Large-scale data-mining workflows are increasingly able to predict successfully new chemicals that possess a targeted functionality. The success of such materials discovery approaches is nonetheless contingent upon having the right data source to mine, adequate supercomputing facilities and workflows to enable this mining, and algorithms that suitably encode structure-function relationships as data-mining workflows which progressively short list data toward the prediction of a lead material for experimental validation.

This talk describes how to meet these data science requirements via a large-scale data-mining case study that aims to discover materials with panchromatic optical absorption for solar-cell applications [1]. In particular, the presentation shows how to auto-generate large material databases of photovoltaic-relevant experimental information from documents, using natural language processing and machine learning, via our ChemDataExtractor tool [2-4]. A workflow that executes large-scale electronic structure calculations to afford a computational counterpart to these experimental data is then described. These wavefunction calculations are used to extend knowledge beyond experiment. The resulting large database of chemical structures and their optical properties is then mined for materials discovery using custom-built algorithms that are encoded forms of structure-function relationships. These molecular design rules progressively filter the parent set of chemicals until a lead candidate appears, which is experimentally validated. The highly promising photovoltaic device outputs afforded experimentally from our predicted lead materials demonstrate the power of data-driven materials discovery.

The talk closes by translating the generic data-science aspects of this case study into the wider perspective of an overarching template for data-driven materials design, prediction and experimental validation of functional materials.

Despite significant progress in natural language processing and machine learning, there remains a gap between the current data extraction needs in fields such as materials science and the capabilities of state-of-the-art tools. In this talk we describe our efforts to develop human-machine methods for automatically extracting scientific facts from literature. Our overarching goal is to decrease the amount of manual extraction—a tedious, time-consuming, and error-prone process—by automating extraction activities where possible. With the assumption that our automated approaches require some supervision we seek to prioritize human involvement while optimizing overall extraction accuracy. We focus initially on the task of extracting polymer names and properties with the aim to create an outline database of polymer properties. In this context, we have explored hybrid human-machine Information Extraction systems with varied amount of human involvement.

Our recent machine learning-based approaches for automatically identifying scientific named entities in text. To circumvent the need for a large annotated corpus, we use an ensemble of word embedding models and limited domain-specific knowledge to propose candidate entities (candidates are words that are deemed similar to a reference entities by our models). We assign the labeling of these candidates (identifying strings that were not actually target entities) to an expert material scientist. This task is more straightforward than reading and recognizing the entities in documents. Finally, we train a semi-supervised named entity word vector classifier to select actual target names from candidates proposed by the word embedding model. Our preliminary results are promising as they are comparable (within 10% recall or number of entities retrieved) to results extracted by a state-of-the-art, domain-specific Natural Language Processing toolkit. However, our approach requires only minimal human input and it does not rely on an exhaustively annotated corpus.

We have assembled the largest dataset of resistivity-temperature measurements on temperature-activated metal-insulator transitions (MITs) to date (45 unique compounds). We supplemented this dataset with additional entries on metals and insulators with known transport behavior, i.e., do not undergo temperature-driven MITs, for comparison. We then collected features for the 147 compounds which describe chemical composition (e.g. mean electronegativity, atomic radii, and elemental heat of fusion); overall and local atomic structure; and estimates of the on-site electron repulsion, charge transfer energy, and compound polarizability. From this data, we constructed a machine-learning classifier to predict whether a material would undergo a MIT or not. Our model achieves a cross-validation AUC score of 88.24 +/- 11.63 and a mean accuracy of 79.23 +/- 9.23% on this metal-insulator transition prediction task. We also conducted a survey of 51 graduate students, faculty, and staff scientists to estimate the ability of scientists to classify metals vs. insulators vs. MIT. The mean accuracy for humans was 59.8%.

Artificial Intelligence for Knowledge Generation in Materials Science

The process of scientific inquiry involves observing a signal (data) and interpreting it to generate information (knowledge). For example, in electron microscopy the signal may be a diffraction pattern from which information on crystal orientation may be deduced by applying diffraction theory. Science advances both through improvements in gathering data and in techniques for extracting knowledge from it. Artificial intelligence (AI) – a broad term comprising data science, machine learning (ML), neural network computing,
A Self-Driving Laboratory for Accelerating Materials Discovery

Kiran Vaddi, Surya Vamsi Devaguptapu, Fei Yao, Brian Hayden, Olga Wold and Krishna Rajan; Materials Design and Innovation, University at Buffalo, The State University of New York, Buffalo; New York, New York, United States; University of Southampton, Southampton, United Kingdom.

This presentation will focus on our self-driving laboratory for thin film materials discovery and optimization. Discovering high-performance, low-cost materials is an integral component of technology innovation cycles, particularly in the clean energy sector. The linear methodology currently used to develop optimal materials can take decades, which impedes the translation of innovative technologies from conception to market. Our interdisciplinary team is utilizing advanced robotics, machine learning, and computational screening to overcome this challenge. We are closing the feedback loop in thin film materials research by enabling our self-driving robotics platform named “Ada” to design, perform, and learn from its own experiments efficiently and in real time. As a proof-of-principle set of experiments, we will show how Ada discovers and optimizes high-performance, low-cost hole transport materials for use in advanced solar cells. We will also showcase how Ada’s modular design can enable the automated and autonomous discovery of materials for other clean energy technologies.
The research was conducted at ORNL's Center for Nanophase Materials Sciences (CNMS), which is a U.S. DOE Office of Science User Facility.

This talk addresses the challenges of engineering a software package, which facilitates the development and deployment of the self-driving laboratories. Recently, we made significant progress towards addressing these challenges and have implemented ChemOS; a versatile, flexible, and modular orchestration software, which contains the essential layers indispensable for operating the self-driving laboratories. ChemOS coordinates the overall computational and experimental workflow, monitors experiments, administers data collection, storage and sharing as well as details about the configurations of the available automated laboratory equipment, potentially distributed across different physical laboratories. The functional design of ChemOS and its modular structure allow for the global control of complex heterogeneous automation platforms. ChemOS facilitates interaction between researchers, AI algorithms, and robotic hardware by providing various intuitive interfaces via natural language processing. One of the crucial components of ChemOS are the various AI algorithms encapsulated in the learning module. Notably, this module includes Phoenixes and Chimera, two in-house developed AI algorithms specifically designed to enable an optimal use of automated equipment for Pareto optimization in chemistry and materials science. These algorithms learn procedures on-the-fly, with no prior assumptions allowing to follow unprecedented routes to scientific discovery.

We demonstrate the performance of ChemOS on the optimization of blends consisting of hole-transport materials, stabilizers, and dopants with the goal to maximize both the conductivity and the stability of spin-coated film on glass substrate. In this example, the experimental procedure is remotely orchestrated by ChemOS, and experiments run in full autonomy.

Data Services to Increase Data Accessibility and Adoption of Data-Driven Materials Science Research

Ben Blaiszik1, Logan Ward1, Marcus Schwarting1, Jonathon Gaff3, Ryan Chard1, Zhuozhao Li2, Kyle Chard1, Yadu Nand1, Evan Pike1, Michael Franklin1, Steve Tuceke1 and Ian Foster1; 1Data Science and Learning, Argonne National Laboratory, Darien, Illinois, United States; 2Computer Science, Cornell University, Ithaca, New York, United States; 3Computer Science, The University of Chicago, Chicago, Illinois, United States.

Increasing the accessibility, application, and adoption of data-driven materials science research techniques requires a software and data service infrastructure to enable simple and broad access to large sources of materials data and state-of-the-art machine learning and physical models. For these data and models to be most useful, researchers must be able to find, access, gather, and use them. Yet datasets may be large (i.e., terabytes or gigabytes in size or comprised of millions of files), of varying qualities, heterogeneous (i.e., many file types), or located on distributed storage resources or behind varying service layers. Similarly, models of interest to a researcher may be difficult to find, completely unavailable, out of date with current data, or require a high level of technical proficiency or significant computational resources to recreate and run. Thus, building a data service infrastructure capable of simplifying and automating aspects of data and model discovery, access, and usage remains a key challenge towards speeding the pace of discovery and innovation in materials science. Here, we present a set of such data services: (1) the Materials Data Facility (MDF) to streamline broad data sharing regardless of size and location, automate materials-specific indexing of dataset contents, and enable data discovery to spur new analyses and machine learning efforts; and (2) the Data and Learning Hub for Science (DLHub) to enable publication of models, facilitate invocation of state-of-the-art models on new data through a hosted service, and automate the retraining of models when new data are available. We present the DLHub and MDF services as a means to bring data-driven materials capabilities to a much wider set of research users. These capabilities are shown via a set of examples highlighting the ways MDF and DLHub features can be combined to enable data discovery and model usage with far less effort that previously required.
more than 60 million mentions of materials, structures, properties, applications, synthesis methods, and characterization techniques from our database of over 3 million materials science abstracts. With this data, we can augment conventional materials informatics techniques with NLP-derived features, showing significantly improved performance for materials discovery and design. In particular, we illustrate that commonly used chemical features in property prediction models are outperformed by features constructed from text-mined chemical word embeddings. In addition, we demonstrate that new functional materials, such as thermoelectrics and topological insulators, can be identified using only contextualized word embeddings for materials. These embeddings also prove useful as inputs for more advanced machine learning models.

