorption Langmuir-type equilibria.

The experimental set-up consisted of a cell with a radial architecture. A mixture of sodium nitrate and sodium chloride entered the axisymmetric cell stack from the outer periphery. After treatment, the water exited the cell through a channel along the axis to minimize dispersion. We used ion chromatography to measure the concentration of each ion. We measured the intrinsic selectivity (~7.7) of our CTAB functionalized electrode with an ex-situ experiment. We defined and measured cycle selectivity of nitrate versus chloride as a function of the inlet nitrate concentration and regeneration voltage. We observed that cycle selectivity increases with lower values of voltage, with a maximum of ~6.5 at 0.4 V. We compared and validated our multi-species dynamic model with our quasi-steady state experimental data.

In brief, functionalization of AC electrodes provides a selective ion capture system with that can be regenerated with applied voltage. We demonstrated a nitrate-specific functionalization with up to 6.5-fold cycle selectivity. We also validated a dynamic model which incorporates a Donnan treatment for EDL and Langmuir-type equilibria for surface chemistry.

Faster and energy-efficient condensation of water vapor contained in atmospheric air has emerged as a solution to the demand for water in some regions of the planet. In these deserts or isolated areas the only accessible source of water is atmospheric air. In this way, academic and industrial research works that seeks to develop water collection devices with high efficiency has great relevance for the scientific community. It’s known that droplets coalescence on nanostructured superhydrophobic surfaces may result in droplet jumping from the surface. It can happen due to the release of excess surface energy because the surface roughness is much smaller than the coalesced drop size. In this work, we aim to show that if designed properly the modified carbon nanotubes forest can block the condensed drop at micrometric length scales during condensation easier than the hydrophobic, hydrophilic and superhydrophilic surfaces. In addition, this behavior occurs, for our surface, at high super saturation level which is an innovative aspect of this work. The Vertically Aligned Carbon Nanotubes were grown on stainless steel pipes. We used a CO2 laser and a O2 plasma to perform the post treatments that changed the nanotubes to superhydrophobic and superhydrophilic, respectively. In addition, the CO2 laser treatment added a second level of roughness in the surface by etching the walls of the nanotubes. Due the low adhesion of the carbon nanotubes with the substrate a Polyethylene layer was deposed on carbon nanotubes avoiding the removal of them. We experimentally demonstrated a 30% higher vapor condensation rate at high supersaturations levels in comparison to the others prepared surfaces.
In this work a V-O cell achieves total efficiency between 42 and 62% depending on the current density and stable operation was demonstrated during extended tests.

The “dual circuit redox flow battery” takes advantage of a conventional all-vanadium redox flow battery (VRFB) combined with a catalytic hydrogen evolution reactor in a separate external circuit. Depending on demand, the VRFB can be conventionally discharged by an electrical load or by using the catalytic reactor to yield $\text{H}_2$.

The dual-circuit vanadium redox flow battery coupled with a catalytic reactor, water is oxidized to oxygen and $\text{VO}_2^{2+}$ does not possess a potential high enough to spontaneously drive the oxygen evolution reaction; an additional energy input is required. Thus, in this work the reaction is performed electrochemically in a secondary flow cell (V-O$_2$ cell) to provide a high rate of conversion while minimizing the energy required. In the V-O$_2$ electrolyzer, which was added to the VRFB with catalytic reactor, water is oxidized to oxygen and $\text{VO}_2^{2+}$ is reduced to $\text{VO}^{3+}$ electrochemically providing state-of-charge and proton rebalancing for the dual-circuit redox flow battery system.

The main advantage of this approach is that there are no additional chemical species. Water oxidation reaction proceeds with the support of a stable and commercially available DSA® electrode. Moreover, from a practical point of view the V-O$_2$ cell, being actively driven by current can be switched on and off asynchronously with the hydrogen production in the catalytic reactor. Also, in principle, this system can guarantee much higher hydrogen and oxygen purity than a typical electrolyzer, because of the physical, local, and temporal separation on the production of the two gasses. In this work a V-O$_2$ cell is proposed and optimized according to its energy input and a final prototype which integrates a catalytic reactor, a VRFB, and the V-O$_2$ electrolyzer is successfully tested. A laboratory scale cell was investigated in a complete dual-circuit system including a V-O$_2$ cell. The dual-circuit vanadium redox flow battery coupled with a V-O$_2$ cell achieves total efficiency between 42 and 62% depending on the current density and stable operation was demonstrated during extended tests.

Capacitive deionization (CDI) is an emerging water desalination technology accomplished by electrosorption of ions at the interface between saline solutions and nanoporous carbon electrodes. By employing the strictly physical process of ion electrosorption, salt adsorption capacities of typically 15-20 mg/g (mg salt per g of the electrode) have been reported. The use of carbon limits the maximum achievable charge storage capacity and restricts the applicability of CDI to low molar media (typically below 20-50 mM). This issue originates from unfavorable co-ion expulsion from carbon nanopores concurrently occurring during counter-ion adsorption. Only once all co-ions have become depleted in the pores, permselective ion removal is accomplished. To transfer CDI from a niche technology to a more largescale use, new electrode materials and cell concepts need to be explored.

The use of ion intercalation or conversion reaction electrodes has recently re-energized the research field for electrochemical water desalination. The presentation will summarize key aspects of the implementation of ion intercalation materials for the desalination of aqueous media with ion concentration levels typical brackish water and seawater. We demonstrate the facile use of pseudocapacitive materials to effectively remove cations and anions from saline media. Such materials, like transition metal carbides (MXene), some transition metal dichalcogenides (e.g., MoS$_2$), or some metal oxides (e.g., V$_2$O$_5$) allow energy efficient desalination in the absence of an ion exchange membrane. These benefits also can be accessed using electrode materials with battery-like charge/discharge behavior, such as TiS$_2$. With enhanced ion mobility and lowered energetic barriers, there is even an improved desalination performance when increasing the salt concentration from low (10 mM) to high levels (1 M). The adaptation of intercalation materials requires careful considerations for the desalination cell design.
The rising demand of clean & safe drinking water is one of the primary concerns because of the water scarcity, growth of human population, urbanization, & natural & anthropogenic pollution. Ground water & surface water resources are being contaminated by pervasive low molecular weight hydrophilic compounds (LMHcs) which are not effectively removed by current water treatment technologies. The US Environmental Protection Agency (USEPA) is focused on the removal of many classes of LMHcs from drinking water & wastewater, including; disinfection byproducts precursors, pharmaceuticals, personal care products, heavy metals & perfluoralkylated substances (PFAs). These LMHcs, especially PFAS, do not hydrolyze or degrade in water. Some of these have been reviewed to have adverse health effects while for others the long term exposure effects are still unknown. In order to address removal of these pervasive contaminants, an anion exchange resin polymer (AEP) functionalized Single Walled Carbon Nanotubes (SWCNTs) in the form of NanoResin has been developed. The large surface area of SWCNTs increases the availability of active ion exchange sites of the AEP. These NanoResins have higher & faster adsorption capacity compared to currently commercialized materials like magnetic ion exchange resins, DOWEX, etc.

This NanoResin was synthesized by modified activator regenerated electron transfer atom transfer radical polymerization technique in all aqueous media where the growing hydrophilic polymer brushes get attached the surface of hydrophobic SWCNTs. The hydrodynamic diameters of the purified AEP & NanoResins measured using dynamic light scattering were 1.660 ± 0.10 nm & 194.9 ± 11.3 nm, respectively. The ratio between D & G bands, measured using Raman Spectroscopy, increased by 100% compared to pristine carbon nanotubes which is indication of covalent functionalization of the AEP. The proton nuclear magnetic resonance of the growing AEP showed 33 % conversion from monomer to polymer in 40 minutes. The scanning electron microscopy of nanoresin films fabricated on mixed ester cellulose membrane for performance testing showed a smooth morphology of mesoporous architecture of SWCNTs with conformal polymer coating. The step height of fabricated film (0.046 mg-NanoResin/cm²) measured under atomic force microscopy was 142.31 nm. The measured membrane resistance of the thickest nanoresin film (0.184 mg-NanoResin/cm²) was determined to be R = 2.11x10¹¹ m⁻¹ which is smaller than typical ultrafiltration membranes with R = 2x10² m⁻¹ and hence, demonstrated its high water flux capacity.

We demonstrated the removal of several types of pharmaceuticals (viz., tetracycline hydrochloride and carbencillin disodium), pesticides (viz., bentazon, terbacil, and bromacil), DPBs (viz., bromocetic acid and chlorocetic acid) and PFAS (viz., perfluorooctanoic acid (PFOA) and perfluorooctanesulfonate (PFOS)), from water via adsorption capacity measurements. The percentage removal of PFOA and PFOS, for a starting concentration between 2-4 mg/L of contaminant, was 92.7% and 95.8%, respectively. Since, the US EPA has been challenging systems to measure ~95% removal of PFAS at low concentrations, we established adsorption of PFAS at a starting concentration of 3-5 μg/L and removed PFAS upto ~98%. The regeneration studies performed upto 20 cycles, showed a slope of -0.23 ± 0.18% per cycle which demonstrates that the NanoResin could be regenerated without significant degradation. Recently, we have been employing sonochemistry to synthesize Aq-SNR to be more consistent with the principles of green chemistry.

EPA has been challenging systems to measure ~95% removal of PFAS at low concentrations, we established adsorption of PFAS at a starting concentration of 3-5 μg/L and removed PFAS upto ~98%. The regeneration studies performed upto 20 cycles, showed a slope of -0.23 ± 0.18% per cycle which demonstrates that the NanoResin could be regenerated without significant degradation. Recently, we have been employing sonochemistry to synthesize Aq-SNR to be more consistent with the principles of green chemistry.

We later show is a signature of electron-conduction limitations in PBA NP agglomerates. Galvanostatic cycling of electrodes with different average NP-agglomerate sizes reveals that two-fold higher rate capability is achievable when agglomerate radius reduces two-fold, despite having the same NP size distribution. By way of comparison with theory and by characterizing the effective conductivity of PBA-NP compacts, we show that apparent cation diffusion in PBAs is limited by electronic conduction through NP agglomerates. Building on these findings we also measure the effective electronic and ionic conductivity and hydraulic permeability of porous electrodes incorporating non-conductive nanoparticles from which we build process/structure/property relationships to inform materials selection for desalination devices using cation intercalation materials. We subsequently identify optimal electrode formulations by introducing electrochemical Ashby diagrams with guidelines determined using device-level metrics for electrochemical desalination.

The continual increase in global population, along with a rapid progression towards extensive urbanization and industrialization, serves as the driving force for the upsurge in the development of water desalination technologies. There are only a limited number of ion removal technologies available on the market. Distillation is used for ion streams with high salt concentration, reverse osmosis (RO) is used for both intermediate salt concentrations as well as brackish water, and electrochemical technologies like electrodialysis (ED/EDR) and capacitive deionization (CDI) are used for brackish water with relatively low salt concentrations. In addition to desalination, there is an increasing demand for the selective uptake of ions. Along this line of motivation, CDI has the potential to offer diverse means to accomplish selective ion separation from aqueous solutions.

CDI is a water desalination technology that facilitates adsorption of ions via two oppositely polarized porous electrodes. In a traditional sense, CDI typically utilizes high surface area carbon materials, where the ions are trapped within the electrical double layers (EDLs) formed in the pores of the carbon electrodes [1]. However, in recent times, new hybrid carbon-intercalation electrodes employing materials with redox activity have been introduced to CDI [2, 3], in which the ionic species are stored in the crystallographic sites of the intercalation host compound (IHC).
Preferential ion electrosorption in capacitive deionization (CDI) has been the primary focal point of a number of contemporary studies. In general, the major influential factors that regulate ion selectivity of these porous electrodes include: (i) operating conditions such as applied cell voltage and initial ion concentration, (ii) ion properties like ion valence, hydrated size, and electronegativity, and (iii) micropore characteristics such as chemical surface groups and pore sizes. Hence, the technological hurdles associated with the development of efficient CDI electrodes with enhanced ion selectivity are manifold. Furthermore, a comprehensive knowledge of the underlying mechanisms and the materials involved is of prime importance to enact successful optimization of relevant process parameters (e.g., voltage, current, flow, cycle time), to attain preferable ion selectivity during the adsorption/regeneration phase.

This talk will be centered on the comparative analysis between conventional CDI electrodes with porous carbons, and the most recent intercalation electrodes [4, 5-6], utilized for the purpose of water desalination and selective ion separations. In the case of the latter, redox-active nickel hexacyanoferrate (NiHCF) nanoparticles embedded in a carbon matrix facilitates the intercalation and de-intercalation of Na+ ions, producing fresh water via a cyclic charging and discharging CDI process. Conclusively, alternate materials that can offer potential in advancing ion separation process will be also discussed.

This presentation provides a general overview addressing various material challenges in relation to ion removal within the domain of CDI.

References:
difficult to achieve both high conductivity and high selectivity simultaneously. We have synthesized a series of ion conducting membranes incorporating a novel physical crosslinking mechanism that appear to have significantly increased conductivity with little to no decrease in counter-ion selectivity, compared to covalently-crosslinked membranes. Physical crosslinking also enhances the mechanical properties of the membranes by increasing their ductility. The observed behavior cannot be rationalized via the conventional understanding of the conductivity-selectivity tradeoff, which is based on membrane swelling and its effect on Donnan exclusion. As such, our results suggest that our understanding of the physicochemical factors governing ion sorption and transport in charged membranes is incomplete. In this presentation, we propose an additional physicochemical mechanism to explain our findings and discuss its implications for design and optimization of ion-conducting membranes.

Layered Manganese Oxides as Intercalation Electrodes for Water Desalination via Hybrid Capacitive Deionization Ekaterina Pomerantseva; Drexel University, Philadelphia, Pennsylvania, United States.

With increase in the world population and climate change, the importance of and demand for the water desalination systems continue to grow. Liquid surface freshwater constitutes only ~0.5% of the water available on Earth, and thus, desalination of brackish and saline water is becoming increasingly important as the water crisis escalates. An emerging method, hybrid capacitive deionization (HCDI), is a derivative of capacitive deionization (CDI) approach for water desalination, in which one carbon electrode is replaced with a redox-active intercalation electrode, resulting in substantial improvements in ion removal capacity over traditional CDI. However in order to keep pace with rising levels of water consumption, the performance of HCDI systems needs to be improved while maintaining low cost and minimizing environmental impact. As a result, novel scalable and cost-efficient materials that exhibit superior performance are sought for.

In this study, two crystallographically and chemically distinct layered manganese oxides (LMOs), Na-birnessite and Mg-buserite, were investigated as intercalation electrodes for HCDI. The layers in crystal structures of LMOs consist of edge sharing MnO₆ octahedra, while Na⁺ and Mg²⁺ ions, known as stabilizing ions, occupy the interlayer positions in the Na-birnessite and Mg-buserite, respectively, along with water molecules. The large difference in interlayer spacing of Na-birnessite (7.2 Å) and Mg-buserite (9.7 Å) is attributed to the different amount of structural water residing between the layers: one layer of water in Na-birnessite compared to two layers of water in Mg-buserite. To understand the ion removal performance of these two materials, Na-birnessite and Mg-buserite electrodes were cycled in NaCl and MgCl₂ solutions in an electrochemical cell with the HCDI configuration. The chosen electrode materials and solutions provide a platform to investigate ion dynamics when stabilizing ions in the electrode structure and ions in solution are the same and when they are different. To gain insights into the stability of layered manganese oxides as HCDI electrodes, the cells were stopped after both 200th ion adsorption step (IAS) and ion release step (IRS), followed by post-mortem analysis of the electrode materials structure and composition. Replacing carbon electrode after 200 cycles with a fresh one, allows us to evaluate the contributions of capacity decay related to the structural changes in layered manganese oxides and oxidation of carbon electrodes. Both materials demonstrated excellent initial ion removal performance with the highest capacities of 37.2 mg/g (637 μmol/g) exhibited by Mg-buserite in NaCl solution and 50.2 mg/g (527 μmol/g) exhibited by Na-birnessite in MgCl₂ solution. The performance decay observed over the course of 200 ion adsorption/ion release cycles was attributed to two major phenomena: oxidation of carbon electrode and evolution of the structure/composition of LMO electrodes. The latter involves disorder in stacking of Mn-O layers and changes in the interlayer spacing/interlayer ions reflecting the composition of the solution being desalinated. This work highlights the importance of understanding the interactions between the HCDI electrodes and solutions containing different ions and the structural analysis of redox active materials in intercalation electrodes over the course of operation for gaining insight into the fundamental processes governing desalination performance and developing next-generation HCDI systems with long-term electrochemical stability.

The rate of phase change between the homogeneous mixture and the separated IL/water biphasic mixture upon heating or cooling should be rapid but may require facilitation via proper engineering. An example of LCST ILs continuous flow FO reactor will be presented and discussed. This scheme could radically reduce the energy-intensity of water purification.

Capacitive Deionization—Leveraging the Electric Double Layer for Selective Water Desalination  Eric Guyes, Tahel Malka and Matthew Suss; Technion Israel Inst of Technology, Haifa, Israel.

Capacitive deionization (CDI) is a fast-emerging water desalination technology, most often applied to brackish water desalination and water softening.[1,2] CDI cells desalt feedwaters by storing ions in electric double layers within micropores of electrically charged carbon electrodes. CDI cells have demonstrated a size-based ion selectivity wherein smaller ions are preferentially electroabsorbed over larger ions due to ion volume exclusion interactions.[3] Selective ion removal is a highly desirable feature in water treatment systems, as selectivity mechanisms can be leveraged towards preferential and energy efficient removal of toxins and other undesirable ions. We here demonstrate that the size-based selectivity exhibited by microporous CDI electrodes can be substantially boosted through addition of chemical charge to micropores via surface functionalization.[4] We develop a theory of size-based ion storage in micropores including the effect of chemical charge,[5] which predicts such enhancements and demonstrates they are a result of enhanced counterion crowding in functionalized micropores. Desalting an electrolyte consisting of competing potassium and lithium ions, we demonstrate that a surface functionalized (oxidized) cathode increases the selective removal of the smaller potassium ion. We observe that the largest enhancements are measured at lower cell voltages, for example from a selectivity factor of ~1 for typical electrodes to 1.8 for surface functionalized electrodes at 0.4 V charging voltage. This counter-intuitive result is demonstrated to be due to significant cathode chemical surface charge degradation occurring at higher cell voltages, a phenomenon which has not been previously reported upon in the CDI literature to our knowledge. Model results show that achieving stabilized surface groups at high electrode potentials can lead to further enhancements in size-based selectivity factors achievable by CDI electrodes

9:45 AM ES09.09.04 Enhanced Tunable Ion Selectivity in Flow-Through Electrode Capacitive Deionization with Advanced Carbon Aerogel Electrodes  Patrick G. Campbell, Steven A. Hawks, Maira R. Ceron, Jennifer Knipe, Tuan Anh Pham and Michael Stadermann; Lawrence Livermore National Lab, Livermore, California, United States.

The selective removal of toxic or otherwise undesirable water has the potential to dramatically reduce the cost of water treatment. Capacitive deionization (CDI) removes ions from solution using charged electrodes and has demonstrated significant energy savings compared with reverse osmosis for removal of salt from low salinity or brackish water. By tailoring electrode properties such as pore morphology and surface functionality, as well as cell operating parameters, selective separation of ions can be achieved. Lawrence Livermore National Laboratory’s unique flow-through electrode CDI platform has demonstrated remarkable selectivity for removal of toxic nitrate in the presence of chloride and sulfate ions, as well as tunable preferential absorbance of monovalent over divalent cations based on electrode material properties. In this talk, we will present our latest results including the development of a multi-scale model (FE + QMD) to help elucidate the mechanism(s) for ion selectivity in CDI.

Thursday Morning, April 25, 2019

PCC North, 100 Level, Room 131 A

10:30 AM *ES09.10.01 Water Technologies by Interface Engineering Seth B. Darling1,2,3, Ruben Waldman2,1,3, Hao-Cheng Yang4, Edward Barry4, Subramanian Sankaranarayanan4 and Jeffry Elam1,2; Chemical Sciences and Engineering Division, Argonne National Laboratory, Lemont, Illinois, United States; 3Advanced Materials for Energy-Water Systems (AMEWS) Center, Argonne National Laboratory, Lemont, Illinois, United States; 4Nanoscience and Technology Division, Argonne National Laboratory, Lemont, Illinois, United States; 5Institute for Molecular Engineering, The University of Chicago, Chicago, Illinois, United States; 6Center for Electrochemical Energy Storage, Skolkovo Institute of Science and Technology, Moscow, Russian Federation.

Driven by climate change, population growth, development, urbanization, and other factors, water crises represent the greatest global risk in the coming decades. Advances in materials represent a powerful tool to address many of these challenges. Understanding—and ultimately controlling—interfaces between materials and water are pivotal.1 In this presentation, we will lay out the challenges and present several examples of work based on materials science strategies for addressing applications in water. In each instance, manipulation of interface properties using either atomic layer deposition (ALD) or sequential infiltration synthesis (SIS) provides novel functionality, ranging from selective transport to energy transduction to pollution mitigation.

11:00 AM *ES09.10.02 Anion-Based Redox Pseudocapacitance of the Perovskite Library La1−xSrxB03−δ (B = Fe, Mn, Co) Keith Stevenson2 and Caleb Alexander1;1University of Texas at Austin, Austin, Texas, United States; 2Center for Electrochemical Energy Storage, Skolkovo Institute of Science and Technology, Moscow, Russian Federation.