GI01.04.03
Augmenting Machine Learning of Energy Landscapes with Local Structural Information Shreyas Honrao, Stephen Xie and Richard Henning1, 2; 1Materials Science and Engineering, Cornell University, Ithaca, New York, United States; 2Materials Science and Engineering, University of Florida, Gainesville, Florida, United States.

We present a machine learning approach to calculate formation energies of compounds relative to the ground state crystal structure of the pure components in the context of structure predictions. Typical methods for structure predictions such as genetic algorithms often rely on density-functional theory codes to perform such calculations at a relatively high computational cost. Here, we explore commonly used learning algorithms such as kernel ridge regression, support vector regression, and artificial neural networks. The efficiency of machine learning approaches relies on suitable data representations that encode the relevant physical information about the crystal structures. We illustrate a novel representation using local radial and angular distribution functions. We apply the machine learning approaches to binary systems and show that these methods provide small root-mean square prediction errors of a few meV/atom across the composition and structure space. The high accuracy makes our machine learning models great candidates for the exploration of energy landscapes.

GI01.04.04
Predicting Material Properties Using a Novel Descriptor “Elemental Fingerprints” with Neural Networks Jackyun Hwang and Satoshi Watanabe; Department of Materials Engineering, The University of Tokyo, Tokyo, Japan.

Thanks to the rapid growth of machine learning (ML) techniques, it has become possible to predict various material properties, screen promising candidate materials having desired properties, and select important features. In many cases, however, a model for ML is applicable to a specific family of materials or often requires information about atomic arrangements that are difficult to obtain in real experimental situations. On the other hand, it is well known that the insufficiency in information degrades ML accuracy severely. In this study, we focus on cases where only limited information, such as a concentration of raw materials or chemical formula, is available for ML. We propose a novel descriptor set named “elemental fingerprints set” for such a situation. The elemental fingerprints set is made from the frequency distribution of properties of the elements in the target material. This set has an advantage that no information on atomic arrangements, such as crystal structure and coordination numbers, is necessary for its construction. This feature fits well with the real situation of experiments where actual atomic arrangements are not known, and only the experimental conditions and target materials are controllable. To demonstrate the effectiveness of this elemental fingerprints set, we tried to train and predict the standard formation energy, band gap energy, and volume per atom (or density) using data taken from Open Quantum Materials Database (OQMD). For materials having more than one atomic structure in OQMD, we used the most stable crystals to establish the one-to-one correspondence between materials and their properties. The models for ML were constructed using the neural network ensemble with adversarial training. This method enabled us to reduce the prediction error by more than 25% compared with a naive single neural network model. It is also worth noting that this ensemble method is suited for modern parallel computing, enabling fast training and prediction.

The elemental fingerprints set shows always better performance than the two descriptor sets suggested previously. The best performance in our study was obtained when the combination of three descriptor sets, i.e. the previous two and ours, was used together. The standard formation energy is predicted with the mean absolute error of 31.7 meV/atom and coefficient of determination of 0.981 in the test of 25,315 compounds after training with 227,838 compounds.

Machine Learning Accelerates the Characterization of Functional Materials Tonio Buonassisi; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

During a typical R&D cycle of learning, approximately a quarter of the time is directly invested in diagnosing the root cause(s) of underperformance, and additional time is indirectly wasted due to faulty diagnoses resulting in less productive experimental cycles. In this presentation, I demonstrate a >10x acceleration of diagnosis, with improved accuracy, using classification, regression, and advanced statics algorithms. I’ll dive deep into how classification and analysis of spectra, including X-ray diffraction data, can be performed within seconds using fully convolutional neural networks with global averaging layer, leading to an accuracy improvement of ~5% over conventional neural networks. We identify and distinguish between sources of error using class averaging maps (CAMs). This allows us to visualize the output of our algorithm, and observe what features in the spectra are used more heavily by the FCN to perform the analysis. We demonstrate that characterization problems constitute a non-trivial classification problem, by employing the t-SNE methodology, as different classes are often not linearly separable. In closing, I’ll highlight several other cases where neural networks and Bayesian inference have shed light on characterization, aiding scientists in more rapidly improving their materials.

GI01.04.06
Optimization of Transparent Hole-Conducting Materials Via Machine Learning Jingfei Wei1, 2, Xiaojie Xu1, James Bullock3, Gurudyal Gurudayal2 and Joel W. Ager1, 2; 1Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Chemistry and Chemical Engineering, Southeast University, Nanjing, China; 3Lawrence Livermore National Laboratory, Livermore, California, United States; 4Department of Electrical and Electronic Engineering, The University of Melbourne, Melbourne, Victoria, Australia; 5Department of Electrical Engineering and Computer Sciences, University of California, Berkeley, Berkeley, California, United States; 6Joint Center for Artificial Photosynthesis, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 7Materials Sciences and Engineering, University of California, Berkeley, California, United States.

P-type transparent conducting thin films (p-TCMs) are essential components of optoelectronic devices including solar cells, ultraviolet detectors, displays, and flexible sensors. Cu-Zn-S (CZS) thin films prepared by chemical bath deposition (CBD) can have both high transparency in the visible range as well as excellent hole conductivity (>1000 S cm^-1). However, the interplay between the deposition parameters in the CBD process (metal and sulfur precursor concentrations, temperature, pH, complexing agents, etc.) creates a multi-dimensional parameter space such that optimization for a specific application could be time-consuming. Here, we show that fractional factorial design of experiment (DoE) combined with machine learning allows for efficient optimization of p-TCM performance. The approach is guided by a figure of merit (FOM) related to the film conductivity and transmission T in the desired spectral range for the application (FOM, Φ = 10^{-16}RJ), where R is the sheet resistance. A specific example will be shown with 4 CBD deposition factors, leading to 62 experiments including repetitions. The machine learning model is based on Support Vector Machine Regression (SVM) employing a radial basis function (RBF) as the kernel function. 10-fold cross-validation scheme was performed to mitigate overfitting. Predicted areas in the parameter space with maximal FOMs were selected for a second round of optimization (48 experiments). Performance of optimized films as hole contacts in solar cells and in UV photodiodes will be presented. The optimization approach shown here will be generally applicable to any materials synthesis process with multiple parameters.

In case of high-throughput materials exploration, we have to treat about several hundred samples in one day. In conventional method for synchrotron powder X-ray diffraction, we have to fill fine capillaries (0.2 mmΦ) with well-grounded powder. We need more than 10 hours for only sample filling when we measure 100 sample in one day. In this study, we made a prototype for effective and high-throughput evaluation in synchrotron X-ray powder (XRD) diffraction.

Well-grounded perovskite-type Ca$_3$Bi$_2$MoO$_{12}$ powder library were set on a reaction plate (35×35×5mm$^3$), which had 36 reaction wells (diameter 4 mm and developed for high-throughput materials exploration in our group. Powder library deposited in evenly arranged wells were picked up by polyimide tape and set them to the prototype data collection tool developed as an alternative to fine capillaries. Tool were created with 3D printers. The powder adhered to the polyimide tape was made to enter the X-ray irradiation position continuously like a cassette tape.

Ideal diffraction data was obtained by swinging the tape several degrees around the irradiation position when X-rays were irradiated on the powder fixed to the tape. The lattice constant change according to Bi substitution amount can be calculated in a short time from the automatic structural analysis program developed by our group. And it was confirmed that the result was roughly the same as conventional Rietveld analysis by manual.

Acknowledgements:
These XRD and XAFS experiments were conducted at the BL5S1 and BL5S2 of Aichi Synchrotron Radiation Center, Aichi Science & Technology Foundation, Aichi, Japan (Approval No.2017P0202).

Distribution of Zr Atoms in Σ3(1-12)/[100] Ce$_x$Zr$_2$O$_9$ Grain Boundary Using Genetic Algorithm and Substitution Region Restriction Method
Ki-Yung Kim, Young-Bok Kim and Yeong-Choel Kim. KoreaTech, Chonan, Korea (the Republic of).

Since most technical materials are polycrystalline, it is very important to study how grain-boundaries affect the atomic distribution in crystalline materials. When Zr is added to the Σ3(1-12)/[100] Ce$_x$Zr$_2$O$_9$ grain-boundary structure to make CeO$_2$-ZrO$_2$ solid solution, the number of cases where Zr can be substituted to the Ce site is too many; in the grain-boundary structure that is composed of 48 Ce and 96 O atoms, the number of cases for 9 Zr atoms is about 10$^9$. Because added atoms are usually segregated to the grain-boundary, Mizoguchi group restricted the substitution of atoms only to atom sites around grain-boundaries and obtained an optimum structure at high speed [1, 2]. When the atoms, however, are added more than certain amount, they may start to go to bulk region. We used lattice statics and genetic algorithm to study Zr distribution in the grain boundary structure; Zr atoms gathered around the grain-boundary. We increased the structure size further to reduce the effect of grain-boundary interaction and consider the bulk region in the structure. In order to reduce the computation time, some amount of Zr atoms were first substituted to the atomic sites near the grain-boundary, and then the remaining Zr atoms were substituted to the remaining Ce sites excluding the already substituted sites in the whole Ce sites. This substitution region restriction method could help reduce the number of cases and find optimum structures at high speed.

Construction of Neural Network Potential to Investigate Interface Structures, Ion Migration Under Electric Fields and Phonon Properties
Koji Shimizu$^1$, Takanori Moriya$^2$, Masayoshi Ogura$^3$, Wei Liu$^4$, Wenwen Li$^5$, Yasunobu Ando$^6$, Etsu Minamitani$^7$ and Satoshi Watanabe$^8$. 1Department of Materials Engineering, The University of Tokyo, Bunkyo-ku, Japan; 2Research Center for Computational Design of Advanced Functional Materials, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan; 3Research and Services Division of Materials and Data System and Integrated System (MaDIS), National Institute for Materials Science, Tsukuba, Japan.

Recently, the construction of interatomic potentials using first-principles calculation data and machine-learning technique has been widely tried because of higher reliability and low computational costs. Our group previously constructed the interatomic potentials of amorphous-Li$_2$PO$_4$ using neural network (NN) [1], and showed that the calculated Li-ion conductivities agree well with experimental data [2]. In the present study, we have tried to extend the application range of the NN potentials (NNPs) in the following three aspects: (1) Metal/solid electrolyte interface structures (Au/LiPO$_4$ for the development of all-solid-state Li-ion batteries and novel memory devices) [3], (2) ion dynamics under electric fields (Li migration in amorphous-Li$_2$PO$_4$), and (3) phonon properties (wurtzite GaN for the power semiconductor devices).

(1) The construction of NNPs for Au/LiPO$_4$ is challenging because this is a four-elements system which involves a large number of input structures and parameters. We have explored the possibility of accelerating the construction process by the following procedure: First, we constructed two separate NNPs optimized for Au and Li$_2$PO$_4$, respectively, and then constructed the NNp for the Au(111)/Li$_2$PO$_4$ system with adding the interactions of Au-Li, P-Li and O-Li to the two NNPs. We have found that the NNPs show comparable accuracy with the conventional one, while the present approach required less computational time for NN potential optimization.

(2) The charge state is of critical importance to evaluate the change in atomic forces due to applied electric fields. By examining the forces acting on atoms in amorphous-Li$_2$PO$_4$ under electric fields using density functional theory (DFT) calculations, we have found that a proportional relationship between the changes in atomic forces and the electric field, and a strong correlation between local atomic structures and Born effective charges. Based on these findings, we have constructed the NNP which can predict the Born effective charges. In the presentation, we will also show the molecular dynamics simulation results under electric fields.

(3) Since the prediction of phonon behavior needs higher-order derivatives of energy than that of force, the accuracy of NNPs constructed with the conventional procedure [1] is often insufficient for phonon properties. Therefore we have optimized the NNPs so as to reproduce the atomic forces obtained by DFT calculations. The phonon dispersion calculated using this NNP agrees well with DFT results. In the presentation, we will also discuss the thermal conductivities of wurtzite GaN obtained by non-equilibrium molecular dynamics simulations.

This work was supported by CREST, JST and JSPS KAKENHI, Japan.

Infrared Design of Thermoelectric Materials—Results and the Case for a Database of Charge Scattering Times
Kedar Hippalgaonkar$^1,2$; 1Institute of Materials Research and Engineering, Singapore, Singapore; 2Nanyang Technological University, Singapore, Singapore.

Deep Learning algorithms such as neural networks have recently emerged and have the potential to enable data-driven discovery of new material properties. Functional properties
are especially difficult to predict as they not only depend upon ground state properties that are routinely calculated by first principles DFT, but also transport properties such as scattering times and energy dependence. We show the first demonstration of utilizing fully connected neural networks to not only predict thermoelectric properties of the known database of materials, but also towards inverse design and feature selection for both atomic and material descriptors. The limitation of such a technique is that data on non-equilibrium descriptors such scattering times does not exist and I will talk about our foray into creating and learning from such a dataset - the Singapore Materials database (singmat) enabled by high performance computing.

8:15 AM *GI01.05.02
Pursuing the Next-Generation of High-Efficiency Phosphors with Machine Learning Jakoah Bragoch; University of Houston, Houston, Texas, United States.

The development of new phosphors that are necessary for the next generation of high efficiency LED lighting requires a unique approach for materials discovery. Researchers often rely on chemical substitution or serendipity to identify new materials; however, this inevitably leads to slow, incremental advances in technology development. Our work has recently created a new approach that uses computational chemistry and machine learning to identify new material guiding our experimental efforts. By predicting the vibrational properties and electronic structure of potential phosphors compounds, high-efficiency materials can be screened a priori ensuring the only best materials are experimentally explored. Following this methodology, our research has developed a number of materials ranging from borates to nitrides with high efficiency and thermal stability at elevated temperatures. Moreover, the complementary use of computation, machine learning, and synthesis provides a fundamental understanding of the composition, structure, and property relationship necessary for the continued advanced optical materials.

8:30 AM *GI01.05.03
Graph Networks as a Universal Machine Learning Framework for Molecules and Crystals Chi Chen1, Weike Ye2, Yuxin Zuo1, Chen Zheng2 and Shyeu Ping Ong3; 1 Nanoengineering, University of California, San Diego, San Diego, California, United States; 2 Chemistry, University of California, San Diego, San Diego, California, United States.

Fast, accurate and transferable surrogate models for property prediction have the potential to rapidly accelerate materials design and discovery. However, classical machine learning models typically depend on feature engineering and the transferability is limited in vast chemical space. Graph networks are a new ML paradigm that supports both relational reasoning and combinatorial generalization. Graphs are a natural representation for a system of atoms and the bonds between them. In addition, graph networks employ graph-level attributes to include structural independent states. Here, we develop, for the first time, MatErials Graph Network (MEGNet) for accurate property predictions in molecular and crystalline materials. We show that the MEGNet models outperform existing ML models in 11 out of 13 properties of the QM9 molecule data set. Furthermore, a single-task MEGNet model can accurately predict internal energy, enthalpy and free energy using temperature, pressure and entropy as graph-level inputs. Similarly, the MEGNet models trained on ~60,000 crystalline materials achieved significantly lower errors compared to the state-of-the-art models on formation energy, band gap and elastic moduli. Such MEGNet models are interpretable and well-known chemical trends of elements can be extracted from the model-learnt elemental embeddings. Lastly, we demonstrate that transfer learning of elemental embeddings trained from a larger data set can accelerate the training of property models with smaller amounts of data, addressing one of the critical bottlenecks to application of machine learning in materials science.

8:45 AM *GI01.05.04
Automated Machine Learning Applied to Diverse Materials Design Problems Anubhav Jain; Lawrence Berkeley National Laboratory, Berkeley, California, United States.

There have been many recent machine learning efforts aimed at determining composition-property or structure-property relationships. Typically, each application and data set requires fitting its own model. In this presentation, I will describe a general algorithm called “automatminer” that automatically determines a machine learning model for composition-property or structure-property relationships given a data set. Automatminer generates materials science descriptors, performs feature selection, and conducts model and hyperparameter optimization all as a “black box” process. With automatminer, no user intervention is necessary to form a machine learning model. I will report automatminer's performance on a diverse array of materials data sets reported in the literature, showing performance that is comparable to or exceeds that of hand-tuned models for many different types of problems. In addition to its applications as a quick and easy way to generate machine learning models for materials, automatminer can serve as a consistent benchmark against which to evaluate the predictive power of new methods.