This presentation will describe the synthesis of a library of perovskite oxides with the composition La1−xSrxB03−δ (x = 0-1; B[KJP1] = Fe, Mn, Co) to systematically study anion-based pseudocapacitance. The electrochemical capacitance of these materials was evaluated by cyclic voltammetry and galvanostatic charging/discharging in 1 M KOH with the highest specific capacitance of 492 F g−1 at 5 mV s−1 for La0.5Sr0.5MnO3−δ. We find that greater oxygen vacancy content (δ) caused by systematic incorporation of Sr2+ increases the surface-normalized pseudocapacitance for the three B-site transition metal series investigated, but the slope of the trends is controlled by the B-site element.
Furthermore, the first all-perovskite asymmetric pseudocapacitor has been successfully constructed and characterized in neutral to alkaline aqueous electrolytes with a maximum voltage window of 2.0 V in 1 M KOH. An asymmetric, perovskite pseudocapacitor’s cell voltage can be increased by increasing the voltage difference between the perovskites’ different transition metal redox potentials in the B-site. Asymmetric capacitors constructed from SrCoO$_2$-$x$, La$_{0.8}$Sr$_{0.2}$MnO$_3$, and BM-Sr$_2$Fe$_2$O$_5$/SrCoO$_2$$_7$ combination performing the best with a high energy density of 31 Wh kg$^{-1}$ at 450 W kg$^{-1}$ and power density of 10,000 W kg$^{-1}$ at 28 Wh kg$^{-1}$.

11:30 AM ES09.10.03

The Flow Efficiency Limits Capacitive Deionization Performance for Relevant Separations

Steven A. Hawks$^1$, Patrick G. Campbell$^2$, Ashwin Ramachandran$^3$, Juan G. Santiago$^1$ and Michael Stadtmann$^1$; Lawrence Livermore National Laboratory, Livermore, California, United States; $^1$Department of Aeronautics & Astronautics, Stanford University, Palo Alto, California, United States; $^2$Department of Mechanical Engineering, Stanford University, Palo Alto, California, United States.

The flow efficiency is an underappreciated loss mechanism inherent to cyclic capacitive deionization (CDI) operation. This efficiency factor ultimately limits performance and desalination depth when approaching industrially-relevant separations. The flow efficiency parameter is defined to reflect the fact that desalinated water inside a cell is partially lost to re-salination if desorption is carried out immediately after adsorption. This efficiency is distinct from, and yet multiplicative with, other highly-studied current efficiencies. Flow efficiency losses can be minimized by flowing more feed solution through the cell; however, this also results in less efficient concentration reduction due to mixing with the feed.

We show that the flow efficiency concept is a key tool for identifying loss processes occurring during desalination, understanding the performance of different operation modes, and recognizing the key scaling factors that underlie the operational response.

Atmospheric Water Harvesting with Composite AQSOA Zeolite Layers

Alina LaPotin$^1$, Sameer Rao$^2$, Hyunho Kim$^2$ and Evelyn Wang$^1$; Mechanical Engineering, The University of Utah, Salt Lake City, Utah, United States; $^1$Korea Institute of Science and Technology, Seoul, Korea (the Republic of k); $^2$Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Atmospheric water harvesting has received recent interest owing to the abundance of water in the atmosphere. This approach is distinct from state-of-the-art dewing approaches because it can efficiently operate in extreme conditions, that is at low relative humidity and temperature. When the moisture content of air is low, AQSOA zeolites (Z01 and 202) are aluminophosphate-based microporous molecular sieves that are stable in water and have been extensively studied for adsorption-based refrigeration. Their pore filling mechanism, i.e., Type IV or V isotherm behavior, leads to a sharp uptake at a low relative humidity (5-15% RH) which is indicative of uniform micropore size and a relatively low adsorption enthalpy. In addition, the adsorption enthalpy and the temperature required to desorb the water vapor is lower compared to other zeolites (e.g., 65 degrees C for AQSOA Z01). In this work, we characterized AQSOA zeolites for water harvesting. One challenge of using solid adsorbents is the relatively slow vapor transport via diffusion in the bulk material. The vapor transport occurs at two length scales: through the bulk material (intercrystalline) and to the pores within an individual crystal (intracrystalline). In a practical device, the intracrystalline transport resistance of AQSOA zeolites can have a significant influence on the kinetics because it occurs over a length scale roughly three orders of magnitude larger than the intracrystalline vapor transport. Transport resistance is also highly dependent on the packing porosity of the adsorbent, which can inhibit mass transfer at high packing densities. Therefore, we fabricated composite adsorbent layers using AQSOA zeolites and metal foam to facilitate both heat and vapor transport. To study the mass transfer characteristics of AQSOA zeolites in this composite layer, we performed adsorption, desorption, and vapor condensation under controlled pressure and temperature. We compared our experimental results to our detailed computational models which capture the diffusive processes at these different length scales. Our results indicate the promise of using composite AQSOA zeolite layers, and can be extended to design other composite adsorbent materials for water harvesting.

Turning a Cheap, Poor Catalyst into a Cheap, Excellent Catalyst—Optimizing Layered MnO-Based Materials for Water Oxidation Using Experiment and Theory

Efficient catalytic water oxidation is an important milestone for the development of solar hydrogen as a source of green energy. Extraction of high energy electrons from water for the preparation of fuel leaves O$_2$ as a byproduct. Nature boasts the only truly effective catalyst for this reaction, the oxygen evolving complex (OEC), a tetramanganese-calcium-oxygen-oxo cluster. The exploration of solid-state manganese oxides inspired by (or possibly a primordial precursor to) this inorganic cluster is of interest for the chemical and electrochemical oxidation of water, and while promising catalysts have been discovered, an understanding of their active sites structures and mechanisms has been elusive, precluding incremental improvements in design. This lecture is focused on the bimimsette phase of MnO$_2$, typically viewed as a poor water oxidation catalyst. The Center for Complex Materials at Temple University is undertaking a combined experimental and theoretical approach where Density Functional Theoretical (DFT), and Molecular Dynamics (MD) computations inform and guide experimental approaches as to understand the functioning of, and thereby identify ways to improve the catalytic activity of these materials. Modification of bimimsette by enrichment with Mn(III) defect sites, intercalated interlayer Co or Ni ions, and alloying of the layers with Co(III) has turned this relatively poor catalyst into one competitive with excellent IrO$_2$, cobalt-oxide-, and double-layer-hydroxide-based catalysts. The discoveries have been guided by MD simulations which show enhanced geometric frustration of water enhances electron transfer rates, and DFT calculations which describe geometric features that optimize band structure for beneficial electronic conductivity and charge separation.

Amorphous Photocatalysts for Photocatalytic Solar-to-Chemical Production

Candace K. Chan; Arizona State Univ, Tempe, Arizona, United States.

In the last decade, remarkable efforts have been devoted to the development of novel approaches and materials to convert solar energy directly into storable fuels and other chemicals. One approach to achieving lower cost, more sustainable photocatalysts is to use amorphous materials. Since high temperature treatments for crystallization are not required, amorphous materials can be potentially much cheaper to synthesize and easier to adapt for large-scale preparation. However, for efficient solar energy conversion, it has been commonly accepted that highly crystalline materials are required for effective electron-hole pair generation and separation. In photocatalytic systems, photogenerated carriers must diffuse to the electrolyte interface to catalyze redox reactions at the surface of the photocatalyst; hence, avoiding recombination at defects in the bulk is important. On the other hand, several recent studies have shown that amorphous or disordered materials can display higher photocatalytic activity than crystalline counterparts, particularly in high surface area and unstructured, and/or mesoporous materials. This can be explained by the fact that small nanoparticles or mesoporous materials have a small bulk volume and large accessibility to the electrolyte. This means that photogenerated carriers only have to diffuse a short distance before they can reach the electrolyte interface where the catalytic reactions occur.

In this work, amorphous titania-based photocatalysts are synthesized using a facile, UV-light mediated method and evaluated as photocatalysts for hydrogen evolution and nitrogen
reduction to ammonia. The photocatalysts are prepared through the direct injection of a titanium alkoxide precursor into a water/methanol mixture, with subsequent hydrolysis, condensation, and polycondensation to form TiO2(OH)x species under UV-irradiation. The resulting amorphous titania materials exhibit an overall higher hydrogen evolution rate compared to a crystalline TiO2 reference (P25) due to the highly porous structure and high surface area (~500 m²/g). Synchrotron pair distribution function data show that the short-range local structure of the freshly synthesized materials is brookite-like, but that ageing and re-crystallization to anatase occurs after storage in ambient conditions.

Under photocatalytic reaction conditions, the formation of surface Ti³⁺ species in the amorphous photocatalyst was observed, as indicated by the deep blue coloration of the materials, is thought to play an important role on the chemical reactivity of the catalyst. The Ti³⁺ species are also used to reduce protons to H₂ in the absence of light irradiation or reduce Pt²⁺ to form Pt nanoparticles. The results show that this is a facile approach for the preparation of high surface area titania photocatalysts containing Ti³⁺ species with good photocatalytic activity and unique porous morphology to overcome the limitations presented by increased likelihood of charge carrier recombination in amorphous materials.

Biomimetic Carbon Nanotube Water Treatment Systems Utilizing Electro-Dynamic Interfaces
Bruce Hinds; University of Washington, Seattle, Washington, United States.

An important challenge for the membrane community is to mimic natural protein channels that outperform, by orders of magnitude, man-made systems based on pore size and coarse chemical selectivity. To mimic protein channel pumping on a robust engineering membrane platforms, applied bias can be used to actuate charged gatekeepers and induce ionic pumping. Carbon nanotubes have three key attributes that make them of great interest for novel membrane applications 1) atomically flat graphene surface allows for ideal fluid slip boundary conditions and extremely fast flow rates 1,2 2) the cutting process to open CNTs inherently places functional chemistry at CNT core entrance for chemical selectivity and 3) CNT are electrically conductive allowing for electrochemical reactions and application of electric fields gradients at CNT tips. The CNT membrane, with tips functionalized with charged molecules, is a nearly ideal platform to induce electro-osmotic flow with high charge density at pore entrance and a nearly frictionless surface for the propagation of plug flow 3,4. Use of the electro-osmotic phenomenon for responsive/programmed transdermal drug delivery devices for nicotine addiction [5]. Electrophotois and electroosmosis phenomena are discussed in detail through CNT conduits. Another approach is to mimic natural protein channel transport cycles with binding/transit/release/reset events. Porous alumina (AAO) membranes have top and bottom electrodes coated with thin Au layers with pore dimension tuned to match protein dimensions. At this thin layer at pore entrances, Ni-NTA is able to bind to hystag residue on target protein, as is commonly employed in chromatography. A binding voltage pulse attracts anionic target protein to top electrode and blocking the pore, while repelling the cationic imidazole release agent. The second voltage cycle attracts cationic release agent to top of membrane while pumping anionic target protein to bottom permeate and resetting the pumping cycle. The separation efficiency of 1cm² of membrane was comparable to conventional 1cm² volumes used in chromatography [6]. Further modeling of system kinetics shows order of magnitude increase in throughput with sub-second cycle times enabled with high imidazole concentrations in a continuous cross flow operation.

Direct Solar Absorption Nanoparticle-Doped Membranes for a Hybrid Membrane Distillation/Photovoltaic Cell
Alejandro Espejo, Drake Norman and Todd Otanicar; Mechanical Engineering, The University of Tulsa, Tulsa, Oklahoma, United States.

The growing demand for clean water supplies is driving the need for an innovative approach of water desalination. Developing a method for treating water with high salinities is possible with membrane distillation (MD). Additionally, MD is very attractive for pairing with solar energy due to the low temperature requirements which integrate well with solar thermal. Integration of a membrane distillation system with a photovoltaic (PV) system will result in the co-production of electricity and clean distillate; and therefore, improve the economics of MD. Such a hybrid system will directly absorb thermal energy in the membrane for desalination while taking advantage of the spectrally selective nature of PV to generate electricity. At the top of the system is a PV cell that will filter the visible light wavelengths and transmit the remaining ultraviolet and infrared to a membrane doped with absorbing nanoparticles located at the core of the system. This provides the means to integrate this system but also provides an avenue for increasing the temperature polarization coefficient and improving the membrane performance. The proposed membranes will be fabricated using a multi-step phase inversion approach that will allow for controlled distribution of nanoparticles across the membrane. The model developed here can be used to systematically evaluate the hybrid design where heat is provided from PV cell waste heat and selective transmission and absorption directly into the membrane. The overall project would lead to increased use of renewable energy for desalination while improving the ability to use MD for desalination purposes. Additionally, the spectral optical properties of the membranes and potential PV cell materials are integrated into the model for realistic device performance predictions.

The Promise and Challenges of Implementing Insertion and Phase Change Compounds in Electrochemical Deionization Devices
Jay E. Whitting,1; and Meagan Mauter1,2; 1Department of Civil and Environmental Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States; 2Department of Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States; 3Department of Engineering and Public Policy, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

Insertion compound materials, which can attract significantly higher volumetric ion concentrations compared to high surface area activated carbons commonly used for CDI, are appealing and still underexplored. These materials posses stable redox potentials that can be leveraged to avoid electrolysis losses and commensurate pH shifts, and can have excellent long-term stability depending on operational conditions. They are also inherently ionically selective in that insertion compound will attract some species and reject others during electrochemical biasing. In this talk, we seek to comprehensively address benefits and challenges of using insertion compounds for CDI in different water concentrations, pH values, and compositions. Specifically, our presentation will explore (a) the origins of electrolysis and other losses in CDI systems and how insertion compounds might be used to overcome these issues, (b) the behavior of two different compound materials in solutions with a wide range of concentrations and compositions, and (c) comparative assessment of deionization devices that used static vs. slurry flow electrodes. Multiple insertion and phase change compounds will be discussed, and their performance in salt concentrations ranging from 10 to 1000 ppm will be discussed using half cell and full CDI device – level data. Results suggest that while better voltage control and volumetric ion densities are possible, overpotential losses and transport asymmetry issues can be problematic, particularly in solutions of lower concentration. The ability for insertion compounds to selectively remove one ionic species over another will also be addressed and contextualized.
In response to compounding challenges to global water-energy systems, researchers are investigating advanced membrane structures to reduce the energy costs associated with separations and fluid manipulations. Janus membranes are an emerging class of separation materials in which the two sides of a membrane are engineered to have opposing properties. Examples of such properties include wettability, surface charge, and catalytic activity. Janus membranes have been studied for oil/water separations, ionic rectification, and efficient water aeration. The Janus property interface’s placement within the membrane is critically important in dictating how the membrane behaves. However, many fabrication methods rely on interfacial reactions that are highly sensitive to processing conditions and offer limited control of the property interface position. A method for fabricating Janus membranes providing tunable control of the property interface position would enable optimization of the Janus structures for advanced fluid manipulations.

We have used atomic layer deposition (ALD) of hydrophilic Al2O3 to achieve Janus membranes on hydrophobic polypropylene (PP) ultrafiltration membranes.1 While ALD is normally considered a conformal material growth technique, two factors in the PP membrane system cause a gradient deposit to form. The trimethylaluminum precursor used to grow Al2O3 has a low sticking probability on PP, and the mean free path of the precursor vapor molecules far exceeded the pore path lengths in the tortuous high-aspect-ratio PP membrane. The combination of PP membrane poor surface chemistry for ALD nucleation and physical dimensions that yield Knudsen flow, coupled with physical masking that limited vapor exposure to one membrane face, are what allowed for Janus membrane fabrication. ALD processing parameters including the number of cycles, duration of each vapor exposure, and purge time between co-reactant vapors, were found to influence the resulting gradient of Al2O3 coverage within the membrane interior. Using energy-dispersive x-ray spectroscopy (EDS) on the membranes prepared in cross-section, the concentration profiles of aluminum as a function of depth in the membrane were measured. These data demonstrated clear control over the shape and position of the concentration profile.

The ALD-derived Janus membranes were used in an anion experiment. The membranes were secured supporting a column of water above pressurized air. Air coated the hydrophobic surface of the untreated PP membranes and was released as large bubbles. In contrast, the hydrophilic surface of the PP membranes was poorly wet by the emerging air bubbles. This served to reduce the adhesion force between the air and the membrane surface, allowing buoyancy to release the bubbles at a much smaller size at the same air flow rate for rapid gas diffusion into the water. These ALD-derived Janus membranes offer a platform for study on the role of gradient wettability interfaces in novel fluid manipulations. Applying this technique to other materials such as TiO2 may introduce catalytic activity as an additional functionality.

Mechanisms of Aqueous Charge Storage and Degradation in Manganese-Rich P2 Oxides

Shelby Boyd1, Natalie R. Geise2, James B. Mitchell3, Rohan Dhall1, James M. LeBeau1, Michael F. Toney2 and Veronica Augustyn1; 1North Carolina State University, Raleigh, North Carolina, United States; 2Stanford University, Stanford, California, United States.

Transition metal oxides are of interest as aqueous intercalation materials in neutral-pH electrolytes for alkali ion batteries and redox-active desalination because of their high capacity and ion intercalation potentials, but few possess high stability in aqueous electrolytes. Understanding the behavior of transition metal oxides, particularly the more stable manganese-based oxides, could enable the design of high capacity, safe, and long-life aqueous electrochemical energy storage. The P2 layered Na3 manganese-rich oxides widely studied in non-aqueous electrolytes have higher theoretical capacities and voltages for Na intercalation than other manganese-based oxides. While they have previously been shown to be redox active in aqueous electrolytes, this work presents the first systematic study of the factors controlling the interlayer chemistry and redox behavior of these P2 materials in aqueous electrolytes. We show the intertwined effects of applied potential and composition on the interlayer chemistry and redox activity of P2 oxides by investigating compositions previously shown to exhibit a range of moisture stability: Na1.82Mn2.86Fe0.12O2 (NaFeMn), Na1.82Mn2.86Co0.12O2 (NaCoMn), Na1.82Mn2.86Cu0.12O2 (NaCuMn), and Na1.82Mn2.85Cu0.15O2 (NaCuMg). When cycled beyond a critical Na content, all compositions experience an irreversible loss of Na in the first anodic cycle and subsequently intercalate water to form a brinesite-like phase. The composition determines the potential at which this critical Na content occurs, with the Cu substituted materials exhibiting greater retention of the P2 phase. The behavior in aqueous electrolytes is characterized using in situ transmission electron microscopy and X-ray diffraction (XRD) to understand the structural effects of the presence of water, and in situ synchrotron XRD to understand the phase transformation accompanying the intercalation of water. In addition, the effect of electrolyte water concentration on the intercalation behavior and potential window is studied using water-in-salt electrolytes. Overall, these results present a study of the factors that determine the stability and performance of P2 oxides in aqueous electrolytes, and offer guidance for designing transition metal oxides compatible with aqueous electrolytes.

Atom Probe Tomography as an Emerging Characterization Technique for Materials Applications to the Water-Energy Nexus

Ingrid McCarroll1, Daniel Haley2, Paul Bagot3, Michael Woody4 and Julie Cairney1; 1The University of Sydney, Sydney, New South Wales, Australia; 2Materials, The University of Oxford, Oxford, United Kingdom.

Here we will present new tools that allow atomic scale characterization of samples relevant to the water energy nexus, providing valuable information about, for example, nanoconfinement or liquid/solid interface chemistry. Custom adaptations to the local electrode atom probe (LEAP) allow for the transfer of atom probe samples, under ultra-high vacuum and cryogenic temperatures, between a purpose built glovebox, an SEM/FIB with cryo-stage and EBSD/TKD characterization capabilities, and the atom probe analysis chamber. Examples of the capabilities of this new environmentally controlled sample preparation and characterization suite are to be presented for the first time. The current research is focused on the phenomenon of hydrogen trapping within steel samples susceptible to hydrogen embrittlement and the corrosion of magnesium alloys. However, the potential application is much broader and could be used for the study of electrocatalytic reactions. Of particular note is the potential of the current workflow to capture and characterize metal/liquid interfaces.

Atom probe tomography (APT) is a characterization technique recognized for its ability to provide near atomic resolution in three dimensions, providing mass-to-charge-state ratios for each identified ion. A recent adaptation to a local electrode atom probe, at the University of Oxford, enabled vacuum transfer of samples between a catalytic reaction cell and the atom probe analysis chamber. This adaptation has been used to analyze magnesium alloys after controlled gas exposure, without the potential for further reactions to occur within incidental atmospheres encountered during sample transfer. Through this study we were able to observe a correlation between the presence of hydrogen within the magnesium alloys and an increased rate of oxidation. This study highlights the ability of APT to characterize properties such as nanoconfinement and interlayer chemistry, key concerns of the water-energy nexus.

4:45 PM ES09.12.05
Chemical Pre-Intercalation as a Means to Control the Structure and Electrochemical Performance of Layered Oxide Electrode Materials

Mallory Clites and Ekaterina Pomerantseva; Drexel University, Chesapeake Beach, Maryland, United States.