9:15 AM *GI01.05.05
JARVIS-ML—Physics Inspired AI for Fast and Accurate Screening of Materials Kamal Choudhary, Brian DeCost and Francesca Tavazza; Materials Science and Engineering Division, National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

One of the main difficulties in applying AI to Material Science is choosing effective descriptors for materials. In this work we developed a complete set of chemo-structural descriptors to significantly extend the applicability of machine-learning (ML) in material screening for multicomponent systems. These new descriptors allow differentiating between structural prototypes, which is not possible using the commonly used chemical-only descriptors. We developed ML models for formation energies, bandgaps, static refractive indices, magnetic properties, modulus of elasticity, k-point integration grid and plane-wave cutoffs for 3D materials as well as excitation energies of two-dimensional (2D) layered materials. We used a gradient boosting decision tree (GBDT) algorithm and the training data consisted of 24549 bulk and 616 monolayer materials taken from JARVIS-DFT database. JARVIS-ML allows to make on the fly prediction using machine learning models trained using our JARVIS-DFT database.

10:15 AM *GI01.06.01
Active Learning Driven Mapping of Combinatorial Libraries of Functional Materials Ichiro Takeuchi; University of Maryland , College Park, Maryland, United States.

Over the years, the challenges in the high-throughput combinatorial experimentation has evolved from synthesis of large number of disparate compounds to developing quantitatively accurate rapid characterization tools to analysis and digestion of large amount of data churned out by the methodology. To address the last challenge, we have been increasingly relying on machine learning techniques including pattern recognition within diffraction data to construct phase diagrams and mining experimental databases to look for trends in materials properties for future predictions. We have previously demonstrated on-the-fly analysis of synchrotron diffraction data, so that a rough picture of the structural phase diagram is attained immediately after all the measurements have been carried out. We are now developing techniques to let the algorithm dictate the sequence of experiments in order to maximize attainable knowledge, minimize experimental resources, and as a result further speed up the materials discovery procedure. In this active learning exercise, a Gaussian process is used to steer the mapping of combinatorial libraries. Examples of dynamic mapping of structural phase diagrams performed at a synchrotron beamline as well as with an in-house diffractometer with a variable temperature stage will be discussed. This work is performed in collaboration with A. Gilad Kusne, V. Stanev, A. Mehta, B. DeCost, J. Hattrick-Simpers, and Y. Liang, and it is funded by NIST and ONR.

10:45 AM *GI01.06.02
Exploring the Materials Genome Through Nanomaterial Megalibraries Chad A. Mirkin; Department of Chemistry and International Institute for Nanotechnology, Northwestern University, Evanston, Illinois, United States.
Throughout history, the materials we have used and rely on have evolved over time, slowly becoming more and more complex. The progression from the stone tools used by early-man to the polymeric materials used today has been relatively slow due to the massive parameter space that materials encompass. Indeed, when one considers the 91 metal elements in the periodic table, and all possible combinations, a nearly infinite number of possible materials exist. This is particularly true at the nanoscale where small changes in size or shape, even at a fixed composition, can dramatically change a material’s properties. Computational methods, or data mining of the current materials genome, can narrow the parameter space to areas of interest for a specific reaction, but experimental methods of fabricating and analyzing these nanomaterials in a high throughput manner are still required, as they often exhibit properties different from their bulk-scale counterparts. In this presentation, an approach to combinatorial nanoscience relying on “megalibraries” consisting of as many as 5 billion positionally encoded nanoparticles will be described. The libraries can be tailored to encompass a wide variety of alloy and phase-separated nanoparticles that are comprised of as many as 8 different elements. Importantly, one megalibrary contains more new inorganic materials than scientists cumulatively have produced and characterized to date. From these libraries, important insight into how thermodynamic phases form in polyelemental nanoparticles has been obtained, and design rules for engineering heterostructures in a polyelemental nanoparticle have been identified. The libraries were used to megalibarize to identify new materials and catalysts for important chemical transformations will be presented. The resulting data sets created by this platform are enormous and require new methods of analyzing them in order to decipher the implications of polyelemental nanomaterials for a wide range of applications. Therefore, this novel approach lays the foundation for creating an inflection point in the pace at which we both explore the breadth and discover the capabilities of the materials genome.

11:15 AM GI01.06.03
Generating the Largest Experimental Materials Database and Initial Findings on the Science It Enables
John M. Gregoire; Joint Center for Artificial Photosynthesis, California Institute of Technology, Pasadena, California, United States.

In an era of rapid advancement of algorithms that extract knowledge from data, the importance of data and metadata management is more important than ever. The largest and most well annotated solid state materials databases are based on computational results, which have enabled successful implementations of machine learning in materials research. Experimental materials databases for specific data types, such as powder diffraction patterns, have been developed, but the challenges in managing and linking data across disparate synthesis and characterization experiments have hampered establishment of large databases with heterogeneous data. The recently published HITEM (Zakutayev 2018) comprises a notable advancement in this area with its well-organized and searchable database of primarily optoelectronic and structural properties of thin film materials. We present a complementary effort with measurements based on photoelectrochemistry research using methods including XRD, XRF, Raman, UV-vis, and electrochemistry. By developing a lightweight data management framework that is generally applicable for experimental science and beyond, we have compiled 5 years of experiments to produce the Materials Experiment and Analysis Database. MEAD contains raw data and metadata from ~15 million experiments on ~1 million materials, as well as the analysis and distillation of that data into property and performance metrics via software in an accompanying open source repository. The unprecedented quantity and diversity of experimental data is searchable by experiment and analysis attributes generated by both researchers and data processing software. The search web interface allows users to visualize their search results and download zipped packages of data with full annotations of their lineage. As the world’s largest open source materials database, MEAD provides substantial challenges and opportunities for incorporating data science in physical sciences, and the associated data and algorithm management framework will foster integrated incorporation of automation and autonomous discovery in materials and chemistry research.

11:30 AM GI01.06.04
Reversible Perovskite Electrocataysts for Oxygen Reduction / Oxygen Evolution for Fuel Cells and Metal-Air Batteries
Brian E. Hayden1, Kieren Bradley2, Kyriakos Giagloglou2, Hugo Jungas3 and Chris Vian4; 1University of Southampton, Southampton, United Kingdom; 2‘Uliko Technologies, Southampton, United Kingdom.

The identification of electrocatalysts mediating both the oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) are prerequisite for the development of reversible fuel cells and rechargeable metal-air batteries. The question arises as to whether a bifunctional catalyst, or a single catalyst site, will exhibit potentials converging to the equilibrium potential of +1.23 V_RHE. Transition metal-based perovskite provide tunable catalysts where site substitution can influence both the ORR and OER catalytic activity. However, substitution in the pseudo-binary phases results in an anti-correlation in ORR and OER activities. We reveal that for LaMnNiO4 compositions with lanthanum A-site sub-stoichiometry exhibits reversible activity correlating with the appearance of the Mn3+/Mn4+ redox couple. The Mn3+/Mn4+ couple is associated with Mn5+ co-existing with Mn3+ in the bulk, as La3+ is substituted by Ni2+ at the A-site to create a mixed valent system. We also show that a direct A-site substitution by the Ca2+ cation in LaCa1-xMnO3 perovskites also results in the creation of Mn5+, the appearance of the Mn3+/Mn4+ redox couple, and a concomitant reversible activity. These results would only have been accessible with an effective combinatorial synthetic and comprehensive high-throughput screening strategy, and highlight a general strategy of optimizing oxide electrocatalysts with reversible activity.

SESSION GI01.07: Accelerating Materials Research with Machine Learning II
Session Chairs: Muratahan Aykol, Elsa Olivetti and Logan Ward
Wednesday Afternoon, April 24, 2019
PCC West, 100 Level, Room 102 C

1:30 PM GI01.07.01
Predicting Properties is not Enough—Realizing the Full Potential of Machine Learning in Materials Discovery
Bruce Meredith; Citrine Informatics, Chicago, Illinois, United States.

Much attention in the materials informatics community has centered on developing machine learning (ML) models to predict materials properties, based on training data derived from experiments and simulations. While such models can be helpful tools, they are (on their own) not sufficient to enable real-world materials discovery. Furthermore, the ongoing focus on property prediction creates the risk that we miss out on the value ML can provide across other critical aspects of the materials discovery process. In this talk, we discuss ML considerations beyond property prediction for materials discovery, including ML model trustworthiness and applicability, automated data analysis, and substitution of simulations or quick experiments for time-consuming, expensive characterization.

2:00 PM GI01.07.02
Design of Molecules with High Hole Mobility by Applying Machine-Learning Technologies
Nobuyuki N. Matsuzawa1, Hideyuki Arai1, Masaru Sasago2, Eiji Fujii2, Erinn Anton2 and James Saal2; 1Panasonic Corporation, Osaka, Japan; 2Citrine Informatics, Redwood, California, United States.

Materials exhibiting higher mobilities than conventional organic semiconducting materials, such as fullerenes and fused thiophenes, are in high demand for applications such as printed electronics. For hole conducting materials, derivatives of benzothieno[3,2-b][1]benzothiophene are known to exhibit the highest hole mobility, yet their carrier transport performance is still not satisfactory. The FUELS sequential learning framework was used to explore new molecules that might show improved mobility using a machine-learning (ML) guided approach. An initial ML model was trained on a set of DFT calculated hole mobilities of molecules in the amorphous state, based on the percolation treatment as derived by Evans et al. [3] According to the sequential learning process, the ML model is used to identify promising candidate molecules, hole mobilities of the candidate molecules are then calculated by applying the DFT method, and the new data are added to the training set to improve the ML model. This iterative loop was performed for several tens of times. Through this process, over 1 million candidate structures were evaluated, and about 100 DFT mobility calculations were performed. New candidate molecules having a fused thiophene structure were identified which had DFT calculated mobility that exceeded the maximum DFT mobility used in the training data set by 25%. Further details will be presented on the extrapolative design of molecules with improved carrier transport property.

Modern semiconductor architectures enabling electronic, optical, sensing, robotic, bio-system or energy transport devices, compose of aggressive insertion of computing components to perform multitudes of data-centric operations at high rates. Advances of fabrication techniques have reached the sizes of quantum confinement regime, therefore making it possible to model electronic properties of device components with first principle calculations. The contact interfaces between these components dictate the device performance, especially as the device dimension approaches nanoscale. These interfaces are often marked by point defects, dislocations and additional strains due to lattice mismatch between the components. Ab initio methods become expensive and infeasible to predict electronic properties of integrated architectures with such a great number of compositional and configurational degrees of freedom. In recent years, there has been a large effort in the materials science community to employ data driven methods to accelerate materials discovery or to develop new understanding of materials behavior. However, the number of efforts, employing first-principle based data-driven methods to predict device performance incorporating processing variability, is almost non-existent. 

In this study, we employ machine learning (ML) algorithms to predict electronic structure and transport properties of non-ideally fabricated multilayered thin film Si/Ge nanostructures. The ML model is trained on inexpensive -200 DFT calculations of Si6Ge1-x substitutional alloys: the training data set is populated exploiting the relationship between geometrical features or local atomic environments in these systems and their electronic structure properties. The predictor variables are obtained with Voronoi tessellation approach and the response variables are calculated with the decision tree regression algorithm. [1] This approach has successfully predicted formation energies to expedite materials discovery. [2] Our ML model trained on random alloys, has shown remarkable ability to predict electronic band structures and Onsager electronic transport coefficients of large non-ideal thin film Si/Ge superlattices. We show the predictive power of our model by comparing the predicted band structures learned from small 16-atom alloy unitcells with the electronic states of large Si/Ge superlattices unfolded to 4x4 monolayer superlattice Brillouin zones [3]. The ML framework has been especially effective in capturing crucial trends in electronic properties for a range of multilayered structures. Our ML framework will facilitate the development of inverse design approach to engineer interface profiles of integrated semiconductor architectures, to accomplish desired device performance and functionalities. The project is funded by the DARPA (DSO) MATRIX program. This work used XSEDE, which is supported by NSF grant number ACI-1053575.

Segmentation in 3D Atom Probe Tomography Using Deep Learning-Based Edge Detection

Sandeep Madireddy, Ding-Wen Chung, Troy Loeffler, Olle Heinonen, Prasanna Balaprakash, and David Seidman

Atom probe tomography (APT) facilitates nano- and atomic-scale characterization and analysis of microstructural features. APT is well suited to study the interfacial properties of granular or heterophase systems. Traditionally, the identification of the interface between, e.g., precipitate and matrix phases, in APT data has been obtained by extracting iso-concentration surfaces. These surfaces are constructed based on the marching cubes algorithm, which extracts an iso-surface from a discrete scalar field with a user-specified concentration value, or by manually perturbing the concentration value until the iso-surface qualitatively matches the interface. These approaches are rather subjective, not scalable, and may lead to inconsistencies due to local composition inhomogeneities.

We propose a digital image segmentation approach based on the holistically-nested edge detection (HED), an end-to-end edge detection approach that performs image-to-image prediction (i.e., takes an image as input, and outputs the prediction at each pixel). This is obtained using deep learning models that leverage fully convolutional networks (FCN) and deeply supervised nets. A key challenge in using deep learning approaches for our task is a lack of large amounts of ground truth segmentation data for training. We mitigate this by adopting a transfer-learning approach, where the weights in the convolution layers are initialized using a VGGNet model pre-trained on Imagenet data, and then training the HED model on the Berkeley Segmentation Dataset and Benchmark (BSDS500) dataset; both of these datasets consist of annotated natural images. The trained HED model is then used to automatically segment the data obtained from APT into different phases. Thus, this approach not only provides an efficient way to segment the data and extract interfacial properties, but also does so without the need for expensive interface labeling for training the segmentation model.

The APT data are prepared for segmentation by converting them from a 3D point cloud to a regular voxel grid composed of relative atomic concentrations of species. The trained HED model is used for interface detection on this 3D concentration space by extracting 2D slices of it in each of three orthogonal directions, detecting the 2D edges on them, and then merging all of them to obtain an edge map in 3D. The obtained edge map serves as the interfacial surface between the two phases.

We demonstrate the proposed segmentation approach using three material systems with inclusions of a precipitate phase in a matrix, each with different interface modality (layered, isolated, and interconnected, respectively), that correspond to different relative geometries of the precipitate and matrix phases. We demonstrate the accuracy of our segmentation approach through qualitative visualization of the interfaces as well as through quantitative comparisons with proximity histograms obtained using traditional approaches. We also note that the edge detection on multiple 2D slices and hence the 3D edge map extracted using the trained HED model for each of these cases is near real-time, taking only a few seconds.

Our approach demonstrates the power of machine learning techniques in the analyses of APT data. It should also be readily applicable to analysis of other tomographic data of multi-phase or multi-grain systems, such as X-ray tomography of alloy systems, or transition electron microscopy tomography. By using transfer learning the fully convolutional network can be trained in advance of experiments, and be applied in real time during the conduction of experiments. This may be especially valuable not only for 3D APT and transmission electron microscopy tomography but also for X-ray tomography, where rapid data analysis during the experiment may provide valuable real-time feedback to the experiment.
world a better place, the PSU college of engineering is seeking to make to more transformational increases in the number of women engineering graduates. This activity leverages the success of WEP and engages academic programs to provide compelling student experiences to draw interest from women and other persons from groups underrepresented in engineering. Success towards equity requires careful review of all programs with an eye towards inclusivity. Advancement of gender inclusion also demands that engineering programs identify and articulate the “why” for engineering majors. In addition, success requires that engineering programs establish collaborations with academic programs where gender balance must be aggressively addressed (mechanical engineering, aerospace engineering and computer science and engineering). Enacting efforts to reach aspirational inclusion goals also provides opportunities to identify descriptive programs (such as Humanitarian Engineering and Social Entrepreneurship) in which future engineers can be further inspired to use engineering practice to improve global societal outcomes.

To effectively change the face of the engineering workforce requires that colleges engage men as allies. Experience in gender balanced classrooms and engineering teams in college can help produce professional colleagues who interrupt many of the challenges currently faced by women in working environments. In this presentation we will discuss the success of WEP programs. We will describe efforts of the Gender Equity Initiative to increase the number of women to reach 50% of engineering graduates by 2026. We will also discuss new programs to help engage and graduate men and women who advance equity as allies for inclusion in the global workforce.

Writing Personal Stories About Thermodynamics Improves Professional Identity

Eric Jankowski, Sara Hagenah and Liz Neeley; Boise State University, Boise, Idaho, United States; The Story Collider, Washington, District of Columbia, United States.

Establishing Identity is at the core of the Chickering model of professional development and prior work has shown that underrepresented engineering students are more likely to be retained and graduated if students identify as a member of their major. In this work, we use a one-assignment intervention in a Junior-level materials thermodynamics course to test the hypothesis “Writing a true, personal story about a time thermodynamics happened improves self-identification as a materials scientist.” We measure student attitudes with a Likert-scale survey before and after the assignment. Preliminary results show that all of the attitudes surveyed, the only measurable change is an increase in agreement with the statement “I identify as a materials scientist.”

We discuss the impact of hosting a public Story Collider show with stories curated from the in-class assignment. We find that the attendees of the storytelling show were surprised to be emotionally affected by student stories, that the event catalyzed department discussions for how to better support students, and provided a unique forum for engagement between students, faculty, and the public. In aggregate, we find that narrative-focused activities have high potential to improve student self-identification with their profession through metacognition, with potential for increased retention of underrepresented engineering students. In parallel, the public storytelling events hold promise for improving culture, climate, and caring between stakeholders in a materials science and engineering department.