Beyond Li-ion (BLI) alkali ion-based batteries are rising in interest among researchers because of their utilization of more abundant, cost-effective charge carriers, including Na+ and K+. In these systems, compared to traditionally used Li+ ions, however, because such systems utilize electrochemically cycling ions with larger ionic radii, achieving fast diffusion and high insertion rates of the BLI carriers into traditional, close-packed electrode materials is challenging. As such, these new systems require the development of novel electrode materials with high capacity, rapid charge transfer, and stable behavior over extended cycling. Materials with open, layered crystal structures have proven themselves among the most reliable electrode materials for Na-ion and K-ion based systems, exhibiting high performance in these emerging systems. Tuning and control of interlayer spacing and chemical composition in open layered structures, can be accomplished via simple wet chemical modification approaches. Such tailoring has the capability to increase ion mobility and insertion rates as well as enable new redox chemistry. One approach that may lead to improvements in electrochemical performance of these electrode structures. Layered vanadium pentoxide (V2O5) phases are promising cathode materials for BLI systems as vanadium can be present in its highest oxidation state, 5+, and can undergo multiple reductions to a 3+ state, allowing for the transfer of up to two electrons per vanadium ion. One family of vanadium oxide phases that demonstrates advanced electrochemical performance in Li-ion and BLI Na- and K-ion systems is the bilayered δ-M3V2O7 family, where M represents alkali (Li+, Na+, K+) and alkal-earthy (Mg2+ and Ca2+) ions.1-3 The bilayered structure is built from double layers of VO2 polyhedra which are separated by a large interlayer spacing. When no ions are intercalated within this
interlayer spacing, the δ-V\textsubscript{2}O\textsubscript{5} phase exhibits an interlayer spacing of 11.5 Å which is stabilized only by intercalated water molecules. In this non-ion containing structure, capacity typically decays over extended cycling, due to lattice breathing and the gradual breakdown of the lamellar stacking of the V-O layers. Ion-containing δ-M\textsubscript{2}V\textsubscript{5}O\textsubscript{10} phases can be synthesized via chemical pre-intercalation and allow for the tunability of the interlayer spacing from 9.65 to 13.44 Å depending on the nature of the inserted ion.[3] Further, synthesis of the electrode materials via chemical pre-intercalation approach can lead to increased capacities and electrochemical stability in Li-ion, Na-ion, and K-ion cells.

This presentation will focus on the chemical pre-intercalation approach as a means to improve electrochemical performance of bilayered vanadium oxide electrodes in Na- and K-ion systems. Electrochemical performance of δ-M\textsubscript{2}V\textsubscript{5}O\textsubscript{10} (M = Li, Na, K, Mg, Ca) in Li-ion cells will also be presented as a reference. This chemical pre-intercalation technique will be demonstrated to improve electrochemical performance through two modes: (1) pre-intercalation of charge-carrying into the bilayered phase can lead to tailored ion transport and increase overall specific capacities, and (2) pre-intercalation of electrochemically inactive ions to stabilize the bilayered structure and improve capacity retention through BLI ion cycling. While this pre-intercalation may lead to the partial reduction of the oxidation state of vanadium present in the structure, high discharge capacities over 200 mAh/g are observed in all three ion-based systems. A detailed study of the mechanism of charge storage and the effect of charge-carrying ion size on demonstrated capacities and electrochemical stability in Li-ion, Na-ion and K-ion batteries will also be discussed.

SYMPOSIUM ES13

TUTORIAL: Data-Driven Design of Sustainable Materials Process and Products in Early State R&D: Al/Machine learning, Coupled Techno-Economic and Life Cycle Analysis, and Metrics for a Circular Economy
April 22 - April 22, 2019

* Invited Paper

TUTORIAL
Data-Driven Design of Sustainable Materials with Artificial Intelligence, Machine Learning and Assessment
Monday Afternoon, April 22, 2019
PCC North, 100 Level, Room 123

Materials are critical enablers for reducing the resource intensity of society’s industrial, commercial and energy systems. But materials themselves also require resources and can negatively impact humans and the environment, thereby compromising the sustainability of our world. To promote materials development for a more sustainable world, it is essential that the material footprint be better understood and improved for all products and processes. Fundamental research is required that addresses: the creation and sharing of sustainability-related data, metrics and assessments of materials, processes, and performance; use of this knowledge to inform sustainability-focused decision making; improved decision-making tools to enable product and process designers and engineers to incorporate sustainability metrics at the earliest stages of the design phase; and establish better defined sustainability metrics for policy makers. This tutorial brings together leading experts in sustainability who are using machine learning and data-driven design of materials and processes to focus equally on the economic, performance and societal dimensions of sustainability.

This tutorial will introduce approaches and tools for quantifying not only the technological performance impacts of selecting specific materials and processes, but also their economic, environmental, societal, and human health impacts. This approach puts design tools in the hands of materials researchers for creating materials and processes that meet the needs of humanity, not just for today but for future generations.

1:30 PM
Using AI for Sustainable Materials: New Approaches, New Challenges Elsa Olivetti; Massachusetts Institute of Technology

Tutorial will present case examples of the role that AI might play in materials development with an eye towards improving environmental and economic sustainability. These examples will be drawn from academic research as well as industrial cases. Particular focus will be on accounting for the context in which a material operates to understand the appropriateness of particular mitigation strategies. Participants should gain insight into methods to quantify environmental impacts of materials choice on all aspects of the life cycle considering the context in which the material operates and the role that data analytics might play.

2:30 PM BREAK

3:00 PM
Tools for Techno-Economic, Life-Cycle, and Logistics Analyses for Creating Sustainable Materials, Processes and Circular economies Hongyue Jin; The University of Arizona

This tutorial will show the power of using techno-economic, life-cycle, and logistics analysis in assessing the opportunity for early-stage technologies to provide sustainable solutions. Techno-economic analysis (TEA) aims to identify, quantify, and ultimately surmount the technical and financial barriers that hinder the commercialization of new technologies, products, and processes. Life cycle analysis (LCA) identifies the environmental hotspots and pinpoints improvement opportunities that influence consumers, companies, and policy makers in their purchasing behaviors, product design, and policy development decisions. Since the data required for LCA is often a subset of the data required for TEA (or vice versa), an integrated study of TEA and LCA is beneficial as it maximizes the knowledge gained from a given set of information. With TEA and LCA, a better knowledge may be obtained from multiple perspectives. For example, TEA informs us of the potential profit structure of a business, which helps formulate a strategy to maximize the financial gain. By combining the knowledge from TEA and LCA, a problem may be formulated for maximizing the overall economic and environmental benefits. One example of such integrated approach is demonstrated by the optimization of reverse logistics. Operations research techniques are applied to develop mathematical models and derive practical solutions. In this tutorial, several examples will be demonstrated for value recovery of rare earth containing products, using TEA, LCA, and optimization techniques described above.
This tutorial will present two tools – GreenScreen for Safer Chemicals and Chemical Footprint Project – and examples of their application for measuring the chemical footprint of products and organizations. Chemical footprinting is the process of measuring chemicals of high concern in products and supply chains. GreenScreen provides a framework for both identifying chemicals of high concern and safer chemicals. Chemical Footprint Project specifies how to aggregate chemical of high concern data from products to the organizational level. This tutorial will detail examples of how companies and standards use GreenScreen to identify chemicals of high concern and safer chemicals, and how companies use Chemical Footprint Project to calculate their chemical footprint, quantify their baseline use of chemicals, and report reductions in their chemical footprint.

**Quantitative Tools to Advance the Use of Safer Chemicals and Sustainable Materials**

Mark S. Rossi; Clean Production Action

This tutorial will present three tools – GreenScreen for Safer Chemicals and Chemical Footprint Project – and examples of their application for measuring the chemical footprint of materials and products. Chemical footprinting is the process of measuring chemicals of high concern in products and supply chains. GreenScreen provides a framework for both identifying chemicals of high concern and safer chemicals. Chemical Footprint Project specifies how to aggregate chemical of high concern data from products to the organizational level. Plastics Scorecard applies GreenScreen to measure the chemical footprint of plastic materials. This tutorial will detail examples of how companies and standards use GreenScreen to identify chemicals of high concern and safer chemicals, and how companies use Chemical Footprint Project to calculate their chemical footprint, quantify their baseline use of chemicals, and report reductions in their chemical footprint.
Metal recovery from electronic product is currently focused on high-volume metals that are easily recoverable and on low-volume, high-value precious metals. Current and future electronics will increasingly contain small quantities of materials which are not recovered in today’s recycling infrastructure. These materials include rare earth elements that are critical to today’s technology-driven society due to their importance to clean energy as well as the risk associated with their near-monopolistic supply. In this talk, an INEMI (the International Electronics Manufacturing Initiative) project will be discussed on value recovery from hard disk drives that include critical materials. Demonstration projects were completed on direct reuse of entire hard drive, direct reuse of voice coil magnet assemblies, transformation of used rare earth magnets into “new” magnets, and production of rare earth oxide from shredded hard drives. The relevant life cycle inventory data were collected from project participants across industries and national laboratories to perform life cycle assessment. Accordingly, the environmental impacts were quantified for each recovery pathway and were compared with the virgin production impacts. The study also identified the environmental hotspots of each technology, highlighting the future work directions. The ultimate goal of this research is to support closing the material loop, reducing solid waste, and aligning industry with circular economy.

Implementing a Circular Economy results in major changes across product life cycles, including new business models, advanced remanufacturing and recycling processes, but might also involve a change of product designs. On the example of circular design trends of electronics products apparent material trends will be explained. Modularity of products is one such design trend, which is supposed to facilitate reparability, recyclability, and/or upgradeability. However, modularity requires some design changes. In case of mobile communication technology, such as smartphones or tablet computers, the most evident design change is the need for connectors to provide mechanical and electrical contact between individual modules. Depending on the nature and use scenario of a connector reliability, robustness, wear resistance and non-reactive surfaces are required. Gold is the material of choice for such interfaces. In recent years the amount of gold used in electronics decreased, now with emerging modularity among ICT devices gold as a material with a high environmental impact might return into devices in larger amounts. For reversible mechanical fasteners a broader range of technologies might be employed, frequently magnets are proposed as a simple and robust option. To achieve strong magnetic forces rare earth elements are used, mainly neodymium or other critical raw materials, such as cobalt. Rare earth elements are not yet properly recovered from waste electrical and electronic equipment, thus modularity might even contradict better recyclability. The presentation will explain different modularity approaches for smartphones, some of these being already available in the market others are still in a conceptual phase. This variety of modularity approaches is related to different value propositions, thus leading also to a broader range of modularity archetypes. Analyzing technologies for modularity leads to a group of “Modularity Materials”, which are essential for such circular design approaches, but at the same time are among those materials with a large environmental footprint or limited recyclability. Furthermore, some standard materials are likely used more excessively, such as module housing or larger printed circuit boards to accommodate for on-board connectors. A Life Cycle Assessment of a modular smartphone shows a roughly 10% higher environmental life cycle impact compared to a conventional design. This needs to be compensated by reaping the Circular Economy benefits of a modular design, i.e. higher likelihood of getting a broken device repaired, extending the lifetime through hardware upgrades and refurbishment. The Life Cycle Assessment of the Fairphone 2 has shown, that a lifetime extension from 3 to 5 years leads to a significantly lower environmental impact despite the use of “modularity materials”. Consequently modularity is an appropriate approach for a Circular Design, but the user is key for a materialization of the theoretical benefits.

With a detailed view on such correlations the presentation gives a sound overview of trade-offs between different Circular Economy strategies. This research facilitates the understanding of future material trends in smart mobile devices and paves the way to improve the whole product eco-system for lower total environmental impacts.

The research presented in this paper is an outcome of the project sustainablySMART. The project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement no. 680640.

Since new electronic technologies for information and communications and renewable energy are developed at a rapid rate, various materials are significantly used in electronic industry. Among them, rare and precious metals need to be secured for the industry regardless of economic and political situations because they are used as essential materials for the technologies. Also, some metals need to be safely managed in the production, disposal, and recycling stages by preventing their releases to the environment because they are hazardous and toxic to human health and ecosystems. Since newly developed technology affects the contents of metals contained in electronic products, technology development itself can positively or negatively affect potential environmental impacts of products. Thus, this study assesses environmental effects of technology development to figure out whether advanced electronic technology is desirable and what metals are to be managed with priority to prevent environmental impacts. Five case studies are carried out to demonstrate the various environmental effects of technology developments: (i) technology evolution of smart phone; (ii) technology transformations from liquid-crystal display (LCD) to organic light emitting diode (OLED) display, hard-disk drive (HDD) to solid-state drive (SSD), and polycrystalline silicon to amorphous silicon and copper/indium/gallium/di-selenite (CIGS) solar photovoltaics (PVs); and (iii) technology convergence to tablet PC. The resource depletion, hazardous waste, and toxicity potentials of the respective technologies are assessed based on the mass and concentrations of metals contained in the samples of the representative electronic products and environmental impact characterization factors used in life cycle impact assessment methods. The results of this study shows that all the technology developments do not contribute to reducing the environmental impact potentials and that the priority heavy metals are different depending on the technology. Therefore, environmental impacts assessments on advanced technology are required to inform manufacturers to reduce the priority materials and potential environmental impacts of advanced technology-based products in the product design stage and recyclers to safely recover and manage rare, precious, and toxic materials in the end-of-life stage for sustainable circular economy.
Additive manufacturing (AM) is beginning to enter commercial manufacturing, but its environmental impacts can often be larger than traditional mass manufacturing. Many inventors are developing new "green" materials for 3D printing, but almost none have measured their benefits, and no government agencies have set targets for desired impacts. This study establishes a protocol by which to quantify environmental and functional properties of AM materials, to guide the industry towards developing more sustainable materials and processes.

Previous studies show that AM's environmental impacts are dominated by the energy used during printing, but alternative materials can radically decrease AM energy demand. Instead of necessitating high temperatures to melt thermoplastics, materials that bond or harden chemically at ambient temperature can reduce printing energy use, while also reducing other environmental impacts such as resource depletion, toxicity, and waste. In order to identify viable green alternatives that meet industry performance standards and provide gains in sustainability, this comprehensive protocol combines three environmental metrics into one overall sustainability score and combines three market viability metrics into one overall functionality score. Together, these can be used to aid decision-making, benchmarking, and goal-setting, to drive the industry toward more sustainable production.

Based on the National Academy of Sciences (NAS) method for chemical alternatives assessment, this protocol is customized for relevance to AM. The three environmental metrics are whole-system life cycle assessment (LCA), toxicity, and resource circularity. The LCA integrates seventeen ecological impacts into a unified score using the ReCiPe methodology, and measures not only material production, but the whole printing system, including printing energy, printer embodied impacts, and end of life. Resource circularity is calculated using the Cradle to Cradle Nutrient Reutilization formula. Toxicity is measured using an enhanced version of GreenScreen, using its eighteen hazard categories but providing additional precision and displaying uncertainties (quite common in hazard data). The three functionality metrics are mechanical performance, cost, and expert print quality evaluation. Mechanical performance is measured by a combination of ultimate strength and modulus of elasticity, comparing to ABS plastic's properties. Cost includes only the cost of materials, not saved printing energy costs, because the latter are usually small. Print quality is measured by industry experts handling physical samples and quantitatively rating them on a Likert scale while adding qualitative comments.

Once environmental and functional scores are determined, new alternative materials can be compared to other AM materials, such as ABS and PLA plastics, and can be evaluated on their fitness for a variety of AM applications. This should help inventors of new materials quantify their benefits; it should also help set benchmarks of current best practices and targets for future goals. Together, these metrics and goals can drive the additive manufacturing industry toward a future that is not more damaging, but more sustainable than current production.

Additive manufacturing methods have great potential for rapid production of parts and devices in remote areas with limited access to supply chains. This work examines the use of mineral resources for inexpensive and low-energy additive manufacturing. In particular, Earth abundant minerals in conjunction with polymeric binders such as polyethylene glycol (PEG) were used as the material base to print structural components. Silicate, basaltic, and other refractory minerals were chemically functionalized and incorporated in tandem with binders in fused filament fabrication (FFF) or in paste printing. Filaments with powder loading up to 50 vol.% were achieved and used in a commercial FFF printer to fabricate structures, while higher loading was achieved in printing similar structures using commercial paste printers without compromise in structural and mechanical integrity. This work paves way for efficient in situ resource utilization in hostile environments.

Additive manufacturing and 3D printing are synonymous with rapid prototyping and production in limited quantities of or more complex parts and design. Can 3D printing be an important component of a more circular economy? Will it replace traditional high throughput manufacturing? What are the materials challenges for the Six-R concept? Polymers and metals are the materials of primary interest for materials sustainability. An important aspect of 3D printing is distributed production and digital manufacturing that can cross traditional blockchain supply models and distribution. This talk will outline and review important developments and the value chain of 3D printing towards the following: 1) Challenges of adopting the right 3D printing methods and the intricate relationship with the starting material and desired part properties, 2) Savings in time, cost and reduction of waste materials in 3D printing by materials design, 3) Unique applications of 3D printing and replacement of traditional manufacturing modes towards high performance and limited production, and lastly 4) Bio-inspired and design paradigms towards high strength and lightweight materials from aeropace to biomaterials. The talks will also highlight our work employing fused deposition modeling (FDM), selective laser sintering (SLS), and stereolithographic apparatus (SLA) or photopolymerized fabrication of nanocomposite materials. Lastly, the importance of designing polymer materials for the six-R can be emphasized in the early stages of new materials and process development.

Additive for Clays as a Sustainable Alternative in Construction

The construction is a sector that consumes a significant part in the environmental impact throughout the life cycle. Along with the infrastructure, consume on average half of the materials extracted from the earth's crust. Likewise, it adds millions of tons of CO2 poured into the atmosphere each year, accelerating the greenhouse effect and global warming. With this situation, many efforts begin to be notable, innovations and inventions are made every day in order to reduce the degradation of the environment. One of the most promising paths is the use of sustainable materials in the building, among which clay stands out for its characteristics, such as disposal, reintegration into the environment and low energy cost. The present article presents the results of laboratory tests of clay mixed with an additive of natural components for the most part, which improves the resistance of the clay to compression, as well as the drying time, which allows its hardening without the need of high temperatures. The text also suggests that clay with additive can be used in the construction of building elements such as bricks, in molds or extruder methods.

Approaches to the Development of Environmentally Friendly and Resource-Saving Technology for Solar-Grade Silicon Production

Currently, the main material for the production of solar cells is still silicon. More than 70% of global production of solar cells is silicon based. For solar-grade silicon production the technologies based on the reduction of silicon from organosilicon compounds are mainly used. These technologies are energy-consuming, highly explosive and unsustainable. The paper presents the comparison results of a new chlorine-free solar-grade silicon production technology based on purification of metallurgical-grade silicon by vacuum-thermal
methods with the existing technologies. The proposed technology provides environmental safety, energy consumption reduction, the process scalability and the cost reduction of obtained silicon.

In this paper, the following studies have been carried out—technical processes of vacuum-thermal and plasma-chemical purification of metallurgical-grade silicon under the conditions of electromagnetic stirring of silicon melt by the mathematical modeling; comparison study of the existing technologies for the production of solar-grade silicon and the investigated technology as far as material consumption, energy intensity of the processes concerned.

The research results are—the results of the study of a new chlorine-free technology for solar-grade silicon production are shown; a comparison study of the existing solar-grade silicon production technologies and the investigated technology is performed; it is shown that the use of the proposed technology reduces the cost, material consumption and energy intensity of the process.

ES13.02.02 Structural, Optical and Electrical Properties of Transparent Conducting Oxide Based Thin-Film Transistors Kelsey Yarbrough, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, Norfolk, Virginia, United States.

In the past few years, intensive studies on oxide thin film transistors (TFTs) have been reported for their widely use in driving active matrix organic light emitting diodes (OLEDs). Zinc oxide (ZnO) has been the primitive material that is widely used to fabricate TFTs due to its good optical and electrical properties, good uniformity, and low process temperature. Among various ZnO-based TFTs, one of the most promising materials is indium gallium zinc oxide (IGZO), which shows high electron mobility. However, IGZO thin film requires high film deposition and annealing temperature as well. Similarly, indium element is a rare element, and the storage of indium in the form of ore is very limited on earth. The indium-free oxide-based channel materials such as tin doped zinc oxide (TZO) thin film deposited on glass substrate have been optimized using physical deposition technique and their structural, optical and electrical properties have been extensively studied. Sn is a non-toxic, abundant on earth, and it is reported to possess excellent electrical and optical characteristics. This work focuses on TZO thin film performances grown by Pulsed Laser deposition on n-type silicon and glass at different temperatures to analyze the effect of growth morphology. The effect of Sn content on microstructures, surface morphology and optoelectronic properties of the films were investigated by X-ray diffraction, Atomic Force Microscopy (AFM), Field Emission-Scanning Electron Microscopy (FE-SEM), Ultra-violet visible spectroscopy, and electrical characteristics. AFM provided thin film roughness, grain size, and surface morphology for both glass and silicon substrates. FE-SEM was used to show the surface morphology with change in deposition time and temperature. The present work will provide valuable scientific input of TZO thin films for the improvement of TFT devices.

ES13.03.03 Establishment of a Tea-Waste Recycling System Based on the Concept of Chamu Pin Gao, Kyushu University, Fukuoka, Japan.

Tea produces a large amount of waste during the production process, and the current use of such tea waste does not fully exploit its value. This study reprocessed tea waste to create a new kind of biodegradable material dubbed CHAMU, and, based on the Six-R processes, the concept of a tea-waste recycling system was proposed. In studying this concept, the composition and characteristics of tea waste were analyzed through a literature review. Tea waste is classified into fiber and non-fiber elements, and the different kinds of waste should be processed in different ways. In a molding experiment, the fiber waste was subjected to hot pressing and injection-molding, while the non-fiber waste was subjected to an injection-molding experiment. A universal testing machine (UTM) was used to test the mechanical strength of the CHAMU material, and the biodegradability of the material was examined using the soil-burial test method. These experiments established the practicality of the tea-waste recycling system. The article concludes by describing how the CHAMU material was redesigned to make a series of CHAMU products, and, using the method of design and perceptual analysis, discusses the potential of the high-value-added recycling of tea waste based on this system.