9:15 AM BI01.01.03
Princeton University Materials Academy for Minority High School Students, a MRSEC Education and Outreach Program

Daniel J. Steinberg and Sara Rodriguez Martinez; Princeton University, Princeton, New Jersey, United States.

During summer 2018, the Princeton Center for Complex Materials gave 16 underrepresented high school students from Trenton and Princeton, New Jersey, the opportunity to learn materials science and its influences on and from society. Lectures and labs included discussions on sustainability, including the UN’s Sustainable Development Goals, and coding from Princeton University professors and researchers. The Princeton University Materials Academy (PUMA) is an education outreach program for minority high school students and it is part of the Princeton Center for Complex Materials (PCCM), a National Science Foundation (NSF) funded Materials Research Engineering and Science Center (MRSEC). PUMA has been serving the community of Trenton for since 2002 each year providing daily lectures from Princeton Materials Science professors, workshops, tours and access to Princeton University laboratories, a glimpse into a real STEM academic environment. We have reached almost 300 students from 2002-2018, with many students repeating multiple years. 100% of our PUMA students have graduated high school and 98% have gone on for college, compared with the overall Trenton district graduation rate of 48% and a free and reduced lunch of 83%. This year, we discuss new initiatives and partnerships with Princeton’s makerspace “StudioLab”, a Princeton Council on Science and Technology space for collaboration and creation across disciplines (STEM, arts, humanities and social sciences), bringing in a coding and wearable technology production component to the program while meeting Next Generation Science Standards (NGSS). In addition to this, we will also discuss our launch of a new evaluation system with pre- and post-content and attitude tests. We also plan to share the curriculum online to enhance PCCM’s PUMA reach and to help teachers and high school students at a national level and improve diversity and accessibility in STEM.

9:30 AM BI01.01.04
Bystander Intervention as a Component of Developing an Inclusive Culture in STEM

Stephen D. Albright; Yale University, New Haven, Connecticut, United States.

Great opportunity exists for the fields of science, technology, engineering, and mathematics (STEM) by expanding the diversity of its workforce. Increasing diversity of an institution has been shown to improve education and increase productivity and profitability. However, the raw numbers of “diversity,” only tell part of the story. True opportunity lies in increasing the inclusivity of STEM environments, so scientists and engineers of underrepresented identities are not only present, but welcome and celebrated. A central piece to building inclusion in STEM must be changing the underlying culture, which for too long has been defined by only a narrow slice of humanity. There are many components to changing a culture; this work focuses on one, bystander intervention. Specifically, I will present details of a workshop custom-designed to teach graduate students methods for intervening in instances of disrespect and unprofessionalism. Over the course of two years, approximately 4,000 graduate and professional students at Yale, including 350 in STEM fields, have participated in this workshop. Through facilitated discussion of several tailored scenarios, participants are encouraged to develop a wide range of interventions, so anyone can find methods of intervening with which they are comfortable. By empowering community members to intervene in low stakes situations, they can break down ingrained disrespectful behavior that excludes those underrepresented in the community.

Priming the Materials Science Pipeline—Research Opportunities for Community College Students

Scott D. Johnson, Paul S. Sabila, Joshua Halpern, Scott A. Sines and Tito E. Huber; Prince George's Community College, Largo, Maryland, United States; Howard University, Washington, District of Columbia, United States; LibreTexts, Davis, California, United States; Gallaudet University, Washington, District of Columbia, United States.

Community colleges and other small institutions lack the research equipment for students to do cutting edge undergraduate research. Moreover faculty tend to have a large teaching load, less time for research and also a lack of committed and/or trained students in the research labs as opposed to larger universities which have graduate students. Prince George's Community College (PGCC), a large urban minority institution, and Gallaudet University, an institution for the deaf and hard of hearing, have partnered with Howard University, an HBCU and R2 research university, for over a decade. Since 2007, three NSF grants have funded 46 ten-week summer intern positions that have been filled by minority students including women. Many students had multiple year experiences and were supported during the regular academic year.

Six faculty members from PGCC and Gallaudet were either involved with the students' research or the development of educational materials, including a LibreTexts textbook and matsci excels (interactive spreadsheets), and three new courses were developed while partnering with Howard colleagues. Gallaudet funded the remodeling of its science laboratories. Guidelines and procedures were also developed for dealing with the special needs of deaf and hard of hearing students in the laboratory. Nanotechnology related topics have been included in various courses in chemistry and physics at Gallaudet University. Howard faculty have also served as guest lecturers at PGCC and partners in successful grants from NASA and the Department of Education.

We will discuss the workings of a productive partnership that has given our students unique opportunities including five student co-authors on published papers. Tracking of student to bachelors degrees and beyond will be presented. PGCC and Gallaudet faculty publications with Howard colleagues have also been a productive endeavor, including a case where a Howard faculty member became involved in discipline-based educational research through collaborating with PGCC colleagues. PGCC has received NASA support for further engineering and support course revisions and laboratory equipment. Gallaudet University also has NASA support for research and student internships within the
How good can American science, engineering, mathematics, and technology (STEM) be when we are missing more than two-thirds of the talent? (i.e., everyone who is not white and male) The now-false and tired contention that “the statistics of small populations” is the operative reason for the slow advancement of underrepresented groups (women and people of color) in science and engineering, especially to positions of power and impact, has too often been used to deflect action that would transform the culture of STEM research—intensive institutions to one that adapts to the diversity of scientific talent endemic to all of humankind. Teaching academic survival skills, such as COACH (the Committee on the Advancement of Women in Chemistry) has done in workshops held for over fifteen years, without addressing the still-too dysfunctional culture in which one seeks to thrive has been shown to lead to minimal improvement in recruiting, hiring, and recognizing female academic chemists. As noted in coverage of these findings: “Perceptions of inequality remained constant across younger and older faculty, racial and ethnic lines, and levels of experience in administration.”[2] Similar difficulties are apparent among the scientific staff of national/federal laboratories.

So how can we change the world of science? Subvert the standard operating procedure. Create a microclimate that shows—over time—how new patterns of operation and inclusiveness yield productive, innovative science—including incorporating undergraduate researchers for full time (six-to-twelve months) of off-campus research. Use the scientific capital and street credentials accrued over time, thanks to the humane but challenging microclimate and the concomitant research productivity of one's team, to challenge the status quo with reasoned and bold arguments for change. Remember the importance of uppity behavior and applying “tipping point” mechanisms to move beyond initial reactions of dismissal to—over time—accepted inevitability (such as greeted my audacious suggestion in March 2000 to withhold federal funds from non-diversified chemistry departments through application of Title IX).[3] And do not forget market forces—the most important resource in research is smart, motivated students and the most important product of funded research is not peer-reviewed papers, but the critically thinking graduate. It is time to assemble a faculty diversity index that delineates who enters a group to do research, how long to degree, and where each student goes after leaving the group—all disaggregated with respect to gender, race, and ethnicity. This prize demographic—the STEM majors seeking a research program—can then make an informed decision with respect to which universities and departments and groups win their talents. We can then see who among the lovers of the status quo in the research-intensive universities really wants to play hardball. It is time to “out” the toxic departments and research groups.

1 Rolison heads the Advanced Electrochemical Materials Section at the U.S. Naval Research Laboratory (NRL). The views are those of the author and are not necessarily those of the NRL or the U. S. Department of Defense.

10:30 AM B101.01.06
Science is Too Important to Be Left Just to Men
Debra R. Rolison; Consultant, Arlington, Virginia, United States.

In our presentation, we will discuss each program component, our measures of success which include self-efficacy, retention results and academic performance of our freshman fellowship. Students have had socials highlighted by various activities including basketball and hockey games as well as riverboat rides. Monthly socials provide professional development opportunities for students. Students are visited by industry partners to discuss resume writing, interview tips, networking and groups and receive tutoring and academic support. The students generally perform 10-15 points higher than their counterparts. These Collaborative Courses including Calculus and Physics supplement their first-year course loads. Through the support of our programming, our students generally perform 10-15 points higher than their counterparts.

The retention program consists of 4 main components, the summer bridge program, monthly socials, collaborative math and science courses and Sunday dinners. The Summer Bridge Scholars Program is a 7-week summer bridge program. Incoming first-year students participate in a seven-week bridge program. In the program, the students live on campus and are immersed in a campus experience. They take a full course load of classes including: Calculus/Pre-Calculus, Chemistry, Biology, Engineering Design and English. The students participate in study groups and lunch and learn series to help them prepare for their first-year experience. Students who perform well in their Mathematics, Chemistry and Biology courses receive English credit that go towards their graduation requirements. In their first year on campus, the students are grouped into a cohort and provided support to transition into their academic careers. They participate in Collaborative Courses which are offered through IEEC. These Collaborative Courses including Calculus and Physics supplement their first-year course loads. Through the support of our programming, our students generally perform 10-15 points higher than their counterparts.

The office also hosts a weekly Sunday dinner. During the dinner, the students receive a home-cooked meal and have a chance to network with students in all cohorts. The dinner provides a safe space for students who are often facing stereotype threat and implicit bias in their courses. In addition to fellowship and networking, the students also work in study groups and receive tutoring and academic support. Monthly socials provide professional development opportunities for students. Students are visited by industry partners to discuss resume writing, interview tips, networking and etiquette. Many of our industry partners use this time to develop authentic relationships that feed into an informal mentoring network. We also use monthly social time for fellowship. Students have had socials highlighted by various activities including basketball and hockey games as well as riverboat rides.

In our presentation, we will discuss each program component, our measures of success which include self-efficacy, retention results and academic performance of our freshman cohort.

Holistic Retention Strategies for Underrepresented Minority Students
Whitney Gaskins and Dewey Clark; University of Cincinnati, Cincinnati, Ohio, United States.

A small percentage of underrepresented minority high school graduates pursue STEM majors. Often, underrepresented minority students are subjected to stereotype threats, such as being labeled as intellectually inferior, purposely not being selected to participate in classroom discussions and a lack of sense of belonging, such as a lack of inclusivity from class peers and academic advisors while matriculating through the academic programs. The Office of Inclusive Excellence and Community Engagement (IECE) has a retention program focused on increasing the retention, self-efficacy and sense of belonging of underrepresented minority students in the College of Engineering and Applied Science.

The retention program consists of 4 main components, the summer bridge program, monthly socials, collaborative math and science courses and Sunday dinners. The Summer Bridge Scholars Program is a 7-week summer bridge program. Incoming first-year students participate in a seven-week bridge program. In the program, the students live on campus and are immersed in a campus experience. They take a full course load of classes including: Calculus/Pre-Calculus, Chemistry, Biology, Engineering Design and English. The students participate in study groups and lunch and learn series to help them prepare for their first-year experience. Students who perform well in their Mathematics, Chemistry and Biology courses receive English credit that go towards their graduation requirements.

In their first year on campus, the students are grouped into a cohort and provided support to transition into their academic careers. They participate in Collaborative Courses which are offered through IEEC. These Collaborative Courses including Calculus and Physics supplement their first-year course loads. Through the support of our programming, our students generally perform 10-15 points higher than their counterparts.

Professional Societies and African American Engineering Leaders—Paving Pathways and Empowering Legacies
Christine S. Grant1, Tonya L. Peeples2 and Lynnette D. Madsen3; 1Department of Chemical and Biomolecular Engineering, North Carolina State University, Raleigh, North Carolina, United States; 2Department of Chemical Engineering, The Pennsylvania State University, State College, Pennsylvania, United States; 3National Science Foundation, Alexandria, Virginia, United States.

Diversity and inclusion in science, technology, engineering, and mathematics (STEM) fields is a global issue. The challenging issues facing the world relating to STEM diversity cross national borders and require leveraging the talents of diverse constituents. Active international efforts at inclusive talent development are being undertaken to empower persons from groups historically underrepresented in STEM communities. The US National Action Council for Minorities in Engineering (NACME) reports that in the United States, African Americans are one of the most underrepresented minority groups in engineering relative to their population. This is in spite of the fact that there has been a great deal of progress in “growing African American scientists, engineers, and technologists since the Howard University School of Engineering opened in 1910.” The number of
African Americans in engineering at all degree levels is not representative of their percentage in the US population.

In 2012, a workshop on “Ethnic Diversity in Materials Science and Engineering” was co-sponsored by the National Science Foundation (NSF), the Department of Energy (DOE), the MRS Foundation, North Carolina State University, and the University Materials Council (UMC). Comprised of Department Heads, Chairpersons, Directors, and group leaders from academic programs in the materials field in United States, Canadian, and Australian universities, UMC is a forum for sharing best practices related to materials science and engineering (MSE). Focusing on issues affecting recruitment and retention and long-term success in MSE, the workshop participants examined diversity data in MSE departments. According to the US National Center for Science and Engineering Statistics, although African Americans make up 12.2% and Latinos 16.3% of the US population, they received only 2.5% and 5.3% of MSE degrees awarded in 2010, respectively. At the heart of the recommendations to increase retention, recruitment, and career success of ethnically diverse groups were topics with a focus on the following three groups: (a) Individuals, (b) Academic Leaders, and (c) Federal Agencies.

Our goal in this paper is to shift this conversation away from the dire message about the lack of African Americans in the field and focus on positive advancements, namely, the leadership of African Americans in engineering and the role of professional societies in their leadership development. Reflecting on the action plan for ethnic diversity in MSE and STEM, we posit that there is a constituency missing in these discussions, namely, professional societies. While it is critically important to recognize technical achievements and the early champions of change, it is also crucial to highlight the importance of professional societies, and challenge them to develop a greater level of authentic inclusion of African Americans in their organizations. Societies include, but are not limited to, those focused on: (1) advancing diversity and inclusion via empowerment, (2) developing underrepresented groups within specific disciplines, (3) originating and facilitating cross-disciplinary interactions, and (4) leading change in the realm of providing services, information, and tools for stakeholders to create a diverse workforce of engineers. Professional societies can play a pivotal role in the diversification of science and engineering profession and the authentic inclusion of engaged African Americans in the direction of science and engineering disciplines. We will discuss how the development of leaders across academia, industry and governmental entities benefits from the opportunities to grow, serve and eventually lead in student-led, career-enhancing, and paradigm-shifting organizations. This paper highlights the careers of several African American leaders in both industry and academia, including their experiential perspectives on the role of professional societies in their own leadership development.

2:30 PM BI01.02.03
Implementable Group-Based Undergraduate Research Programs for First-Year STEM Students
Matthew Hauwiller, Justin Ondry, Anne Baranger and Paul Alivisatos; University of California, Berkeley, Berkeley, California, United States.

Undergraduate research has numerous positive outcomes for the participating students ranging from improved performance in classes, higher self-identification as scientists, better graduation rates, and better retention of students from underrepresented demographics. By actively carrying out cutting-edge scientific research, students feel like scientific experts with the ability to tackle difficult problems, and this sense of belonging can be especially valuable for first generation and underrepresented students. Ideally, every first-year student at large research institutions would have the opportunity to be a part of the ground-breaking research happening on their campus; however, the current models of undergraduate research are often unable to provide that experience to first-year undergraduate students. Traditional apprenticeship research positions are designed for advanced undergraduate students who want to make a significant time commitment. Course-based undergraduate research experiences have many positive benefits but often lack the ability to replicate a true research experience. We developed a research group-based undergraduate research program for first-year undergraduate students. Our program allowed 20 students to pursue curiosity driven research using cutting edge data previously collected by our research group. This model is transferable to other research groups, departments, and universities, and the implementation of first-year research experiences would be a significant benefit to the educational experience of undergraduate students, especially for students from underrepresented backgrounds in STEM.

In this program, students were given unanalyzed videos of platinum nanocrystals moving, growing, and attaching in solution collected using a state-of-the-art electron microscope and then were able to investigate and analyze phenomena they found intriguing. We assumed the students had no previous research experience nor knowledge of our research area of nanomaterials, so we taught the background information necessary to complete their projects. After learning the fundamentals of the research area, the undergraduate students began brainstorming interesting questions about the data set they were provided. Students were able to test various hypotheses for how nanocrystals grow and interact and learn how to pivot from a failed idea to a more promising hypothesis. Finally, the students learned how to communicate their results in the form of an academic paper and a poster presentation. Going through the scientific process with a project that was scientifically relevant gave the undergraduate students valuable experience as well as a sense of accomplishment.

The immediate returns, both qualitative and quantitative, show the ability for programs like AGURP to make a difference in the education experience of all first-year STEM students. Roughly half of the participants who came to the information session were women, and half of the admitted students were women. The students expressed a sense of ownership of their project at the poster session and were proud of their research achievements. Quantitatively, the students expressed significant gains in their self-identification of their research skills from the pre- and post-program surveys. For a program like AGURP to be sustainable, it needs to be positive for both the students and the research groups, and programs like AGURP can be mutually beneficial. The goal of developing a group-based research program is to build an implementable model for other universities, so every first-year undergraduate student aspiring to achieve a STEM degree can feel a sense of belonging through research and increase their persistence rate to graduation.