ES13.03.04 Thermomechanical Design Optimization for Low Metal Footprint in Hybrid Metal-Polymer Heat Exchanger Manjushri C. Rajagopal, Ho Chen Cheng, Yuquan Meng, Gowtham Kantumalla, Timothy Man, Gabriele Balamontte, Shreemath Sundar, Han Yang Zhao, Srinivasa Salapaka, Placid Ferriera, Chunfai Shao, Nemad Miljovic and Sanjiv Sinha; University of Illinois at Urbana-Champaign, Illinois, United States.

Material and maintenance costs of metal-based heat exchangers surpass profits in waste heat recovery (WHR) from ultra-low temperature (<100°C) sources [1]. A low-cost alternative like polymer pipes suffer from poor thermal conductivity (~0.2 W/mK), and a low overall heat transfer coefficient. Polymers’ thermal conductivity have previously been enhanced through systematic molecular alignment by stretching [2], chemical vapor deposition of extended polymers [3], surface grating [4], etc. However, these approaches suffer from scalability issues for WHR heat exchangers in terms of cost [3], and thermomechanical considerations [5]. In this work, we propose novel hybrid metal-polymer heat exchangers that are made from polymer-copper strips. Through finite element method (FEM) simulations, we first optimize the placement of copper around polymer strips to enhance the transverse thermal conductivity of the strips. The copper cladded polymer strips are wound helically in a roll-to-roll system to form the pipes for a heat exchanger. We then optimize the design of helically wound pipes to reduce thermomechanical strains (< 0.2 % at 100°C and 40°C working conditions. At 25 % volume fraction of copper in the pipe, we predict up to 20 % enhancement in overall heat transfer from a base polymer with a thermal conductivity of 0.2 W/mK. We also compare and contrast the thermomechanical performance of the optimized metal-polymer strips to random metal matrix composites. Finally, we experimentally verify the thermal conductivity of the optimized strips through bulk thermal conductivity and thermal interface resistance measurement setup. By systematically improving the design through FEM and experimental measurements, we provide an optimized design of hybrid metal-polymer pipes that provides a low metal footprint and cost-effective means for harvesting waste heat from ultra-low temperature sources.

Recycling is not an objective in itself, but for the benefit it can bring, including reductions in life-cycle costs, energy use and environmental impacts, and dependence on scarce or imported materials. The options available now for recycling of lithium-ion batteries are not optimal, so research and development (R&D) is needed to make economic processes available for use by the time large volumes of batteries from electric vehicles and other uses go out of service. Even if they find a second use, the batteries will eventually be unusable, and the material will need to be recycled. However, by then the material could be a 20 year-old formulation with little residual value from its structure or contained elements. In particular, cathode formulations are evolving towards varied morphologies, emphasizing formulations that contain reduced quantities of cobalt (the valuable element sought in most current recycling operations), reducing the incentive for recycling with standard pyrometallurgical or hydrometallurgical methods.

Several key questions must be addressed by R&D. Most of these are related to the cathode, which is the most valuable form of material that can be recovered. How can the cathode be separated from the other cell components? Can they be recovered as well? How can optimal cathode function get restored? Can we separate one cathode type from another? Can we modify the cathode composition or morphology to update it for reuse? This presentation will describe new research projects to address these questions.

8:30 AM *ES13.04.02
Niobium Technology—Production, Properties and Applications Rogerio M. Ribas1 and Robson d. Monteiro1,2; Catalysis Consultoria Ltd, Rio de Janeiro, Brazil; CBMM, Araxá, Brazil.

Niobium is a Group V element with relatively abundant of 20 ppm in the Earth’s crust. Though it is not rare and its natural occurrence is similar to most of the transition metals, niobium enjoys a limited market demand, of around 52,000 tons in 2016. Major producing countries are Brazil, with the world’s largest proven deposits that account of more than 80% market share of niobium products, and Canada [1]. Niobium chemistry is very rich and versatile owing to its mult-valence states (-1 to +5), which implies in very attractive physical and chemical properties. Niobium oxides and related compounds show a large variety of polymeric structural modifications and metastable phases. These features allow niobium oxides to be extensively used in the preparation of heterogeneous catalysts and of many roles they can play in catalytic formulations are as active phase, solid acids, promoters, supports and redox components. Several industrial applications are found in selective oxidation, acid-catalyzed reactions, biomass conversion and emission control technologies [2]. More recently, the use of niobium has been extended to energy-related materials by exploring its electronic properties into storage and energy conversion devices such as supercapacitors, fuel cells, lithium-ion batteries and electrochromic materials [3]. The purpose of this contribution is to give an account of the current status of the global niobium industry and its supply of niobium products. It will also highlight the most relevant industrial developments of niobium-containing heterogeneous catalysts and energy-related materials.

9:00 AM *ES13.04.03
Integrating Criticality and Sourcing Considerations into Material Selection Decisions Gabrielle Gaustad1, Michele Bustamante2, Alexandra Leader3 and Elsa Olivetti2; 1School of Engineering, Alfred University, Alfred, New York, United States; 2Massachusetts Institute of Technology, Cambridge, New York, United States; 3Rochester Institute of Technology, Rochester, New York, United States.

Critical and strategic materials are characterized by their importance in key applications and their vulnerability to supply chain disruptions. Much current research focuses on identifying and quantifying metrics and indicators that can predict potential supply chain risks for these materials. Sourcing also plays an important role in the environmental impacts of these materials as well. The complexity of both environmental impact and criticality metrics creates challenges to their integration in traditional material selection tools. This work examines the potential for synthesis of these tools in several case study material systems from the clean energy, defense, and electronics industries. This research work uses a functional unit framework borrowed from life-cycle assessment methodologies to quantify metrics for substitution that can better capture functionality trade-offs. It also uses techno-economic analysis to identify material systems where disruptive adoption could cause criticality induced price volatility. Results indicate this approach has several advantages over current qualitative and semi-quantitative indicators and may be better equipped to inform firm-level research and development activities.

9:30 AM *ES13.04.04
Assessing the Environmental Benefits of Materials Recovery in Commodity Materials Elsa Olivetti; Materials Science & Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Environmental benefits attributed to recycling rely on the assumption that we are substituting energy intensive primary production for lower-impact secondary production. However, this argument tends to be a purely engineering lens on a complex socioeconomic system. Research has begun to test whether closing material and product loops does, in fact, prevent primary production. The basis for this counter argument is that when secondary replaces primary, it decreases the price of secondary and thus more primary will switch to secondary if possible, causing primary price to drop, and driving up demand for more primary which may negate the potential for substitution. There is a strong parallel in this argument to the concept of energy efficiency rebound, and is also related to as the potential for secondary material to displace primary production. The critical aspects that influence displacement are the ability of secondary products to substitute for primary products, and price effects. This presentation will describe tools and analytical modeling efforts that explore the potential for recycling displacement for the case of commodity materials such as paper, copper and aluminum. These approaches help to assess the contexts under which recycling may reduce a material or product footprint.

Challenges and Opportunities for Sustainable Materials Use and Circular Economies in Photovoltaics and Lithium-Ion Batteries Dustin Mulvaney; Department of Environmental Studies, San Jose State University, San Jose, California, United States.

Photovoltaics coupled with lithium-ion battery storage are widely heralded as a major part of climate and air pollution solutions, and early evidence from sustainability science support these claims. However, reaching terawatt levels of global photovoltaic electricity generation will require innovations, policies, and practices to encourage sustainable materials use. Some photovoltaic technologies rely on significant portions of the overall demand for several key metals for semiconductors suggesting future supplies will need to be augmented by circular economy concepts. By 2045, the total mass of electronic waste from photovoltaics will pass all other e-waste combined, suggesting this could be a major source of future supplies of key materials. Similarly, some of the metals used to make lithium-ion battery have supply chains that are linked to human rights abuses and environmental contamination in developing countries, with some companies announcing intention to recycle key materials or avoid sourcing them in the future. My talk will highlight the motivations for a circular economy, identify the challenges and opportunities to transition away from linear material flows in photovoltaics and lithium-ion batteries, and describe recent trends in sustainability and corporate social responsibility (CSR) in practice in these sectors. Key quantitative key metrics produced by life cycle assessment (LCA) will be presented alongside qualitative evaluations (embodied environmental justice). I will also review emerging standards and frameworks (certifications, supply chain disclosures) used to evaluate, highlight and promote sustainability efforts. My talk will conclude with a critical discussion about the limitations of LCA metrics and CSR information that describe and document the environmental, health, and safety performance of these clean technology manufacturers and their supply chains and suggest how to make LCA, sustainability policy, and CSR efforts generate more actionable information to inform circular economy solutions to enhance the benefits of solar energy coupled with energy storage.
Sustainable Development of Silicon-Based Nanocomposite Materials for Next Generation Lithium-Ion Batteries For Electric Vehicles

Chris Yuan, Case Western Reserve University, Cleveland, Ohio, United States.

Current lithium ion batteries used on board of electric vehicles have small energy density due to the small specific capacity of electrode materials used. Silicon nanomaterials, with high specific capacity, are widely recognized as promising anode materials for next generation lithium ion batteries. However, current manufacturing processes developed for producing silicon nanomaterials for lithium ion batteries have significant sustainability issues in terms of heavy use of toxic chemicals, generation of nanoparticle emissions, and high energy consumptions. In this presentation, we will report our most recent results on sustainable development of silicon-based nanocomposite materials for next generation lithium ion batteries. Both mathematical modeling and experimental studies have been employed to study the process wastes and emissions from silicon nanomaterial fabrications. Life cycle assessment (LCA) has also been employed to evaluate the cradle-to-grave environmental impacts of two types of lithium ion batteries using silicon nanowire and silicon nanotubes, as anode in the lithium ion battery. The results could be useful for supporting sustainable development and scale-up of silicon nanomaterials for lithium ion battery applications on electric vehicles in future.

2Mechanical and Aerospace Engineering, University of California, Irvine, Irvine, California, United States;
3Population Health and Disease Prevention, University of California, Irvine, Irvine, California, United States.

The increasing recognition of environmental impacts from the production and usage of conventional energy resources demands that electric grids must achieve high renewable energy adoptions to reduce these impacts. California has established goals to meet, by the year 2050, 100% of the electric demand with carbon-free energy resources and an 80% percent decrease in economy-wide greenhouse gas (GHG) emissions compared to 1990 levels. Meeting these goals will require the deployment of energy storage systems to manage variable renewable resources such as wind and solar. Flow batteries have the advantage of scalability to high capacities, the separation of energy and power modules, long cycle life, and fast response times. While significant research has focused on improving flow battery performance and efficiency, few studies have explored their potential environmental impacts. In this study, we perform a materials life cycle analysis to evaluate the environmental impacts of three battery chemistries. The environmental impacts associated with the raw materials extraction, product manufacturing, and product assembly are evaluated and compared using SimaPro and EcoInvent, with an emphasis on global warming potential (GWP), ozone depletion potential (ODP), particulate matter (PM), acidification (AP), eutrophication (EP), abiotic resource depletion (ADP), cumulative energy demand (CED), and eutocicity (ETP). Impacts associated with the use-phase of flow batteries were evaluated through the application of the energy systems modeling tool HiGRID. The results provide insight into the effects of product design and material selection choices on the potential environmental footprint of these novel energy storage devices.

3Chemical Engineering, Purdue University, West Lafayette, Indiana, United States;
4Mechanical Engineering, Purdue University, West Lafayette, Indiana, United States.

Life cycle assessments (LCAs) are a standard method to perform accurate and thorough environmental assessments on a variety of products and processes. These assessments can be used to generate data about the environmental impact of a product throughout its life cycle, and can be performed to inform decisionmakers, support policy, and guide design. Ideally for product design, LCAs will be performed at every stage throughout the development process. Practically, system and informational limitations create trade-offs between design freedom and assessment reliability: the earlier an assessment is performed the less comprehensive it can be, but the later an assessment is performed the less the design can be changed. Considering this trade-off, this work outlines a life cycle assessment that has been completed on a Cu2AsS4 semiconductor that is a strong alternative solar absorber candidate—if it can be developed sustainably.

Cu2AsS4 has recently gained attention as a solar absorber material after Yu et al.1 calculated its high absorption properties and high spectroscopic-limited maximum efficiency. Density functional theory (DFT) calculations suggest this material may be tolerant to deep defects;2 and it has been experimentally determined to have an ideal direct band gap and exhibit strong photocurrent characteristics on a natural mineral sample.1 Only recently has this material been synthesized into a thin film solar cell architecture and demonstrated a non-zero photoconversion efficiency.3 In conjunction with improving its efficiency, the objective throughout development is its sustainable design, which is particularly relevant for the development of Cu2AsS4 because of the inherent risk of developing a technology that contains arsenic. Although sustainable development must consider more than only an environmental perspective, this work serves to establish the basis of the environmental implications of this potential technology. We present a cradle-to-cradle life cycle assessment of this material and compare its potential impacts to other renewable and non-renewable energy technologies. Scenario and sensitivity analyses are completed to understand the degree of impact that design parameters have on the environmental performance. This information will lead to a discussion on considerations for the sustainable design of Cu2AsS4 solar technology.

Validation of Ostrom Principles to Support the Circular Economy in Used Electronics
Mark Schaffer, Carol A. Handwerker and William Olson; iNEMI, Pflugerville, Texas, United States.

Metals recovery from electronic product recycling is currently focused on high-volume metals that are easily recoverable and on low-volume, high-value precious metals. Current and future electronics will increasingly contain small quantities of materials which are not currently recovered in today’s recycling infrastructure. Trends toward miniaturization, product dematerialization, and increasing materials heterogeneity create increasing challenges with respect to materials recovery, and the financial viability of electronics recycling
generally. In particular, the project examined whether conditions exist in the electronics and recycling industries to develop a voluntary, community-based solution involving adaptive governance systems to self-manage used electronics as common pool resources. This concept was inspired by the work of Dr. Eleanor Ostrom (2009 Nobel Laureate in Economics). It was concluded that the necessary conditions do exist, and that the time was right to take the next steps. Therefore, the International Electronics Manufacturing Initiative (iNEMI) undertook a collaborative project to examine the role its members could play in increasing materials recovery, while promoting sustainable electronics. The main take-home message from the project was that the situation is bad and getting worse if we consider materials recovery as the only option for end-of-use (EoU) electronics. As a result of that project, a new iNEMI project was then launched to focus on value recovery from hard disk drives (HDDs), including multiple existing and possible future dimensions of an EoU system that could improve its effectiveness, financial viability, and sustainability. The dimensions examined ranged from reuse and remanufacturing of HDDs to reuse of components, transformation of components for use in other applications, and recycling of critical materials as well as commodity materials being lost under the existing recycling paradigm. The project aims to study and implement a proof of concept of the necessary conditions and issues involved to develop a voluntary, community-based solution involving adaptive governance systems to self-manage common pool resources. Though the focus is on the reuse and recovery of spinning media (Hard Disk Drives) and rare earth magnets, the principles can be applied to any used electronic product.

It includes:
- Identifying Criteria for Enabling Reuse of used, functioning HDDs and of components from used, non-functioning HDDs
- Identifying Criteria for Enabling Reuse of HDD components in HDD applications – both direct and indirect for metal components, disks, magnets, motors, head, PWBs etc.
- Identifying Criteria for Enabling Reuse of magnets in non-HDD applications

Developing economic and logistics estimates for cases studies

Establishing necessary Design principles for the system for value recovery

Conducting a Demonstration project on HDD recovery to validate the principles identified

Benchmarking the current reuse and recovery (direct, indirect) and barriers with stakeholder input

Identifying the Leverage Points, mapping the supply chain, and identifying key gaps for developing a circular economy including each value pathway for HDDs

A Practical Means for Assessing Circular Economic Value of an ICT Product Mark Schaffer, iNEMI, Pflugerville, Texas, United States.

A review of existing recyclability and reusability metrics revealed that the industry has limited means of practically assessing circular economic value (recyclability, reusability, reparability and refurbishabilty) of an ICT product. Current mass-based metrics, in their most simplistic form, are deficient. Product designers control material and design choices which affect downstream end-of-life costs, while the market controls the materials that are recovered. Yet, no metric or guidance links these attributes together. The iNEMI Reuse and Recycling Metrics Project team has been developing a practical means for assessing the circular economic value of an Information and Communication Technology (ICT) product with the focus on incorporating score factors that assign reasonable impact value to product design features along with the ability to recover (whole products, parts) and return value (from, recycling and/or energy recovery) back to the market. Included in this scoring factor are highlighted aspects that are within the product designer’s control such as material choice and ease of liberation of components and materials and those aspects outside the product designer’s control such as the availability of recovery for reuse/recycling technologies in the markets where the product is placed. The metric assigns a reasonable impact value based on the design and a weighted recovery rate, which brings the actual results into the traditional mass-based metrics. The project is developing an assessment tool for the ability to disassemble a product for repair, reuse, parts harvest, material recovery, or energy recovery/landfill.

ICT stakeholders, including product designers, manufacturers, customers, recyclers, governmental authorities, and environmental advocates can use this means to assess the relative impact of product design choices early in the product life cycle. This will benefit both the industry and the environment to achieve sustainability. The intention for the metric is to identify gaps that prevent return to market value by highlighting the most impactful action(s) needed to close the gaps, and to inform product designers and manufacturers of the end-of-life impacts of their decisions.

The recycling of waste electrical and electronic equipment (WEEE) has been a great challenge for the recycling industry in the last decades. Predictions on the future volume of such waste shows that it will rapidly increase during the coming years (Baldev et al., 2015). Some of the waste fractions derived from WEEE are considered to be hazardous, since they contain toxic compounds restricted by the Directive of EU (2002) for Hazardous substances in WEEE. Therefore, the scientific community are focusing on finding alternative processes in order to minimise their environmental impacts and eliminate the risk of human exposure during recycling. Previous studies have investigated several processes for recycling of WEEE in terms of materials or energy. Pyrolysis is one of the alternatives which combines both energy and partially materials recovery through its production of oil and gas. Moreover, the solid residue, which contains high percentage of metals in non-oxidised form can be recovered through hydrometallurgical process.

The current study involves the decomposition of three representative WEEE fractions, collected at a recycling plant located in Sweden focusing on feedstock recycling. The experiments are performed in a thermogravimetric analyser (TGA) in order to evaluate their decomposition behaviour. Furthermore, pyrolysis experiments have been performed at different temperatures (300-700 oC) in order to correlate the pyrolysis products with the choice of temperature. Through these experiments a kinetic study has been performed aiming to design a process that can maximize the production of specific organic compounds while minimizing the evolution of brominated compounds, which are usually present in the oil (Evangolopoulos 2015).

Tests were also performed in a semi industrial continuous pilot plant designed to treat 1kg of WEEE per hour. The experiments examine the possibility of releasing less brominated compounds according to the different tested temperature conditions. Moreover, the properties of the oils obtained by the process was also investigated experimentally in order to conclude to the application of this as a new material for feedstock recycling or for energy purposes. Finally, the results shows a route that should be followed for implementing pyrolysis in order to minimize the material and energy losses in the concept of circular economy towards a more sustainable way of recycling the WEEE.

Life Cycle Assessment of Bioleaching in Rare Metals Recovery Annemarie Falké1 and Michael Höck2; 1Institute of Business Administration, esp. Resource Management, Technische Universität Bergakademie Freiberg, Freiberg, Germany; 2Institute of Industrial Management, Technische Universität Bergakademie Freiberg, Freiberg, Germany.

In light of growing demand and pollution versus a finite amount of resources, electronic waste recycling is a way towards material circularity. Due to the complex composition of end of life products and the physical characteristics of the materials, it becomes more difficult to recover pure metals from the waste stream. Especially rare metals, which, although abundant in the earth’s crust, only occur in low concentrations, are a sought after commodity as they are important for the economy and are found in numerous products.

The novel existent technology of using bioleaching as a hydrometallurgical process to win indium from electronic waste will be assessed exemplarily. This presentation will focus on preliminary results of batch trials in a lab scale bioreactor, whereby Indium was recovered from the electronic waste recycling process. Hereby Life Cycle Assessment is used to
4:30 PM ES13.05.06/ES14.01.06
Closing the Loop on Fiber Reinforced Composite Materials Ryan S. Ginder, 1, 2 and Soydan Ozcen; 1, 2 Mechanical, Aerospace and Biomedical Engineering, The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 1 Chemical Sciences Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

In the push for a more sustainable economy, fiber reinforced polymer composites (FRPCs) have proved an important component in implementing this vision. FRPCs have improved energy efficiencies in the transportation sector through the lightweighting of vehicles, such as aircraft and cars, and have enabled alternative energy technologies such as wind. The increasing use of FRPCs, however, has led to a corresponding increase in composite waste, such as production scrap from carbon fiber composite aircraft and accumulating end of life wind turbine blades. Up until the last half decade or so, no successful techniques for recycling these materials existed resulting in near 100% of all FRPCs being destined for landfill. Recent successes repurposing waste-to-energy pyrolysis technology, already developed for the processing of feedstocks like e-waste, have resulted in accumulating end of life wind turbine blades. Recent successes repurposing waste-to-energy pyrolysis technology, already developed for the processing of feedstocks like e-waste, have resulted in accumulating end of life wind turbine blades. In these pyrolysis systems, polymer matrix materials are converted to energy while the reinforcing fiber is reclaimed for 2nd generation (and beyond) composite production.

In this talk, research efforts to extend the success of rCF to the recycling of glass fiber reinforced composites (GFRCs) will be discussed. GFRCs comprise over 90% of all FRPC production; however, they also exhibit numerous technical challenges that have limited progress in their recovery. Emphasis will be placed on addressing glass fiber embrittlement incurred during pyrolysis processing and re-engineering fiber surface chemistry for redispersion in new polymer resins. Optimized recovery and postprocessing are essential for producing recycled glass fiber (rGF) of sufficient value that can economically support a rGF industry and begin closing the loop on FRPC materials writ large. Discussion will also include details from initial pilot plant scale pyrolysis trials completed in partnership with the Institute for Advanced Composites Manufacturing Innovation (IACMI) and the American Composites Manufacturers Association (ACMA).

4:45 PM ES13.05.07/ES14.01.07
Characterisation and Determination of the Industrial Potentials of Ugwuaji Clay Deposit Nkem E. Nwankwo; Metallurgical and Materials, Nnamdi Azikiwe University, Awka, Nigeria.

A characterisation study of a virgin clay deposit has been undertaken from Ugwuaji clay deposit in Enugu South Local Government area of Enugu State. The work done consist of chemical analysis, morphology and microanalysis of sample clay with Scanning Electron Microscope equipped with energy dispersive spectrometer (EDS), the major elements are determined by X-ray Fluorescence (XRF), the relative phase quantities of wt% and phases estimated and identified with X-ray Diffraction (XRD), technique and the chemical analysis by Atomic Absorption Spectrometer (AAS) analysis. The results obtained from the investigation show that the clay sample is aluminosilicate refractory and it is within the range of foreclay (25-45% alumina). The potential utilisation of clay for firebricks production for furnace lining is in consideration. It is concluded that mineralogical composition and structure are the application determination parameters.

Benchmarking the current reuse and recovery (direct, indirect) and barriers with stakeholder input
Identifying the Leverage Points, mapping the supply chain, and identifying key gaps for developing a circular economy value pathway for HDDs

3:45 PM ES14.01.04/ES13.05.04
Life Cycle Assessment of Biodeaing in Rare Metals Recovery

Ammerlie Falke 1 and Michael Höck 2; 1 Institute for Business Administration, esp. Resource Management, Technische Universität Bergakademie Freiberg, Freiberg, Germany; 2 Institute of Industrial Management, Technische Universität Bergakademie Freiberg, Freiberg, Germany.

In light of growing demand and pollution versus a finite amount of resources, electronic waste recycling is a way towards material circularity. Due to the complex composition of end of life products and the physical characteristics of the materials, it becomes more difficult to recover pure metals form the waste stream. Especially rare metals, which, although abundant in the earth’s crust, only occur in low concentrations, are a sought after commodity as they are important for the economy and are found in numerous products.

New recycling technologies not only face technical difficulties but also need to overcome challenges of feasibility in both economic and environmental aspects. An assessment regarding environmental impacts and economic factors at the early development stages of such technologies is necessary to ensure a successful establishment. Bioleaching has been specifically applied in copper recovery since the 16th century and is now also used to win metals such as zinc, gold or cobalt. Using this hydrometallurgical approach for the recovery of by-metals such as sodium in an innovative approach in the first development stages. Indium-rich material such as electronic waste is leached in a bioreactor as opposed to the environmentally risky heap leaching. The beneficiation process of indium from electronic waste can be classified into four steps. In a first step, the material is crushed and comminuted. The fines are then fed into a bioreactor, where biodeaing takes places in multiple stages. The third and fourth steps are the solvent extraction and subsequent recovery of the target metal from the solution. In a combined process, indium rich tailings and primary ores could also be added in the reactor to ensure a stable input and independence of the amount of end-of-life products.

A review of existing recyclability and reusability metrics revealed that the industry has limited means of practically assessing circular economic value (recyclability, reusability, reparability and refurbish-ability) of an ICT product. Current mass-based metrics, in their most simplistic form, are deficient. Product designers control material and design choices which affect downstream end-of-life costs, while the market controls the materials that are recovered. Yet, no metric or guidance links these attributes together. The iNEMI Reuse and Recycling Metrics Project team has been developing a practical means for assessing the circular economic value of an Information and Communication Technology (ICT) product with the focus on incorporating score factors that assign reasonable impact value to product design features along with the ability to recover (whole products, parts) and return value (from reuse, recycling and/or energy recovery) back to the market. Included in this scoring factor are highlighted aspects that are within the product designer’s control such as material choice and ease of liberation of components and materials and those aspects outside the product designer’s control such as the availability of recovery for reuse/recycling technologies in the markets where the product is placed. The metric assigns a reasonable impact value based on the design and a weighted recovery rate, which brings the actual results into the traditional mass-based metrics. The project is developing an assessment tool for the ability to disassemble a product for repair and recovery of whole product, components and parts.

The resulting system assesses the environmental feasibility and physical practicality to separate and liberate the parts, components and materials from ICT type products when whole product reuse is not possible. The assessment is divided into three tiers; material choice, ease of liberation and the downstream recycling technology. Regional factors have also been researched and incorporated in the assessment criteria. Additionally, the team reviewed the hierarchy of recovery, which impacts the ease of returning value to the market: repair and reuse, parts harvesting, material recovery, or energy recovery/landfill.

ICT stakeholders, including product designers, manufacturers, customers, recyclers, governmental authorities, and environmental advocates can use this means to assess the relative impact of product design choices early in the product life cycle. This will benefit both the industry and the environment to achieve sustainability. The intention for the metric is to identify gaps that prevent return to market value by highlighting the most impactful action(s) needed to close the gaps, and to inform product designers and manufacturers of the end-of-life impacts of their decisions.

4:00 PM ES14.01.04/ES13.05.04
Pyrolysis and Detoxification of Waste Electrical and Electronic Equipment (WEEE) for Feedstock Recycling

The recycling of waste electrical and electronic equipment (WEEE) has been a great challenge for the recycling industry in the last decades. Predictions on the future volume of such waste shows that it will rapidly increase during the coming years (Baldé et al., 2015). Some of the waste fractions derived from WEEE are considered to be hazardous, since they contain toxic compounds restricted by the Directive of EU (2002) for Hazardous substances in WEEE. Therefore, the scientific community are focusing on finding alternative processes in order to minimise their environmental impacts and eliminate the risk of human exposure during recycling. Previous studies have investigated several processes for recycling of WEEE in terms of materials or energy. Pyrolysis is one of the alternatives which combines both energy and partially materials recovery through its production of oil and gas. Moreover, the solid residue, which contains high percentage of metals in non-oxidised form can be recovered through hydrometallurgical process.

The current study investigates the decomposition of three representative WEEE fractions, collected at a recycling plant located in Sweden focusing on feedstock recycling. The experiments are performed in a thermogravimetric analyser (TGA) in order to evaluate their decomposition behaviour. Furthermore, pyrolysis experiments have been performed at different temperatures (300-700 °C) in order to correlate the pyrolysis products with the choice of temperature. Through these experiments a kinetic study has been performed aiming to design a process that can maximize the production of specific organic compounds while minimizing the evolution of brominated compounds, which are usually present in the oil (Evangelopoulos 2015).

Tests were also performed in a semi industrial continuous pilot plant designed to treat 1kg of WEEE per hour. The experiments examine the possibility of releasing less brominated compounds according to the different tested temperature conditions. Moreover, the properties of the oils obtained by the process was also investigated experimentally in order to correlate the pyrolysis products with the choice of temperature. Through these experiments a kinetic study has been performed in order to minimize the material and energy losses in the concept of circular economy towards a more sustainable way of recycling the WEEE.

4:15 PM ES14.01.05/ES13.05.05
Life Cycle Assessment of Biodealing in Rare Metals Recovery

Ammerlie Falke 1 and Michael Höck 2; 1 Institute for Business Administration, esp. Resource Management, Technische Universität Bergakademie Freiberg, Freiberg, Germany; 2 Institute of Industrial Management, Technische Universität Bergakademie Freiberg, Freiberg, Germany.

In light of growing demand and pollution versus a finite amount of resources, electronic waste recycling is a way towards material circularity. Due to the complex composition of end of life products and the physical characteristics of the materials, it becomes more difficult to recover pure metals form the waste stream. Especially rare metals, which, although abundant in the earth’s crust, only occur in low concentrations, are a sought after commodity as they are important for the economy and are found in numerous products.

New recycling technologies not only face technical difficulties but also need to overcome challenges of feasibility in both economic and environmental aspects. An assessment regarding environmental impacts and economic factors at the early development stages of such technologies is necessary to ensure a successful establishment. Bioleaching has been specifically applied in copper recovery since the 16th century and is now also used to win metals such as zinc, gold or cobalt. Using this hydrometallurgical approach for the recovery of by-metals such as sodium in an innovative approach in the first development stages. Indium-rich material such as electronic waste is leached in a bioreactor as opposed to the environmentally risky heap leaching. The beneficiation process of indium from electronic waste can be classified into four steps. In a first step, the material is crushed and comminuted. The fines are then fed into a bioreactor, where biodeaing takes places in multiple stages. The third and fourth steps are the solvent extraction and subsequent recovery of the target metal from the solution. In a combined process, indium rich tailings and primary ores could also be added in the reactor to ensure a stable input and independence of the amount of end-of-life products.

A new existing technology of using biodeaing as a hydrometallurgical process to win indium from electronic waste will be assessed exemplarily. This presentation will focus on preliminary results of batch trials in a lab scale bioreactor, whereby Indium was recovered from the electronic waste recycling process. Hereby Life Cycle Assessment is used to determine the ecological factors. Further, the environmental risks connected to this technology are summarized and put into perspective. LCA offers a standardized opportunity to determine the environmental impacts over the life cycle of a given product but can be applied to processes. The data is used to establish the feasibility of this recycling technology including both economic and ecologic parameters.
characteristic study of a virgin clay deposit has been undertaken from Uguwuji clay deposit in Enugu South Local Government area of Enugu State. The work done consists of chemical analysis, morphology and microanalysis of sample clay with Scanning Electron Microscopy equipped with energy dispersive spectrometer (EDS), the major elements are determined by X-ray Fluorescence (XRF), the relative phase quantities of wt% and phases estimated and identified with X-ray Diffraction (XRD), technique and the chemical analysis by Atomic Absorption Spectrometer (AAS) analysis. The results obtained from the investigation show that the clay sample is aluminosilicate refractory and it is within the range of foreclay (25-45% alumina). The potential utilisation of clay for firebreaks production for furnace lining is in consideration. It is concluded that mineralogical composition and structure are the application determination parameters.

SYMPOSIUM ES15

Fundamental Understanding of the Multifaceted Optoelectronic Properties of Halide Perovskites

April 23 - April 26, 2019

10:30 AM *ES15.01.01/ES16.01.01/ES17.03.01
Present Status and Next Important Challenge of Perovskite Photovoltaics Towards Industrialization Tsutomu Miyasaka; Toin University of Yokohama, Yokohama, Japan.

Power conversion efficiency (PCE) of lead halide perovskite solar cell (over 23%) has surpassed those of CIGS and CdTe, approaching the top value of crystalline Si cell. Our group has been able to achieve PCE over 21% by low cost ambient fabrication. However, high PCE of single-cell enabled by lead halide-based perovskite absorbers are now being saturated, taking the Shockley Queisser (SQ) limit of open-circuit voltage \( V_{OC} \) (ca.1.32V) into account. Tandem cell making, which can further increases PCE up to 28% or more, leads to higher material and process cost and will raise a question if performance/cost ratio can be accepted in industry. Therefore, a smart way is to create a single cell which has high PCE comparable with that of GaAs (>28%) by reducing bandgap energy to <1.4 eV without accompanied of increase in \( V_{OC} \) loss. This possibility will be in a family of metal halide perovskite out of those depending on use of lead. In addition to such efficiency issue, high performance of organo lead halide materials is not compatible with robust high stability required for practical use. Ensuring the intrinsic thermal stability (desirably >200°C) of the perovskites is a key issue before industrialization. In addition, toxicity of lead-based perovskites are going to become the most formidable challenges for real use (commercialization), in particular, for applications to IoT society, which is one of the most promising field of perovskite photovoltaic device in terms of high voltage output even under weak illumination. These thoughts urge us to concentrate our next research of perovskite photovoltaics (PV) more on development of non-lead high efficiency absorbers. Sn perovskite is still a strong candidate because Sn(II) has been found to be stabilized against ambient air by metal doping method (such as Ge). Regarding Bi-based perovskites, we found AgBiI_3 as a promising all-inorganic absorber having high thermal and moisture stability. Stability also highly depends on the property of charge transport materials (CTMs), especially, the kind of hole transporter. Spiro-OMeTAD does not work at high temperature while P3HT, for example, is thermally stable. In our collaboration with JAXA, P3HT-based perovskite devices showed robust stability by exposure to high (100°C) and low (-80°C) temperatures and also to high energy particle radiations (Science, 2018, 2, 148). Selection of CTMs is another important key in combination with non-lead perovskite materials. In conclusion, next direction of perovskite PV should be to enhance PV performance of non-lead all-inorganic semiconductor materials by extended compositional engineering, in parallel with developing thermally stable CTMs. Our on-going studies on non-lead perovskite materials in our group will be introduced in the talk.

11:00 AM *ES15.01.02/ES16.01.02/ES17.03.02
Issues and Solutions in Perovskite Solar Cells Nam-Gyu Park; Sungkyunkwan University, Suwon, Korea (the Republic of).

Since the first report on the high efficiency, stable solid-state perovskite solar cell (PSC) in 2012 by our group, following two seed works on perovskite-sensitized liquid junction solar cells in 2009 and 2011, PSC demonstrated its power conversion efficiency (PCE) of 23.3% in 2018. According to Web of Science, publications on PSC increase exponentially since 2012 and total number of publications reaches already over 10,000 as of October 2018, which is indicative of a paradigm shift in photovoltaics. Although small area cell exhibited superb efficiency surpassing the performance of thin film technologies, scale-up technology is required toward commercialization. In addition, further higher efficiency toward Shockley–Queisser limit is required in is parallel. In this talk, Large-area coating technology is introduced using perovskite cluster embedded coating solution,
followed by brief introduction on history of perovskite solar cell. Bi-facial stamping method was developed for not only scale-up technique but also interface modification and low-temperature phase stabilization. For higher efficiency, managing recombination is critical. Methodology reducing recombination is developed via interface and bulk engineering. Current-voltage hysteresis is also discussed because hysteresis is related to the stability of perovskite solar cell. Ion migration is now visualized and confirmed to correlate with hysteresis.

11:30 AM ES15.01.03/ES16.01.03/ES17.03.03
Hybrid Halide Perovskite Semiconductors—An Historical Perspective
David B. Mitzi; Duke University, Durham, North Carolina, United States.

Organic-inorganic perovskites enable a combination of useful organic and inorganic properties within a single molecular-scale composite and have attracted substantial interest for use within organic-inorganic electronic devices [1], in part due to the high carrier mobilities, long minority carrier lifetimes, tunable band gaps and relatively benign defects and grain boundaries for systems based on Group 14 metals (e.g., Ge, Sn and Pb) [2]. Indeed, these materials have enabled unprecedented rapid improvement in perovskite photovoltaic performance to levels above 20% power conversion efficiency and with open circuit voltages above 1 V for a single junction photovoltaic (PV) device [3]. This talk will provide an historical perspective on foundational work related to the organic-inorganic perovskite semiconductors, including discussion of crystal structure flexibility [4,5], semiconducting properties, film deposition approaches and electronic device applications of the three-dimensional and lower-dimensional perovskite structures. Recent trends in the field, as they relate to application in photovoltaics and related devices, will also be coupled into this discussion.

SESSION ES15.02: Perovskite Composition and Defects Engineering I
Session Chairs: Jacques-E. Moser and Tom Savenije
Tuesday Afternoon, April 23, 2019
PCC North, 100 Level, Room 130

1:30 PM ES15.02.01
Towards Highly Emissive Halide Perovskites for Optoelectronic Applications
Samuel D. Stranks; Cavendish Laboratory, University of Cambridge, Cambridge, United Kingdom.

Metal halide perovskites are exciting materials for a range of optoelectronic devices. One of their most tantalizing features is the potential for tunable emission with high luminance yields. Such properties are promising for reaching the radiative efficiency limits in single and multi-junction solar cells as well as color-tunable light-emitting diodes. However, there are a number of challenges in attaining high luminance yields and color stability across a range of bandgaps.

Here, I will present a select portion of our ongoing work to understand the origin of non-radiative losses in a range of halide perovskite films, crystals and device systems, and how we can use this information to push materials and devices towards their efficiency limits. We use a selection of nano- and micro-scale imaging techniques including photoluminescence, photo-emission and nano-X-Ray-Diffraction microscopy to visualise the impact of defects and strain on local charge carrier recombination. We also employ passivation techniques designed to remove these spatially heterogeneous losses, which we demonstrate on small and large bandgap bulk 3D perovskites and 2D confined perovskite nano-platelets. Finally, we show that these approaches ultimately lead to improved solar cell and LED performance and bandgap stability.

2:00 PM ES15.02.02
Atomic Scale Analysis of Perovskite CH₃NH₂PbI₃ Ultra-Thin Films by Scanning Tunneling Microscopy
Afshan Jamshaid, Robin Ohmann, Jeremy Hieulle, Collin Stecker, Luís K. Ono and Yabing Qi; Okinawa Institute of Sciences & Technology, Tancha, Japan.

In recent years, the organic-inorganic hybrid perovskite has gained an increasing research interest in academia for applications in thin film solar cells, due to rapidly increased efficiency (from 3.8 to 23.3% within a decade) [1], high absorption coefficient [2], low-cost fabrication process, and material availability [3]. Among the hybrid perovskites, MAPbI₃ (CH₃NH₂PbI₃) based solar cells have shown high power conversion efficiencies but with several obstacles such as thermal instability, hysteresis loss at room temperature. Therefore, the commercialization of these solar cells is still a challenge. Understanding and resolving these issues necessitate the investigation of the sample at the atomic scale to determine the underlying fundamental processes.

Here, we present the growth and experimental characterization of thin MAPbI₃ films on Au (111) under ultra-high vacuum conditions (UHV=1x10⁻¹⁰ Torr). The thin films were prepared by vacuum evaporation of the precursor molecules MAI and PbI₃ with a thickness of a few monolayers (approx. 4 nm). We characterize the sample with scanning tunneling microscopy (STM), and X-ray photoelectron spectroscopy (XPS), obtaining information about the atomic structure, and chemical composition. For the electronic properties analysis, we used ultraviolet photoemission spectroscopy (UPS), and inverse photoemission spectroscopy (IPES). Our study will provide the basis for further understanding ion incorporation and stability at the atomic scale.

Concentration and Precursor Delivery Effects on Hybrid Perovskites Deposited by Resonant Infrared Matrix-Assisted Pulsed Laser Evaporation
Enrique T. Barraza1, Niura Wright1, Maria Folgueras1, Ankst Rastogi2, Ruipeng Li1, Masafumi Fukuda2 and Adrienne Stiff-Roberts1,2, 'Electrical & Computer Engineering, Duke University, Durham, North Carolina, United States; 'National Synchrotron Light Source II, Brookhaven National Laboratory, Upton, New York, United States; 'University Program in Materials Science & Engineering, Duke University, Durham, North Carolina, United States.

Hybrid organic-inorganic perovskites possess a diverse set of properties that make them excellent materials for a variety of applications. New perovskite compounds with complex structures and novel properties promise to further expand the applicability of this class of materials, but may require new processing approaches to be synthesized. Issues of solubility and degradation in the synthesis of complex perovskites can be addressed via resonant infrared matrix-assisted pulsed laser evaporation (RIR-MAPLE). RIR-MAPLE is a physical vapor deposition technique that has been shown to deposit perovskite materials in a manner that preserves the integrity of the perovskite components and maintains the composition of the target source. [1, 2] Because RIR-MAPLE uses lower concentration solutions to form frozen targets (compared to conventional approaches) and has different deposition schemes available to deliver precursors to the substrate, [3] it is uniquely positioned to act as a framework for studying complex perovskites with limited solubility.

Using CH₃NH₂PbI₃ (methylammonium lead triiodide, or MAPbI₃) as an initial model system, the effects of RIR-MAPLE solution concentration and deposition scheme were studied. Because MAPbI₃ can easily be spin-cast and its properties have been widely studied, it acted as a reference to compare any effects of RIR-MAPLE deposition on material properties.

Baseline (21.7 mM) concentrations of CH₃NH₃I (methylammonium iodide, or MAI) and PbI₂ were increased by a factor of 1.5 times to yield solutions that had high inorganic,
high organic, and high overall component concentrations. Reference spin-casting solutions were created by using 1.4 and 1.6 M concentrations of MAI and PbI₂ to create the same relative non-stoichiometric conditions as in the RIR-MAPLE solutions. Also, a small amount (~20 µL) of monooethylene glycol (MEG) was added to additional spin-cast solutions to observe possible effects on material properties because this chemical serves as a co-matrix to resonantly absorb laser energy during RIR-MAPLE deposition.

RIR-MAPLE deposition schemes based upon multiple source solutions within a partitioned target cup were adapted for MAPbI₂ to drastically alter how perovskite precursors are delivered to the chosen substrate. Substrate temperatures were controlled across all deposition schemes to observe any effects on how precursors react in these schemes.

The crystallographic properties of all films were studied using X-ray diffraction (XRD) and synchrotron grazing-incidence wide-angle X-ray scattering (GIWAXS). Film morphology was studied using scanning electron microscopy (SEM) and atomic force microscopy (AFM). The optoelectronic properties of the films were determined by photoluminescence and UV-Visible absorbance spectrosopies.

This work is important to establish fundamental growth mechanisms of perovskite thin films deposited by RIR-MAPLE and expands upon previous foundational studies. By demonstrating versatility in solution compositions and deposition schemes, RIR-MAPLE is positioned favorably to address the requirements to synthesize complex perovskite materials systems.

This research used beamline 11-BM of the National Synchrotron Light Source II, a U.S. Department of Energy (DOE) Office of Science User Facility operated for the DOE Office of Science by Brookhaven National Laboratory under Contract No. DE-SC0012704.

2:30 PM ES15.02.04 Unraveling the Impact of Halide Mixture on Charge Carrier Mobility via Scanning Tunneling Microscopy and Photoluminescence Electronic Spectroscopy: Jeremy G. Hsieh¹, Xiaoming Wang², Collin Stecker³, Dae-Yong Son¹, Longbin Qiu¹, Robin Ohmann¹, Luis K. Ono¹, Aitor Mugaza³, Yafiu Yan³ and Yabing Qi²; Okinawa Institute of Science and Technology Graduate University (OIST), Onna, Japan; ³Department of Physics and Astronomy and Wright Center for Photovoltaics Innovation and Commercialization, The University of Toledo, Toledo, Ohio, United States; ¹Catalan Institute of Nanoscience and Nanotechnology (ICN2), Consejo Superior de Investigaciones Científicas (CSIC) and The Barcelona Institute of Science and Technology, Barcelona, Spain; ²ICREA-Institució Catalana de Recerca i Estudis Avançats, Barcelona, Spain.

Organic-inorganic perovskite solar cells are currently under the spotlight. Despite numerous advantages, their poor stability hinders commercialization of perovskite-based devices. To increase perovskite stability various strategies have been envisaged [1]. Mixing different halides (I, Br, CI) has been shown both experimentally and theoretically to have a strong impact on the device performance and stability [2-5]. However, the stabilizing effect of the halides critically depends on their distribution in the mixed compound, a topic that is currently under intense debate [6-8]. A fundamental understanding remains largely elusive regarding the correlation between the structure of the mixed-perovskites and their electronic properties at the atomic level.

In this work, combining scanning tunneling microscopy (STM), density functional theory (DFT) and UV/X-ray photoelectron spectroscopy (UPS/XPS), we reveal the exact location of I and Cl anions in the mixed CH₃NH₃PbBr₂I and CH₃NH₃PbBr₂Cl perovskite lattices. Additionally, we demonstrate the impact of halide-incorporation on the material electronic properties and stability. Furthermore, we determine the ideal Cl-incorporation ratio for stability increase without detrimental bandgap modification. The increased material stability induced by chlorine incorporation is verified by performing photoluminescence spectroscopy on a device architecture. Our findings provide an important direction for the fabrication of stable perovskite devices.

2:45 PM ES15.02.05 Role of Different Cations (MA⁺, FA⁻ and Cs⁺ and Rb⁺) on Charge Carrier Recombination in Perovskite Solar Cells Ankur Solanki, Swee Sien Lim and Tze Chien Sum; Nanyang Technological University Singapore, Jurong West, Singapore.

Incorporation of inorganic cations has been recently demonstrated a technique to enhance the efficiency and lifetime in perovskite solar cells. However, the understanding and correlation of ultrafast photophysics in relation to opto-electrical properties to the device performance are still lacking. Here, we systematically analysis the role of inorganic cations on the photophysics using photoluminescence techniques and correlate with photovoltaic properties. The lack of the integration of Rb⁺ with organic cations MAFA (MA, methylammonium, and FA, formamidinium,) leads to higher defect density and trap-assisted monomolecular recombination in thin films. While, the incorporation of Cs⁺ increases the perovskite grain size and shows longer charge carrier lifetime by mitigating the defects to enhance the power conversion efficiency (PCE); indicating the better incorporation of Cs⁺ to MAFA. While the concomitant presence of Rb⁺ with Cs⁺, delay the non-radiative losses by suppressing the defect density significantly in quaternary-cation based photovoltaic system (RbCsMAFA) compared to double-cation MAFA system. Lower defects density and a more balanced charge carrier diffusion length results the PCEs over 19% in quaternary-cation-perovskites though photoluminescence quantum yield (PLQY) is comparable. While the concomitant incorporation of Rb⁺+Cs⁺ is the key to suppress the defects and charge carrier recombination for efficient photovoltaics, solitary integration of Rb⁺ with MAFA is still a challenge.

SESSION ES15.03: Carrier Dynamics—Carrier Recombination and Hot Carriers I
Session Chairs: Libai Huang and Koichi Yamashita
Tuesday Afternoon, April 23, 2019
PCC North, 100 Level, Room 130

3:30 PM ES15.03.01 How Charge Carrier Dynamics are Affected by Light Soaking and Additives in (Mixed) Metal Halide Perovskites Dengyang Guo¹, Eline Hutter¹, Zahra Andaji Garmaroudi², Mojtaba Abdi-Jalebi², Samuel Stranks² and Tom Savchenko¹; ¹Delft University of Technology, Delft, Netherlands; ²University of Cambridge, Cavendish Laboratory, Cambridge, United Kingdom.
Due to their unique opto-electronic properties, metal halide perovskites are of great interest as solar energy material. At present, non-radiative losses prevent solar cell efficiencies to reach their theoretical maximum. In this work we suppressed the non-radiative decay in methylammonium lead iodide (MAPbI₃) layers by exposing them to a light soaking treatment under ambient conditions. First of all, this treatment leads to an increase of the PL quantum efficiency from < 1% to 50%. Additionally, photo-induced time-resolved microwave conductivity (TRMC) data demonstrate that while the mobility and the trap density remain constant, the light soaking treatment reduces the non-radiative band-to-band recombination between electrons and holes. We attribute the enhancement in effective carrier lifetimes to an increased fraction of radiative recombination, leading to enhanced light soaking studies were extended to mixed cation, mixed halide perovskites, (FAₓNaᵧMAₓ(1−ξ)CsₓSnₓ)₂Pb₃I₁₀Brₓ (ξ ≤ 0.2) which are known to undergo phase separation under continuous illumination. For x < 0.5 we find that on light soaking in a nitrogen environment, the charge carrier lifetime increases, while for x > 0.5 the lifetime shortens. By analysing the TRMC traces, we propose that for x < 0.5 light soaking leads to a reduction of charge trapping in shallow states. Next, we investigate how additives such as K⁺, Cs⁺ and Rb⁺ affect the mobility and decay kinetics of photo-induced excess carriers in metal halide perovskites. The above results help to provide a framework for which cation and halide composition the best performance and stability can be expected.

4:00 PM ES15.03.02

Grain Resolved Charge Carrier Kinetics in Chalcogenide and Perovskite Materials—A Pump-Probe Microscopy and Spectroscopy Study Elham Chadiari1, Donghyeop Shin2, Ashkan Shafiee1, Qoewe Han1, Warren Warren1 and David B. Mitzi1; 1Chemistry, Wake Forest University, Winston-Salem, North Carolina, United States; 2Chemistry, Duke University, Durham, North Carolina, United States; 3Wake Forest Institute for Regenerative Medicine, Wake Forest School of Medicine, Winston-Salem, North Carolina, United States.

We integrate the state-of-the-art pump-probe microscope and broadband diffuse reflectance spectroscopy techniques for photophysical analysis of charge carriers in photovoltaic materials including recently introduced Cu₂BaSnS₄₋ₓSeₓ (CBTSSe) chalcogenides 1–2 and MAPb₁₋ₓCsₓI₃ perovskites. Pump-probe microscopic imaging 3 enables to localize the photoexcitation patterns and early charge carrier kinetics within the grains of only a few hundreds of nanometers and localize the kinetics of photogenerated carriers in each grain. Based on broadband diffuse reflectance transient absorption spectroscopy 4 the fingerprints of photocarrier absorption, GSB bleaching and electronic states in the vis-near IR region are investigated.

For MAPb₁₋ₓCsₓI₃ perovskite samples, we identify the formation and relaxation of excited state absorption signal (charge carrier’s absorption) within film grains by performing pump-probe microscopic imaging with pump and probe pulses at 720 nm and 817 nm respectively. The time-resolved pump-probe images show a homogeneous pattern across the majority of grains while some heterogeneity is observed across different grains. We further discuss the influence of morphological parameters such as grain size and extra additives such as PbI₂ on the excited state pattern and the ultrafast kinetics of photocarriers within grains of MAPb₁₋ₓCsₓI₃ perovskites. The ultrafast kinetics of the photogenerated carriers in both pristine state and sample with additional PbI₂ is similar, while free carrier relaxation increases for larger grains.

CBTSSe is a recently introduced alternative to Cu(In,Ga)(S,Se)₂ which are known to undergo phase separation under continuous illumination. For x < 0.5 we find that on light soaking in a nitrogen environment, the charge carrier lifetime increases, while for x > 0.5 the lifetime shortens. By analysing the TRMC traces, we propose that for x < 0.5 light soaking leads to a reduction of charge trapping in shallow states. Next, we investigate how additives such as K⁺, Cs⁺ and Rb⁺ affect the mobility and decay kinetics of photo-induced excess carriers in metal halide perovskites. The above results help to provide a framework for which cation and halide composition the best performance and stability can be expected.

We will put our results in the broader perspective of other HaP physico-chemical properties and performances of HaP-based device characteristics.

PCC North, 100 Level, Room 130

8:00 AM *ES15.04.01
Charge Transfer Exciton Dynamics in Mixed-Composition Perovskites and 2D-3D Layered Materials
Jacques-E. Moser; EPFL, Lausanne, Switzerland.

The constituents of hybrid organic-inorganic lead halide perovskite materials have significantly evolved since the first photovoltaic devices made out of the standard methylammonium lead triiodide (MAPI, CH$_3$NH$_3$PbI$_3$) to the latest developments relying on mixed cations, mixed anions perovskite systems and arrangements of 2D-3D layers. Indeed, it appears that mixed-composition perovskites and complex structures including a low-dimensional perovskite layer on top of a bulk three-dimensional perovskite film can perform significantly better than standard systems, via both a better short-circuit current, and a larger open-circuit voltage. These parameters, commonly used to assess the performances of photovoltaic devices, directly relate to more fundamental properties of the material: the bandgap of the absorber, determined by its electronic structure, and the ratio between radiative and non-radiative charge carrier recombination quantum yields, which depends on more complex dynamical phenomena and scattering processes. Here, we use a combination of ultrafast spectroscopic techniques to scrutinize the carrier dynamics in mixed-cations, mixed-halide lead perovskite thin films. Our results evidence the formation of charge transfer excitons (CTE) at the boundaries of domains of various halide compositions. A global analysis of photoinduced transient Stark signals shows that CTE evolve gradually from Br-rich to I-rich domains over tens to hundreds of picoseconds. Rather than constituting recombination centers, boundaries between domains of various halide compositions appear then to favor charge carrier separation by driving photogenerated holes along channels of decreasing bromide content. The ultrafast dynamics of photoinduced Stark signals observed in transient absorption spectra of 2D-3D layered perovskites prepared by use of various long-chain organic cations allowed to evidence charge transfer between domains of different dimensionality taking place in competition with energy transfer. These findings show that vectorial charge separation takes place at the interface, which is at the origin of the improved efficiency of solar cells based on structured materials embodying the low dimensional layer, when compared to pristine 3D perovskite.

8:30 AM *ES15.04.02
Long-Range Hot Carrier Transport in Hybrid Perovskites Visualized by Ultrafast Microscopy
Libai Huang; Department of Chemistry, Purdue University, West Lafayette, Indiana, United States.

The Shockley-Queisser limit for solar cell efficiency of ~33% can be overcome if hot carriers can be harvested before they thermalize. Recently, carrier cooling time up to 100 picoseconds was observed in hybrid organic-inorganic lead halide perovskites, but it is unclear whether these long-lived hot carriers can migrate long distance for efficient collection. We report direct visualization of hot carrier migration in CH$_3$NH$_3$PbI$_3$ thin films by ultrafast transient absorption microscopy, demonstrating three distinct transport regimes. Quasi-ballistic transport was observed to correlate with excess kinetic energy; resulting in up to 230 nanometers transport distance in 300 fs that could overcome grain boundaries. Instead, we observe a non-ballistic transport regime in which energetic hot carriers diffuse over tens of picoseconds and ~600 nanometers before reaching the diffusive transport limit. These new insights would allow the development of extremely thin absorber and concentrator-based solar cells, when compared to pristine 3D perovskite.

9:00 AM ES15.04.03
Utilizing Hot Carriers in Perovskite Nanocrystals for New-Generation Light Harvesting Technologies
Mingjie Li and Tze Chien Sum; School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore.

Thermodynamic calculations revealed that single junction solar cell conversion efficiencies can exceed the Shockley-Queisser limits and reach around 66% under 1-sun illumination if the excess energy of hot photogenerated carriers is utilized before they cool down to the lattice temperature (i.e., hot-carrier solar cells). Organic–inorganic lead halide perovskite semiconductors have recently emerged as the leading contender in low-cost high-performance solar cells. The key for the realization of hot-carrier (HC) solar cell include the slow hot-carrier cooling and effective extraction of hot-carrier energies which requires fast hot-carrier injection into charge collection layer before hot-carrier cooling down to the lattice temperature. Another related approach to leverage slow HC cooling for efficient energy extraction of HCs is multiple exciton generation (MEG). MEG or carrier multiplication (CM) is a process that generates more than one electron-hole pair from the absorption of one high-energy photon (with at least twice the bandgap energy, Eg), which can boost the photovoltaic efficiencies to ~44%. Perovskite NCs with their novel slow hot-carrier cooling are therefore also highly promising candidates for MEG. In this talk, firstly we will present our recent observations that the weakly quantum confined MAPbI$_3$ nanocrystals have up to ~2 orders slower hot-carrier cooling times and around 4 times larger hot-carrier temperatures than their bulk-film counterpart. This is attributed to their intrinsic phonon bottleneck and Auger-heating effects at low and high carrier densities, respectively. Importantly, we demonstrate efficient room temperature hot-electrons extraction (up to about 83%) by an energy-selective electron acceptor layer within ~1 ps from surface-treated perovskite nanocrystal very thin films (~30 nm). These new insights would allow the development of extremely thin absorber and concentrator-type hot-carrier perovskite solar cells. In the second part, we will show our most recent works on the efficient MEG (up to ~75% in slope efficiency) with low MEG thresholds (down to ~2.25Eg) in intermediate-confined colloidal FAPbI$_3$ NCs. Efficient MEG occurs via inverse Auger process within 90 fs, afforded by the slow cooling of energetic hot carriers. These insights may lead to the realization of next generation of solar cells and efficient optoelectronic devices.

Physical Properties of 2D and 3D Hybrid Perovskites—Recent Results
Jacqui Ewen; INSA Rennes, Rennes, France.

Solution-processed organometallic perovskite based solar cells have emerged as a promising thin-film photovoltaic technology. The presentation will review recent optical spectroscopy and diffraction results on monocrystals of halide perovskites, colloidal nanocrystals or thin-films. 2D multilayered phases, composed of perovskites multilayers

9:45 AM ES15.05.02 The Electronic Origin of the Thermal and Phase Instability of Metal Halide Perovskites from First Principle Tao Shu Xia; Applied Physics, Center for Computational Energy Research, Eindhoven, Netherlands.

In just a few years, perovskites solar cells (PSCs) have emerged as one of the most promising solar cell technologies. So far, the PCEs of PSCs above 22% have been reported, which is rivaling values achievable with crystalline silicon solar cells. In spite of the fast growth in the photovoltaic industry, PSCs are severely limited in their large scale applications due to instability issues. These include intrinsic instabilities of the metal halide perovskites, environmental instabilities, and device operation related instability.

In this work, we discuss the intrinsic instability of the metal halide perovskite studied by combining chemical bonding analysis of DFT electronic structure calculations and experimental degradation study using Ultraviolet–visible spectroscopy. A comprehensive set of chemical bonding analysis of DFT calculations are done for AMX$_3$ (where A=Cs, MA, FA, M=PB, Sn, X=I, Br, Cl) perovskites. Bond order, net charge, steric repulsion, and Crystal Orbital Hamilton Population (COHP) analysis reveal the relation of covalent, ionic, and metallic interactions, as well as bonding/antibonding characters with their stability, respectively. As a part of this work, Ultraviolet–visible spectroscopy of AMX$_3$ perovskites film degradation during incremental heating were carried out to probe their thermal stability. A systematic comparison of the theoretical analysis and experimental data points to the most important factors responsible for the trends in the thermal stability of AMX$_3$ perovskites.

Interestingly, this sets of chemical bonding analysis also shows promise in explaining the structural instability of metal halide perovskites, i.e. transition of black phase (3D structure) to yellow phase (2D structure). The results provide important insights in strategies for stabilizing metal halide perovskites by tuning their composition.

10:00 AM BREAK

10:30 AM ES15.05.03 Point Defect Engineering in Lead-Based Mixed Halide Hybrid Perovskites via First Principles Computations Arum Kumar Mannodi Kanakkithodi; Ji-Sang Park2; Duyen H. Cao3; Nari Jeon1; Alex B. Martinson1 and Maria K. Chan1; 1Materials Science Division, Argonne National Laboratory, Argonne, Illinois, United States; 2Department of Materials, Imperial College London, London, United Kingdom; 3Center for Nanoscale Science, Argonne National Laboratory, Argonne, Illinois, United States.

An issue of critical importance in lead-based halide perovskites, much sought-after class of semiconductors in photovoltaics (PV) research, is defects; “deep” defect levels can prove catastrophic to PV performance by causing non-radiative charge carrier combination[1], whereas impurity induced energy levels in the band gap could lead to increased absorption of sub-gap photons which can enhance efficiencies[2]. While experimental detection of defects is non-trivial and identification of the origin of defect states is usually impossible, density functional theory (DFT) calculations have been widely applied to accurately predict defect formation energies and transition levels[3]. In this work, we use DFT to study various intrinsic and extrinsic point defects in mixed bromide/chloride (MAPbBr$_3$Cl) and iodide/bromide (MAPbI$_3$Br$_y$) perovskites (MA = methylammonium) with varying compositions (y = 0, 0.75, 1.5, 2.25, 3). We observe that in MAPbI$_3$, MAPbBr$_3$ and all I-Br alloyed perovskites, vacancy defects are the dominant intrinsic defects and create shallow transition levels (i.e., energy levels close to the valence or conduction band edges), while higher energy defects create deeper levels; this is in good agreement with the computational literature[4]. The equilibrium Fermi level changes from inside the valence band (very p-type conductivity) to mid-gap (intrinsic conductivity) on going from I-Br-rich to Pb-rich chemical potential conditions. In MAPbBr$_3$Cl perovskites, it is seen that vacancy defects are again the lowest energy defects and the equilibrium Fermi level follows the same trend as in MAPbBr$_3$, but halogen vacancies (V$_{ib}$ and V$_{cl}$) create deeper levels in the band gap the higher the value of y, indicating that in mixed Br/Cl or pure Cl perovskites, there is a danger of non-radiative recombination of carriers owing to deep defect levels. In order to study the influence of extrinsic point defects on the optoelectronic properties as determined by dominant intrinsic defects, we further performed high-throughput density functional theory computations to study all elements from periods II to VI of the periodic table as substituents at the Pb-site in MAPbBr$_3$, MAPbBr$_3$Cl$_y$ and MAPbCl$_3$. Our results revealed that several transition metals like Sc, Y, Zr, Nb and Hf create lower energy substitutional defects than the dominant intrinsic defects in the three perovskites, and shift the equilibrium Fermi level towards the conduction band maximum, thus making the semiconductor conductivity more n-type. These substituents can not only help overcome the adverse effect of deep lying intrinsic defects, but their mid-gap energy provide an opportunity for sub-gap absorption which can potentially realize intermediate band solar cells[5]. Lastly, we performed correlation analysis on the computational data and discovered that the electronic and structural properties obtained from a much cheaper unit cell calculation can be used to reliably predict formation energies and transition levels of substitutional defects in lead halide perovskites. Such models can lead to accelerated prediction of impurity levels and allow efficient materials design of defect-tolerant perovskites as well as perovskites with suitably placed defect levels.

10:45 AM ES15.05.04 Charge Carrier Trapping at Surface Defects and Optical Properties of Halide Perovskites Koichi Yamashita; Univ of Tokyo, Tokyo, Japan.

The high performance of recently emerged lead halide perovskite-based photovoltaic devices has been attributed to remarkable carrier properties in this kind of material: long carrier diffusion length, long carrier lifetime, and low electron-hole recombination rate. The charge carrier trapping at defects on surfaces or grain boundaries is detrimental for the performance of perovskite solar cells. In practice, it is one of the limiting factors for carrier lifetime. In my talk, I will discuss about surface defects responsible for carrier trapping and recombination according to first-principles investigations and it is proposed that PbI$_2$-rich condition is preferred to MAI-rich one, while intermediate condition has possibility to be the best choice [1]. On the other hand, in the continuous quest for better performing materials in photovoltaics and in view of their usage in optoelectronic devices, theoretical studies based on density functional and many-body perturbation theories on the electronic and optical properties of the mixed-valence CsAu$_4$I$_6$ fully inorganic double perovskite [2] and Ruddlesden–Popper organic–inorganic halide perovskites [3] will be discussed.

11:15 AM ES15.05.05 Spin Mixing Induced by Dynamical Disorder in Halide Perovskites Liang Z. Tan; Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

The Rashba effect has served as a model for the combined effects of spin-orbit coupling and inversion symmetry breaking in the halide perovskites. Simply interpreted, it is the splitting of spin components of parabolic energy bands, along directions perpendicular to a polar axis. However, the dynamical polar fluctuations of the halide perovskites suggest that they do not conform exactly to this simple model, because of the lack of a singular static polar axis. Computational simulations of the Rashba effect in the halide perovskites.
have often relied on either time-averaged or highly-selective crystal structures, and truncations of simulation cells, which do not accurately reflect the actual dynamics of halide perovskites.

In this work, we present a new model for spin-orbit effects in halide perovskites, treating the fluctuating crystal lattice as a disordered, spin-coupled medium. This model is described by spin transmission amplitudes and spin-flip amplitudes through this disordered medium. We parameterize our model on large-scale molecular dynamics trajectories, which captures the anharmonic, large-amplitude lattice fluctuations. Electronic structure calculations on these large simulation cells are aided by a tight-binding framework based on first-principles density functional theory calculations. We apply our model to carrier dynamics in halide perovskites, describing carrier mobility, relaxation, recombination, spin transport, and clarifying the role of spin-orbit coupling in these processes. Predictions of the temperature dependence of the carrier dynamics are given by this model, and compared with experimental results. We discuss the extent to which these effects on the optoelectronic properties may be interpreted as local and short-lived Rashba effects.

SESSION ES15.06: Spotlight Talks I: Fundamental Understanding of the Multifaceted Optoelectronic Properties of Halide Perovskites

Spotlight Talk—Impact of Flash Infrared Annealing on Growth and Photophysics of MAPbI3 Perovskite Loreta A. Muscarella1, Sandy Sanchez2, Andries Loi1, Michael Saliba1 and Bruno Ehrler1; 1FOM Institute AMOLF, Amsterdam, Netherlands; 2Adolphe Merkle Institute, Fribourg, Switzerland.

Flash Infrared Annealing (FIRA) results in pinhole free layers with micrometer size crystalline domains. The fast annealing times, and comparable solar cell efficiency compared to the traditional antisolvent fabricated perovskites make FIRA a highly promising method for the scaleup of perovskite solar cells. In this work we investigate how the Flash Infrared Annealing affects the crystal growth of MAPbI3 and its dependence on the substrates used. We measure the grain size, crystal structure and orientation using Electron Back-Scattered Diffraction (EBSD). We find a highly oriented cubic structure for perovskite annealed by FIRA and a consistent crystal rotation within perovskite grains. Besides, we study how the structural properties of the resulting films affect its photophysics. Combining photoluminescence lifetime and spectral maps we show how the growth method affects the steady-state and dynamic optical properties of the resulting films. Our findings directly relate structural properties to the photophysics of lead halide perovskites.

11:35 AM ES15.06.02
Spotlight Talk—Planar Perovskite Solar Cell by Two-Step Deposition Method via Blade-Coating Technique Zahra S. Almutawah, Ramez Hosseiniyan Ahanghamejhad, Zhaoning Song, Adam Phillips, Yantfa Yan and Michael Heben; University of Toledo, Toledo, Ohio, United States.

Organic-inorganic metal halide perovskites have attracted much interest and shown great promise in recent years due to their compatibility with cheap solution processing, ease of fabrication, and enhanced power conversion efficiencies. Currently, perovskite solar cells are transitioning from small area devices to large area devices that are compatible with manufacturing. Blade-coating is a promising deposition technique because it is a low cost, environmentally friendly, and easily translated to roll-to-roll processing. Most current work has focused on fabricating high efficiency perovskite solar cells using the single step-based blade coating. However, the most recent 23.3% record efficiency device was fabricated using the two-step spin-coating method. In this study, we investigate the possibility of fabricating large area perovskite solar cells by sequentially depositing PbI2 and mixed organic iodides consisting of FAI and MABr (where FA is formamidinium, and MA is methylammonium) using the blade coating technique. The blade-coated bi-layer precursor films are annealed under different conditions to examine conversion to the perovskite phases. This study will focus on understanding the formation and growth behaviors of perovskites formed in a two-step blade-coating process when the pre-deposited PbI2 films are reacted with various concentrations of mixed FA/MA cations. Comprehensive understanding of the nucleation and growth behavior of perovskites during the intercalation process will provide insights to improve control of the film quality and allow device performance for devices beyond the simple MAPbI3 system to be improved.

11:40 AM ES15.06.03
Spotlight Talk—Quantification of Ion Migration in MAPbBr3 Solar Cells with Varying Grain Size Lucie McGovern, Loreta A. Muscarella, Moritz H. Fuchscher and Bruno Ehrler; AMOLF, Amsterdam, Netherlands.

Hybrid halide perovskites have been attracting extensive interest as next generation photovoltaic technologies. Large bandgap metal halide perovskites such as MAPbBr3 offer a range of applications in multijunction solar cells, electrochemical energy storage, electrocatalysis, and LEDs, as well as providing an interesting platform for comparison with the more commonly studied MAPbI3, and mixed-halide perovskites.

It was shown that substituting Br for I increases the chemical stability making MAPbI3 solar cells more commonly studied MAPbI3 and its dependence on the substrates used. We measure the grain size, crystal structure and orientation using Electron Back-Scattered Diffraction (EBSD). We find a highly oriented cubic structure for perovskite annealed by FIRA and a consistent crystal rotation within perovskite grains. Besides, we study how the structural properties of the resulting films affect its photophysics. Combining photoluminescence lifetime and spectral maps we show how the growth method affects the steady-state and dynamic optical properties of the resulting films. Our findings directly relate structural properties to the photophysics of lead halide perovskites.

11:45 AM ES15.06.04
Spotlight Talk—Versatile Pseudo-Halide Based Perovskites—Photophysics and Utility in Optoelectronic Devices Satyawan Nagane1, Dibhayajoti Ghosh1, Wagnas Rehman1, Vijay Venugopalan1, Laura Herz2, Alison Walker1, Saiful Islam2, Satishchandra Ogale1 and Aditya Sadhanala1, 1Physics, University of Oxford, Oxford, United Kingdom; 2University of Cambridge, Cambridge, United Kingdom.

Pseudo-Halide have started to become a new stream of research because of their capability of not only replacing the scarce options of standard halides in perovskites (CI, Br and I), but also because of the unique and useful optoelectronic properties therein. This work will describe the versatility of using a organic pseudo halide based salt to fabricate various perovskites and demonstrate their resulting - interesting and unique photo-physical and optoelectronic properties.

11:50 AM ES15.06.05
Spotlight Talk—Control the Charge Accumulation for Efficient, Repeatable and Interface Stable Homo-Junction Planar Perovskite Solar Cells Jianxing Xia, Junsheng Luo, Fei Han, Zhongquan Wan, Yu Shi and Chongyang Jia; School of Electronic Science and Engineering, University of Electronic Science and Technology of China, Chengdu, China.

The nature of trap defects such as the under-coordinated ions at the perovskite surface and grain boundaries are always trapping the free electrons or holes by the electrostatic force and speeding up the ion migration via the defect vacancy channels, which is significantly limiting the change extraction efficiency and devices long-term stability in perovskite solar cells. In this work, we induced an interface electric field which supplied by a molecular dipole to the interlayer of electron transfer layer (ETL) and perovskite. We employed Kelvin probe force microscope (KPFM) and Femtosecond transient absorption (fs-TA) to systematic study the states of charge distribution and transport properties in the perovskite after add the extra interface electric field. The results show a strong gradient electron accumulation at the applied interface and forming a homo-junction perovskite which supplied an extra built-in electric field (E_b), and finally resulting in faster interface charge transportation. Furthermore, the ion migration can efficiently be suppressed at the applied interface and thus reduce the disorder of energy level. Based on these results, we fabricated the PCBM based n-i-p architecture perovskite solar cell and achieving a PCE of 20.14% with high Voc of 1.14V, which is the record efficiency of PCBM based n-i-p devices. These devices also show higher stability compared to the standard cells.
Defect Physics and (In)Stability in Metal-Halide Perovskite Semiconductors

Defect Physics and (In)Stability in Metal-Halide Perovskite Semiconductors

SESSION ES15.07: Perovskite Composition and Defects Engineering II

Semiconducting metal-halide perovskites present various types of chemical interactions which give them a characteristic fluctuating structure sensitive to the operating conditions of the device, to which they adjust. This makes the control of structure-properties relationship, especially at interfaces where the device realizes its function, the crucial step in order to control devices operation. In particular, given their simple processability at relatively low temperature, one can expect an intrinsic level of structural/chemical disorder of the semiconductor which results in the formation of defects.

Here, first I will present our results on the role of structural and point defects in determining the nature and dynamic of photo-carriers in metal-halide perovskites. Then, I will discuss our understanding of key parameters which must be taken into consideration in order to evaluate the susceptibility of the perovskite crystals (2D and 3D) to the formation of defects, allowing one to proceed through a predictive synthetic procedure. Finally, I will show the correlation between the presence/formation of defects and the observed semiconductor instabilities. Instabilities are manifested as light-induced ion migration and segregation, eventually leading to material degradation under prolonged exposure to light. Understanding, controlling and eventually blocking such material instabilities are fundamental steps towards large scale exploitation of perovskite in optoelectronic devices.

Effect of Post-Deposition Annealing on Coevaporated CsPbBr3 Thin Films

Sebastian Caicedo Davila1, Jose Marquez Prieto1, Robert Lovrinovic2, Christian Müller1, Michael Sendner1, Thomas Unold1 and Daniel Abou-Ras1; 1Heinlernz-Zentrum Berlin, Berlin, Germany; 2InnovationLab GmbH, Heidelberg, Germany; 3Kirchhoff Institute of Physics, Universität Heidelberg, Heidelberg, Germany.

The all-inorganic cesium-lead-bromide perovskite (CsPbBr3) has attracted the attention of the photovoltaics community owing to its intrinsic thermal stability and high tolerance to humidity and light-induced effects [1–3]. Nevertheless, the coexistence of additional ternary phases (CsPbBr2 and CsPbBr3) in thin-films and single crystals [4], and its influence in the optoelectronic properties of the material is still a matter of debate and research [5]. Recent studies have shown that CsPbBr3 effectively passivates CsPbBr2 and reduces non-radiative recombination, which results in photodetectors and solar cells with outstanding performance [6,7]. Lei et al. reported enhancement of the photoluminescence and power conversion efficiency by controlled PbBr2 excess and high-temperature annealing of solar cells, synthesized by vacuum-thermal coevaporation of the CsPbBr3 absorber [3], while Luchkin et al. measured a significant current increase in coevaporated CsPbBr3 films after moderate-temperature thermal aging [8]. However, the mechanisms by which the optical and electrical properties are enhanced remain unclear.

In the present contribution, coevaporated CsPbBr3 films with excess PbBr2 on glass and Si substrates were studied. We probed the composition and optical properties of the surface and cross-section of the films by energy-dispersive X-ray (EDX) and cathodoluminescence (CL) spectroscopy, as well as by photoluminescence (PL) microscopy in a correlative analysis approach. The samples were investigated as-deposited and after (post-deposition) annealing at 70°C for 30 min in a N2 atmosphere. The EDX and CL cross-sectional analysis reveals that the temperature treatment increases the thickness of the CsPbBr3 layer in the film on Si substrate, while on the glass substrate the change is negligible. We estimate from absolute PL hyperspectral imaging an external PL quantum yield (PLQY) of 0.04% and quasi-Fermi-level splitting (QFLS) values exceeding 1.8 eV under one-sun equivalent conditions. Regardless of the thicker CsPbBr3 layer, we do not observe significant variations on the PLQY or QFLS after annealing. We discuss the effects of the substrate in the phase transformation and the influence of the phases on the optoelectronic properties of the films.

Improved Efficiency and Stability of Perovskite Solar Cells Induced by C=O Functionalized Hydrophobic Ammonium-Based Additives

Zhiyang Wu and Yabing Qi; Okinawa Institute of Science and Technology, Okinawa, Japan.

Organic-inorganic hybrid perovskite solar cells show the promises as the next-generation photovoltaic technology. The efficiency has quickly increased from 3.8% [1] to 23.2% since 2009 [2]. The morphology and crystal quality of perovskite films are the critical factors affecting solar cell efficiency. Here we introduce a new organic ammonium additive (2-NAM), exhibiting strong Lewis acid-base interaction with perovskite. [3] 2-NAM is expected to retard the kinetics for crystal growth instead of generating multiple nucleation points, finally resulting in larger crystal grain sizes. In addition, 2-NAM effectively passivates defect formed by the uncoordinated Pb atom. As result, the number of defects decreases almost three times. After introducing 2-NAM, efficiency increases from the 17.1 ± 0.8% to 18.6 ± 0.9% for 0.1 cm2 cell and 15.5 ± 0.5% to 16.5 ± 0.6% for 1.0 cm2 cell, respectively. Besides the improved efficiency, the stability is enhanced.

Atomistic Origins of Carrier Recombination in Grain Boundaries of Halide Perovskites

Ji-Sang Park and Aron Walsh; Imperial College London, London, United Kingdom.
Hybrid inorganic-organic perovskite solar cells have attracted much attention because of their superior materials properties, inexpensive fabrication methods, and their rapidly increasing solar conversion efficiency from 3.8% to more than 22% within 10 years. To further improve the solar conversion efficiency, all aspects of the device should be comprehensively analyzed at the fundamental level [1]. One problem not completely answered is whether the grain boundaries in halide perovskites are detrimental and which atomic feature makes the grain boundaries have such properties. Density functional theory (DFT) calculation studies claim that grain boundaries do not have gap states [2-3], whereas another group claimed that the lifetime can be reduced on the interface dynamics simulations [4]. Our investigation of extended defects in other materials (e.g., CdTe) shows that grain boundaries can be non-stoichiometric depending on the growth conditions [5,6], indicating that grain boundaries in halide perovskites are likely non-stoichiometric due to segregation of intrinsic or extrinsic defects. In this presentation, we aim to discuss the stability and electrical properties of grain boundaries in halide perovskites in comparison to CdTe and provide a clue to passivate grain boundaries in general.

Long-Range FRET-Mediated Exciton Diffusion in Cesium Lead Halide Perovskite Nanosstructures

Monica Lorenzon1, Anna Loido1, Edward K. Wong1, Matthew Jurove1, Min Ji Hong1, Yi-Hsien Lua1,2, Edward K. Wong1, Miquel Salmonero1, Yi Liu1,2, Stefano Cabrin1, Stephen Whitelam1, Raffaella Buonsanti1, Adam M. Schwartzberg1, Erika Penzo2 and Alexander Weber-Bargioni1
1The Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Materials Science Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Department of Chemical Sciences and Engineering, École Polytechnique Fédérale de Lausanne (EPFL), Sion, Switzerland.

Colloidal inorganic perovskite nanocrystals (PNCs) are solution-processable functional materials whose emission can be easily tuned via both size and composition. 1 Their exciting optical properties such as the large absorption cross-section and high photoluminescence quantum yield (PLQY) make them ideal candidates for a broad range of photonics and optoelectronics applications. 2 In this work, we present an overview of the exceptionally efficient exciton transport mediated by Förster Resonant Energy Transfer (FRET) in perovskite systems of increasing dimensionality. With a specifically designated optical setup, we directly measure the spatial extent of exciton hopping in a controlled two-dimensional assembly of 0D PNCs, which provides a flat energy landscape with minimal geometric disorder. 3 Steady-state and time-resolved PL microscopy, together with physical modeling of exciton transport, shows an exciton diffusion length of 200 nm and diffusivity as high as 0.5 cm2/s, which greatly exceed the values reported for FRET-mediated exciton diffusion in chalcogen-based quantum dot solids, and, importantly, matches the optical absorption depth. We further explore the exciton diffusion paradigm in 1D perovskite nanowires and 2D nanosheets, where we image the diffusion across the whole system, with diffusion lengths larger than 1µm. In addition to the exciton diffusion mapping, a significant portion of this work has been dedicated to the optimization of the substrate and the sample passivation. Specifically, we show that with a thermal-based atomic layer deposition process we are able to apply a ~3nm-thick transparent ceramic coating (aluminum oxide) which ensure optical stability over a four month period, thus overcoming the instability issue which often hinders the actual integration of perovskite materials in optoelectronic devices. Our investigation therefore provides the foundation for employing FRET-mediated exciton diffusion in nanostructured perovskites, while also demonstrating practical guidelines to use these bright emitters in optoelectronic devices beyond proof of principle.

Structural Disordering and Inversion Symmetry Breaking in Layered Hybrid Perovskite Halides

Wei Xie1, Mark Asta and Matthew Sherburne1; Department of Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States.

Layered hybrid perovskite halides are under intense investigation for electronic, optoelectronic, dielectric and photovoltaic applications due to advantages in stability, diversity, tunability and solution synthesizability. We reveal, through first-principles calculations how structural disordering and inversion symmetry breaking adapt as functions of composition and topological dimensionality of the octahedral net (controlled by the number of perovskite layers n) in a prototypical series of hybrid Ruddlesden-Popper halides PnAmpn-1MxAmpn-1Brn. We perform density functional theory (DFT) calculations of these phenomena as the complex interplay of Pb-X covalent bonding, hydrogen bonding between ammonium head of PEA and apical halides, and van der Waals interactions between the aromatic tails of PEA. Our investigation therefore provides the foundation for employing FRET-mediated exciton diffusion in nanostructured perovskites, while also demonstrating practical guidelines to use these bright emitters in optoelectronic devices beyond proof of principle.

Rashba-Dresselhaus Triggered Electronic and Optical Properties in De Novo Designed Mixed Halide Hybrid Perovskites—Implication of Composition Route and Stoichiometry

Amitava Banerjee1, Sudip Chakraborty and Rajeev Ahuja2;Upsala University, Uppsala, Sweden.

The structural peculiarities in hybrid perovskites (ABX3, where A=organic cation, B=metal, X=halide) often lead to a wide range of exciting electronic and optical properties with a consequent effect on the efficiency and stability of the optoelectronic devices based on these materials. The Rashba-Dresselhaus effect is one such consequence that has prevailed in the hybrid perovskite family. The inherent spin-orbit coupling (SOC) effect in a non-centrosymmetric crystal structure of hybrid perovskite systems has laid the foundation of Rashba-Dresselhaus effect. This Rashba-Dresselhaus effect is spin splitting of the charge carrier recombination, which eventually controls the carrier lifetime and diffusion length and therefore the solar cell efficiency for such hybrid perovskite materials. In this work, we depict a vivid picture of Rashba-Dresselhaus effect in hybrid perovskites and the immediate implications in the field of optoelectronics. Here we have performed a rigorous structural search prediction of the mixed cation-mixed halide hybrid perovskites FA0.85MA0.15(PbI2.83Br0.17)3 and FA0.85MA0.15(PbI2.83Br0.17)3 which are the two nearest neighbor structure of record efficiency (22.1%) holder FA0.85MA0.15(PbI2.83Br0.17)3 in the structural composition phase-space. We have found the prediction routes for such structural search as the mixed perovskite structure govern the Rashba-Dresselhaus splitting energy value, depending on whether it is predicted from FPI or MBP as parent structure, which is leading to the mixed phase FA0.85MA0.15(PbI2.83Br0.17)3 and FA0.85MA0.15(PbI2.83Br0.17)3 respectively. The strong dependency of the splitting energy on the structural phase evolution along with the stoichiometry and space-group is also observed, wherein the mixed phase, 0.045 difference in concentration could lead to a remarkable difference in the splitting energy, which is more pronounced in the valence band as compared to the conduction band. We have also determined the Goldschmidt tolerance factor to envisage structural stability of the newly predicted crystal structure from both the chemical route in the composition phase space.
_cells based on Methyl-Ammnonium Lead Triiodide (MAPbI3) perovskite have gained attention due to their remarkable progress in performance efficiency during recent years [1]. However, it has been hampered to put the material on the market due to their device stability under exposure to moisture [2] which is one of the major obstacle toward outdoor application of photovoltaic devices. A comprehensive study on degradation mechanism initiated with water molecules is thus essential for practical realization of MAPbI3 based solar cells. Using first-principles calculation based on the density-functional theory, we here focus on and investigate ion-migration dynamics in a MAPbI3 intercalated with water and their enhancement by the influence of grain boundary (GB). The nudged elastic band (NEB) method is employed to find the barrier potential and corresponding optimal minimum energy path (MEP) of migrated ions. We find that one of H ions of a water molecule segregated into a GB is dissociated, migrated along the GB, and attracted by an N atom in the MAPbI3 with comparatively lower potential barrier (~0.27eV) [3], following the H-ion release from an ammonium. Such migration of H depends upon the subsequent changes of charge states of surrounding atoms [4]. Additionally, a vacant space around the N atom plays as a cage for the diffused H atom. The water intercalation greatly reduces the barrier potential for an H ion motion in the GB interior of MAPbI3 which can be liable to initiate the degradation of crystallinity of the perovskite. The iso-surface of electronic charge distribution at HOMO-LUMO and partial density of state (PDOS) of the ruling N atom reveal the mentioned phenomenon. More importantly, the anisotropy symmetric GB structure is prominent for faster molecular attractions due to their weak activation energies.

Spotlight Talk—First-Principles Study on Water Dissociation in Grain Boundary of MAPbI3 Perovskite

Hybrid organic-inorganic perovskite solar cell (PSC) has been paid much attention due to its rapid progress of power conversion efficiency exceeding 22%. Many methods for preparing the perovskite films have been proposed, such as one-step deposition, sequential deposition, vapor-assisted deposition, and so on. Among them, the sequential deposition, typically synthesized by the immersion of PbI2 into the MAI solution to form the MAPbI3 perovskite film, shows the promise because of its better control over the surface morphology and crystallization kinetics. However, the incomplete conversion during sequential deposition, resulting in the residue of PbI2 left, becomes the problem and thereby influences the device performance reproducibly. In this regard, we introduce a vacuum treatment to treat the samples at the different stages of the sequentially deposition to investigate the level of PbI2 left. The SEM and XRD are used to identify the morphology, the crystallization and the conversion of the perovskite film during the sequential deposition. Our result indicates that the as-prepared PbI3 forms a compact morphology after the vacuum treatment, leading to more amount of PbI3 left within the resulting perovskite film. On the other hand, the vacuum treatment is applied for the PbI2 film right after the MAI immersion, showing a less amount of PbI2 left within the resulting perovskite film. The UV-Vis and EIS are carried out to analyze the optical property and charge transport property, respectively, of perovskite films with different level of PbI2 residue. J-V characteristic of the perovskite solar cells with the different level of PbI2 residue is tested under AM 1.5G illumination. More details of the conversion efficiency of perovskite solar cells, affected by vacuum treatment at the different stages of sequential deposition, will be discussed in the presentation.

4:45 PM ES15.09.04

Spotlight Talk—Analysis of Charge Transfer Dynamics in Planar and Mesoporous Mixed Halide Perovskite Solar Cells

For photovoltaic devices based on hybrid organic-inorganic perovskites thin films has remained elusive. Herein, we have analyzed the influence of chloride substitution on interfacial charge transfer dynamics in perovskite thin films with two different architectures. We compare different mixed MAPbI3 perovskite films fabricated under identical conditions that differ only in the TiO2 residue is tested under AM 1.5G illumination. More details of the conversion efficiency of perovskite solar cells, affected by vacuum treatment at the different stages of sequential deposition, will be discussed in the presentation.

Spotlight Talk—Conductivity Tuning via Doping with Electron Donating and Withdrawing Molecules in Perovskite CsPbX3 Nanocrystal Films

Doping of semiconductors allows tunability of charge carriers and subsequently electronic properties necessary for the development of many technologies. However, controlled doping in lead-halide perovskite semiconductors has proven to be difficult. Lower dimensional perovskites such as nanocrystals, with their high surface area to volume ratio, offer an opportunity for electronic doping via molecular charge transfer. In our work, we explore the tunability of the electronic properties of perovskite nanocrystal films using...
physically adsorbed molecular dopants. Incorporation of the dopant molecules into CsPbI$_3$ nanocrystal thin films is confirmed via infrared and photoelectron spectroscopies. We discover pre-treated CsPbI$_3$ nanocrystal films to be slightly p-type in behavior. Incorporating an electron-accepting dopant increases conductivity while an electron-donating molecule results in lower conductivity, appearing to compensate the p-type nanocrystal arrays. Time-resolved spectroscopic measurements reveal time scales on the order of August-mediated recombination in the presence of excess electrons or holes. Transport measurements demonstrate that both the local and long-range hole mobility is improved by doping of the nanocrystal arrays using an electron-accepting molecule. The improved photo-excited hole mobility in p-type arrays lead to an enhancement in photo-transistors.

Spotlight Talk—Analysis of Charge Transfer Dynamics in Planar and Mesoporous Mixed Halide Perovskite Solar Cells Zhongguo Li,$^{1,2}$ and Clemens Burda$^{3}$; $^{1}$College of Physics and Electronic Engineering, Changshu Institute of Technology, Suzhou, China; $^{2}$Department of Chemistry, Case Western Reserve University, Cleveland, Ohio, United States.

For photovoltaic devices based on hybrid organic-inorganic perovskites thin films, the cell architecture is a vital parameter in defining the macroscopic performance. To date, there are a handful of studies about the carrier dynamics in perovskite devices with various morphologies. However, the correlation between architecture and carrier dynamics in mixed perovskites thin films has remained elusive. Herein, we have analyzed the influence of chloride substitution on interfacial charge transfer dynamics in perovskite thin films with two different architectures. We compare different mixed MAPbI$_3$ solar cells fabricated under identical conditions that differ only in the TiO$_2$ layer, therefore decouple the composition impact from device performance. Our results clearly demonstrate that the enhancement mechanism of power conversion efficiency is dramatically different in planar and mesoscopic architectures. In planar architecture, Cl substitution leads to faster electron injection rate from perovskite to planar TiO$_2$. In contrast, Cl addition demonstrate no discernable influence on electron injection to mesoporous TiO$_2$, suggesting the retarded interfacial charge recombination give rise to improved performance. This result could be useful for future photovoltaic and optoelectrical devices based on halide perovskite.

General Strategy for Defects Passivation in Crystalline Organo-Metal Halide Perovskite Film to Enhance Its Photovoltaic Performance and Stability Kai-Chi Hsiao, Bo-Ting Lee and Wei-Fang W. Su; National Taiwan University, Taipei City, Taiwan.

Outstanding power conversion efficiency of organo-metal halide perovskite solar cell loses its open-circuit voltage (Voc) and stability in ambient environment. Understanding the underlying mechanisms of instability and Voc loss are urgently needed to resolve the issues. Ionic defects (anion and cation vacancies) in perovskite, especially in mixed cation and halide perovskite, are regarded as the major factor to deteriorate the stability and efficiency. Suppress ionic defects can directly retard both trapped-assist recombination of charge carriers and the diffusion of gas molecules (i.e. moisture, oxygen) in perovskite and therefore improve the Voc and stability of device.

Herein, we report a general strategy of post-treatment using Lewis adduct to passivate ionic vacancies in crystalline perovskite film to improve its device performance and stability. The Lewis adducts of organo ammonium salt were investigated. The systematical characterizations of passivated films reveal the electronic disorder and trapped density are successfully reduced after Lewis adduct post-treatment. A more than 50 mV increase in Voc has been achieved due to the less non-radiative recombination of charge carriers as compared with the device without passivation. In term of device stability, less than 1% power conversion efficiency was observed when the device was irradiated 10 min continuously and the 300-second maximum power point was tracked simultaneously in the ambient. Compared with conventional passivation approaches which are carried out at the crystallization step of perovskite film and are difficult to control, this strategy can directly passivate the ionic defects after the film is crystallized. That gives an avenue to the ultrafast or one-step large-scale coating process to obtain a high-quality perovskite film with ease which has potential to become a commercial viable process.

Spotlight Talk—Vapor Growth of In-Plane Directional CsPbX$_3$ Perovskite Nanowires for High-Performance Photonics and Optoelectronic Devices Weihao Zheng, Muhammad Shoaib, Xiaoxia Wang and Anlian Pan; Hunan University, Changsha, China.

Recently, all-inorganic perovskites CsPbX$_3$ (X = Cl, Br, I) nanowires (NWs) have recently demonstrated potential applications in integrated photonics devices such as lasers and photodetectors due to their unique physical and chemical characteristics. Considering the perovskite based integration application, large-scale growth or assembly of perovskite nanowires with horizontal alignment on surfaces is highly desirable. Here, we demonstrate the controlled growth of in-plane directional perovskite CsPbBr$_3$ NWs, induced by graphoepitaxial effect on annealed M-plane sapphire substrates. High-performance photodetectors constructed on these individual NWs exhibit excellent photoresponse with an ultrahigh responsivity of 4400 A/W and fast response speed of 252 μs. Furthermore, we achieved wavelength-tunable CsPbX$_3$ nanowire laser arrays at room temperature with quite low lasing thresholds and high quality factors based on the directional growth approach. Meanwhile, we studied the exciton–photon coupling effect of these perovskite nanowire cavities under the excitation of a pulsed laser, from which highly atomic composition dependent Rabi splitting of ~210 ± 13, 146 ± 9, and 103 ± 5 meV for the CsPbCl$_3$, CsPbBr$_3$, and CsPbI$_3$ are obtained at room temperature. In addition, by using a novel temperature difference triggers growth strategy, high quality CsPbX$_3$ nanowire arrays with the integration of the merits of the liquid- and gas-phase methods was successfully synthesized, these nanowire arrays show excellent stability and good optoelectronic properties at room temperature. This work presents an important step toward scalable growth of high-quality perovskite NWs, which will provide promising opportunities in constructing integrated nanophotonic and optoelectronic systems.

Solar cells based on Methyl-Ammonium Lead Triiodide (MAPbI3) perovskite have gained attention due to their remarkable progress in performance efficiency during recent years [1]. However, it has been hampered to put the material on the market due to their device stability under outdoor application of photovoltaic devices. A comprehensive study on degradation mechanism initiated with water molecules is thus essential for practical realization of MAPbI3 based solar cells. Using first-principles calculation based on the density-functional theory, we here focus on and investigate ion-migration dynamics in a MAPbI3 intercalated with water and their enhancement by the influence of grain boundary (GB). The nudged elastic band (NEB) method is employed to find the barrier potential and corresponding optimal minimum energy path (MEP) of migrated ions. We find that one of H ions of a water molecule segregated into a GB is dissociated, migrated along the GB, and attracted by an N atom in the MAPbI3 with comparatively lower potential barrier (~0.27eV) [3], following the H-ion release from an ammonium. Such migration of H depends upon the subsequent changes of charge states of surrounding atoms [4]. Additionally, a vacant space around the N atom plays as a cage for the diffused H atom. The water intercalation greatly reduces the barrier potential for an H-ion motion in the GB interior of MAPbI3 which can be liable to initiate the degradation of crystallinity of the perovskite. The iso-surface of electronic charge distribution at HOMO-LUMO and partial density of state (PDOS) of the ruling N atom reveal the mentioned phenomenon. More importantly, the antisymmetric GB structure is prominent for faster molecular attractions due to their weak activation energies.

ES15.10.06 Spotlight Talk—Control the Charge Accumulation for Efficient, Repeatable and Interface Stable Homo-Junction Planar Perovskite Solar Cells Jianxing Xia, Junsheng Luo, Fei Han, Zhongquan Wan, Yu Shi and Chunyang Jia; School of Electronic Science and Engineering, University of Electronic Science and Technology of China, Chengdu, China.

The nature of trap defects such as the under-coordinated ions at the perovskite surface and grain boundaries are always trapping the free electrons or holes by the electrostatic force and speeding up the ion migration via the defect vacancy channels, which is significantly limiting the charge extraction efficiency and devices long-term stability in perovskite solar cells. In this work, we induced an external electric field which supplied by a molecular dipole to the interlayer of electron transfer layer (ETL) and perovskite. We employed Kelvin probe force microscope (KPFM) and Femtosecond transient absorption (fs-TA) to systematic study the states of charge distribution and transport properties in the perovskite after add the extra interface electric field. The results show a strong gradient electron accumulation at the applied interface and forming a homo-junction perovskite which supplied an extra built-in electric field (E_B), and finally resulting in faster interface charge transportation. Furthermore, the ion migration can efficiently be suppressed at the applied interface and thus reduce the disorder of energy level. Based on these results, we fabricated the PC61BM based n-i-p architecture perovskite solar cell and achieving a PCE of 20.14% with high Voc of 1.14V, which is the record efficiency of PC61BM based n-i-p devices. These devices also show higher stability compared to the standard cells.

ES15.10.07 Spotlight Talk—Versatile Pseudo-Halide Based Perovskites—Photophysics and Utility in Optoelectronic Devices Satyawan Nagane, Dhabyajoti Ghosh, Wagaas Rehman, Vijay Venugopala, Laura Herz, Alison Walker, Saiful Islam, Satishchandra Ogale and Aditya Sadhanala; 1) University of Cambridge, Cambridge, United Kingdom; 2) Physics, University of Oxford, Oxford, United Kingdom; 3) University of Bath, Bath, United Kingdom; and 4) Indian Institute of Science Education and Research, Pune, India.

Pseudo-Halide have started to become a new stream of research because of their capability of not only replacing the scarce options of standard halides in perovskites (Cl, Br and I), but also because of the unique and useful optoelectronic properties therein. This work will describe the versatility of using a organo pseudo halide based salt to fabricate various perovskites and demonstrate their resulting - interesting and unique photo-physical and optoelectronic properties.

ES15.10.08 Spotlight Talk—Quantification of Ion Migration in MAPbBr3 Solar Cells with Varying Grain Size Lucie McGovern, Loreta A. Muscarella, Moritz H. Fuchscher and Bruno Ehrler; AMOLF, Amsterdam, Netherlands.

Hybrid halide perovskites have been attracting extensive interest as next generation photovoltaic technologies. Large bandgap metal halide perovskites such as MAPbBr3 offer a range of applications in multijunction solar cells, electrochemical energy storage, electrocatalysis, and LEDs, as well as providing an interesting platform for comparison with the more commonly studied MAPbI3, and mixed-halide perovskites.

It was shown that substituting Br for I increases the chemical stability making MAPbBr3 much more stable under environmental conditions when compared to MAPbI3. We study this increase in stability under environmental conditions and show that it stems from a change in ion migration properties when going from MAPbI3 to MAPbBr3. Furthermore, we investigate the evolution of this behavior in different MAPbBr3 solar cells as a function of the grain size of the active perovskite film. Grain boundaries change ion migration by providing alternative pathways for the ions to migrate, thereby affecting crucial properties of the process such as activation energy and diffusion coefficient. In our work, we use Transient Ion Drift to quantify the activation energies, diffusion coefficients, and concentrations of the mobile ions, and show the link between grain size, ion migration, and stability.

ES15.10.09 Spotlight Talk—Planar Perovskite Solar Cell by Two-Step Deposition Method via Blade-Coating Technique Zahrah S. Almutawah, Ramez Hosseinian Ahangharnajad, Zhaoning Song, Adam Phillips, Yanfa Yan and Michael Heben; University of Toledo, Toledo, Ohio, United States.

Organic-inorganic metal halide perovskites have attracted much interest and shown great promise in recent years due to their compatibility with cheap solution processing, ease of fabrication, and enhanced power conversion efficiencies. Currently, perovskite solar cells are transitioning from small area devices to large area devices that are compatible with manufacturing. Blade-coating is a promising deposition technique because it is a low cost, environmentally friendly, and easily translated to roll-to-roll processing. Most current work has ever been focused on the advantages of high efficiencies for perovskite solar cells using the single-step blade coating. However, the most recent 23.3% record efficiency device was fabricated using the two-step spin-coating method. In this study, we investigate the possibility of fabricating large area perovskite solar cells by sequentially depositing PbI3 and mixed organic iodides consisting of FAI and MABr (where FA is formamidinium, and MA is methylammonium) using the blade coating technique. The blade-coated bi-layer precursor films are annealed under different conditions to examine the perovskite phases. This study will focus on understanding the formation and growth behaviors of perovskites formed in a two-step blade-coating process when the pre-deposited PbI3 films are reacted with organic iodide solution with various concentrations of mixed FA/MA cations. Comprehensive understanding of the nucleation and growth behavior of perovskites during the intercalation process will provide insights to improve control of the film quality and allow device performance for devices beyond the simple MAPbI3 system to be improved.

ES15.10.10 Spotlight Talk—Impact of Flash Infrared Annealing on Growth and Photodynamics of MAPbI3 Perovskite Loreta A. Muscarella, Sandy Sanchez, Andries Lof, Michael Saliba and Bruno Ehrler; FOM Institute AMOLF, Amsterdam, Netherlands; Adolphe Merkle Institute, Fribourg, Switzerland.

Flash Infrared Annealing (FIRA) results in pinhole free layers with micrometer size crystalline domains. The fast annealing times, and comparable solar cell efficiency compared to the traditional antisolvent fabricated perovskite solar cells make FIRA a highly promising method for the scaleup of perovskite solar cells. In this work we investigate how the Flash Infrared Annealing affects the crystal growth of MAPbI3 and its dependence on the substrates used. We measure the grain size, crystal structure and orientation using Electron Back-Scattered Diffraction (EBSD). We find a highly oriented cubic structure for perovskite annealed by FIRA and a consistent crystal rotation within perovskite grains. Besides,
we study how the structural properties of the resulting films affect its photophysics. Combining photoluminescence lifetime and spectral maps we show how the growth method affects the steady-state and dynamic optical properties of the resulting films. Our findings directly relate structural properties to the photophysics of lead halide perovskites.

Spotlight Talk—Conductivity Tuning via Doping with Electron Donating and Withdrawing Molecules in Perovskite CsPbI$_2$ Nanocrystal Films Ashley Gaulding1, Ji Hao1, Hyun Suk Kang1, Elisa Miller1, Severin N. Habriseutinger1, Qian Zhao1,2, Abhijit Hazarika1, Joseph Luther2 and Jeffrey Blackburn3; 1National Renewable Energy Lab, Golden, Colorado, United States; 2Nankai University, Tianjin, China.

Doping of semiconductors allows tunability of charge carriers and subsequently electronic properties necessary for the development of many technologies. However, controlled doping in lead-halide perovskite semiconductors has proven to be difficult. Lower dimensional perovskites such as nanocrystals, with their high surface area to volume ratio, offer an opportunity for electronic doping via molecular charge transfer. In our work, we explore the tunability of the electronic properties of perovskite nanocrystal films using physically adsorbed molecular dopants. Incorporation of the dopant molecules into CsPbI$_2$ nanocrystal thin films is confirmed via infrared and photoelectron spectroscopies. We discover pre-treated CsPbI$_2$ nanocrystal films to be slightly p-type in behavior. Incorporating an electron-accepting dopant increases conductivity while an electron-donating molecule results in lower conductivity, appearing to compensate the p-type nanocrystal arrays. Time-resolved spectroscopic measurements reveal time scales on the order of Auger-mediated recombination in the presence of excess electrons or holes. Transport measurements demonstrate that both the local and long-range hole mobility is improved by doping of the nanocrystal arrays using an electron-accepting molecule. The improved photo-excited hole mobility in p-type arrays lead to an enhancement in photo-transistors.

ES15.10.12
Hot Carrier Dynamics in Lead Halide Perovskites from a THz Mobility Perspective Andrés Burgos-Caminal, Aurélien Willauer, Ahmad Ajdar Zadeh and Jacques-E. Moser; Photophysical Dynamics Group, Institute of Chemical Sciences and Engineering, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland.

Ultrafast time-resolved terahertz spectroscopy (TRTS) allows for the direct probing of charge carriers and quasi-particles in semiconductors. The sensitivity of the technique to both the carrier mobility and its density can help elucidate the mechanisms of their temporal evolution. The use of gas photodetectors provides short, ultra-broadband THz pulses and, thus, offers an improved time-resolution.

Here, we present a study of the early stages of the charge carrier dynamics in lead halide perovskite thin films from the point of view of the THz mobility. Taking advantage of a 200 fs time-resolution, we were able to temporally follow the cooling of hot carriers through the observation of the change of the carrier's mobility. This change is understood as resulting from a modification of the effective mass.1

Our results are compatible with a hot carrier cooling mechanism implying LO phonon emission. This is subjected to a phonon bottleneck, and competes with a dynamic screening process, which time-constant is identified as being due to polaron formation.3 While the screened hot carriers take longer to cool down, the dynamic screening process does not produce a change in mobility when only cold carriers are involved.

Measurements applied to perovskite samples of various compositions are compared to elucidate the role of cations and anions in both processes.

SESSION ES15.11 Interface Physics and Charge Extraction
Session Chair: Sanford Ruhan
Thursday Morning, April 25, 2019
PCC North, 100 Level, Room 130

8:00 AM ★ES15.11.01 Interfaces Halide Perovskites: Passivating Defects for Reduced Non-Radiative Recombination David S. Ginger; University of Washington, Seattle, Washington, United States.

In this talk we describe the role of interfaces and surface defects on non-radiative recombination losses in hybrid perovskite semiconductors. Using combinations of microscopy and time-resolved photoluminescence spectroscopy we show that not only are perovskite surfaces sources of significant non-radiative loss, but that chemical passivation of surface states can lead to near-ideal semiconductor properties, achieving over 90% PL internal quantum efficiency and quasi-Fermi level splittings that exceed 96% of the Shockley-Queisser limit under illumination. We next explore the interface between the perovskite and various charge extraction layers, combining experiment and simulation to show that surface recombination at the charge extraction layers is a limitation in current perovskite solar cell architectures.

8:30 AM ★ES15.11.02 Interface Energetics of Halide Perovskites Philip Schulz; CNRS-Institut Photovoltaique d'Ile de France (IPVF), Palaiseau, France.

My talk will focus on the means and developments to analyze and tailor interfaces in halide perovskite (Hp) based semiconductor devices to gain control over the electronic properties at the nanoscale, as interfacial design routes determine the electronic coupling between the perovskite absorber and adjacent charge extraction and transport layers. On the one hand, the device characteristics can be affected by the alignment of the frontier molecular orbitals of an organic charge transport layers (CTL) with the electronic transport level in the perovskite. On the other hand, the doping type of the substrate underneath can template the doping type of subsequently deposited Hp films. In our studies we elucidated these mechanisms by examining a selection of organic, oxide and carbon nanotube charge transport layers adjacent to the perovskite film [1].

In my talk, I will highlight the use of ultraviolet and X-ray photoemission spectroscopy (UPS/XPS) as well as inverse photoemission spectroscopy (IPES) to determine the surface energetics and electronic energy level alignment at the MHP/CTL interface while at the same time tracking the interface chemistry. This approach enables us to explain band offset in the perovskite layer by either chemical interactions or by changes in the electrostatic potential. The results not only suggest guidelines on how to integrate charge extraction layers into perovskite photovoltaic devices but also explain more generally what to expect when the electronic structure of the perovskite is subject to extrinsic perturbations [2].