2:45 PM BI01.02.04
Understanding the Impact of Design in High School Outreach Camps
Kaitlin Tyler, Nicole Johnson-Glauch, Leon Dean and Jessica A. Krogstad; Materials Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Outreach camps are an effective route to increasing interest in STEM disciplines, especially for underrepresented groups. They are also common components in the broader impact plans for many early career researchers. However, there is very little basis for understanding which aspects of outreach camps lead to positive outcomes. This is due in large part to the difficulty in comparing existing camps both within specific STEM disciplines and across them. As a result, there is little science-based guidance for the development of effective outreach camp structure or content. We specifically target the process of design in this study. By comparing different methodologies for incorporating design thinking through a qualitative multi-case study across four engineering disciplines, we have begun to assess whether design can be used to positively affect outcomes of STEM outreach camps and provide guidance for outreach development.

Engineering Change—Strategic Action to Achieve Diversity in Engineering
Jenni M. Buckley, Stephanie Law, Amy Trauth and Rachel Davidson; University of Delaware, Newark, Delaware, United States.

The underrepresentation of women and underrepresented minorities (URM, def. non-White, non-Asian) in the engineering pipeline can be attributed to a multitude of factors, including, but not limited to, insufficient preparation and barriers in recruiting into engineering programs at the K-12 level, low self-efficacy, lack of peer support, inadequate academic advising or faculty support, harmful stereotypes of particular groups that influence interactions in classrooms or in peer groups, and a chilly or unappealing climate. The numerous “leaks” in the pipeline along with the sheer variety of established causes lead many institutions, including our own, to take a scattershot and therefore marginally effective approach to promoting diversity and inclusion.

In this paper, we will demonstrate that the Engineering Design Process (EDP) provides an effective framework for goal-setting and developing targeted interventions to substantively advance diversity and inclusion at the undergraduate and graduate levels. We present this work in the form of a 3-year case study at our own institution, a mid-sized, research-focused, land grant university on the US East Coast with student demographics (gender, racial) that reflect national trends. Our EDP framework consists of three steps: (1) Defining the Problem, (2) Developing multiple unique and viable concepts, and (3) Iteratively designing, implementing, and refining or abandoning interventions based on formative evaluations. We began in Phase 1 of EDP by defining the issue of diversity at our institution relative to other engineering programs nationally using publically available data on graduation and retention rates. To assess climate issues, we conducted in-depth focus groups of women, URM, and majority undergraduate and graduate students; and we folded the common themes from these focus groups into annual surveys. These data were used to establish clear metrics and target values for gender and racial diversity across our graduate programs and within each undergraduate department.
Phase 2 of our EDP involved generating multiple unique and viable interventions that addressed the disparities in recruitment and retention identified in Phase 1. Both working groups engaged in a lengthy phases of divergent concept generation by conducting extensive literature reviews, familiarizing themselves with the educational and social psychology literature around diversity and inclusion in STEM, and benchmarking interventions from other institutions. Early concepts were organized using a novel tool that clusters interventions by area of impact (recruitment or retention) and “activation energy” (economic and political cost).

Phase 3 of the EDP, which is ongoing as of this publication, involves implementation and continuous, formative evaluation of interventions clustered into three Specific Aims: (1) Recruitment, (2) Retention; and (3) Cultural Change. At present, the undergraduate working group has operationalized approximately 80% of the specific interventions clustered in Aims 1 and 2 above and 30% in Aim 3. Based on evaluating data, 10% of the interventions have been discontinued, with an additional 20% being substantially modified based on early results. Both working groups are continuously reviewing admissions data to assess impact on recruitment and leveraging focus group and survey data to monitor student climate.

This case study represents the first explicit use of the Engineering Design Process (EDP) to develop a comprehensive plan to address diversity and inclusion at both the undergraduate and graduate levels. Given how daunting diversity issues can sometimes appear, we have found that framing and addressing this issue like engineers and explicitly using the EDP has made the process of goal setting, intervention, and evaluation remarkably clear. The overall process and specific tools presented in this case study may be easily extended to other institutions.

Nanomaterials Design and Properties at the Extreme Limits of Molecular-Scale Confinement Reinhold H. Dauskardt; Stanford University, Stanford, California, United States.

We review the state-of-the-art in the molecular design and processing of nanomaterials at the extreme limits of molecular-scale confinement. A particular focus is provided on unique mechanical and electrical behavior that can be achieved in the limit of such intimate molecular mixing. We show that molecular hybrids can have marked asymmetric elastic and thermal expansion properties that are inherently related to terminal chemical groups in confinement. We describe a new nanoscale design principle using hyperconnected molecular architectures to achieve remarkable mechanical properties controlled by designing connectivity into the intrinsic molecular structure in innovative ways. We probe the mechanical and fracture properties of hybrids in the extreme limits of molecular confinement, where a stiff inorganic matrix phase confines polymer chains to dimensions far smaller than their bulk radius of gyration. Finally, we demonstrate the synthesis of 1D core-shell nanowires that have electrically conducting copper cores and insulating shells. Nanowires are synthesized via a facile solution process leveraging the strong chemical interaction between organothiol molecular precursors and copper. We use molecular dynamic and density functional theory computations together with atomic resolution characterization to reveal the molecular structure, and electrochemical impedance spectroscopy to characterize the electrical properties.

11:00 AM *CP01.01.02
Role of Graphene in Reducing Fatigue Induced Damage in Cu-Graphene Nanolayered Composite Byungil Hwang1, 2, Wonsik Kim1, Jaemin Kim1, Seoyeon Lim1, Sangmin Kim1, Sangho Oh1, Seunghwa Ryu1 and Seung Min Han1, 2, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 1Sungkyunkwan University, Suwon, Korea (the Republic of); 2BASF Electronics Materials R&D, Suwon, Korea (the Republic of).

Nanoscale metal-graphene nanolayered composite is known to have ultra high strength due to its ability to effectively block dislocations from penetrating through the metal/graphene interface. The same graphene interface can simultaneously serve as an barrier interface for deflecting the fatigue cracks that are generated under cyclic bendings. Cu-graphene composite with repeat layer spacing of 100 nm was tested for bending fatigue at 1.6% and 3.1% strain up to 1,000,000 cycles that indicated ~5 times enhancement in robustness against fatigue induced damage in comparison to the conventional Cu only thin film. Fatigue induced cracks that are generated within the Cu layer were stopped by the graphene interface, which was confirmed using transmission electron microscopy images acquired ex-situ as well as during in-situ tensile strain testing. Molecular dynamics simulations for uniaxial tension of Cu/Gr showed limited accumulation of dislocations at the film/substrate interface, which makes the fatigue induced crack formation and propagation through thickness of the film difficult in this materials system.

11:30 AM *CP01.01.03
From Nano to Macro Ju Li; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Recent advances in nano-manipulation, environmental TEM and MEMS allow us to investigate coupled mechanical and electrochemical phenomena with unprecedented spatial and temporal resolutions. For example, we can now quantitatively characterize liquid-solid and gas-solid interfaces at nm-scale. These experiments greatly complement our modeling efforts, and together they help provide insights into how materials are transformed in synthesis and how they behave in service due to combined electrochemical-mechanical forces. Applying theory, modeling and lab-on-a-chip microscopy, together with cost modeling, can judiciously guide the scalable production of high-performance energy materials.
SESSION CP01.02: Xtreme Materials Design Applications—Wearables and Microrobotics
Session Chairs: Arief Budiman and Young-Chang Joo

PCC West, 100 Level, Room 101 A

1:30 PM *CP01.02.01
Development of Reliable Wearable Electronic Devices Through In Situ Monitoring Young-Chang Joo, Seoul National University, Seoul, Korea (the Republic of).

Flexible and stretchable devices are of significant interest due to their potential expansion of the application of smart devices into various fields, such as energy harvesting, biological applications and consumer electronics. Due to the mechanically dynamic operations of such electronics, their mechanical reliability must be thoroughly investigated to understand their failure mechanisms and lifetimes. Reliability issue caused by bending fatigue, one of the typical operational limitations of flexible electronics, has been studied using various test methodologies; however, electromechanical evaluations which are essential to assess the reliability of electronic devices for flexible applications had not been investigated because the testing method was not established. By employing the in situ fatigue test, we have studied the failure mechanism for various conditions and parameters, such as bending strain, fatigue area, film thickness, and lateral dimensions. Moreover, various methods for improving the bending reliability have been developed based on the failure mechanism. Nanostructures such as holes, pores, wires and composites of nanoparticles and nanotubes have been suggested for better reliability. Flexible devices were also investigated to find the potential failures initiated by complex structures under bending fatigue strain. The recent advances in test methodology, mechanism studies, and practical applications are introduced. Additionally, perspectives including the future advance to stretchable electronics are discussed based on the current achievements in research.

2:00 PM *CP01.02.02
Nano-Chemomechanics at Play—Novel Nickel-Hydroxide Thin-Film Actuating Materials for Micro-Robotics Applications Alfonso H. Nguyen, Runni Wu and Kenneth K. Kwan; University of Hong Kong, Hong Kong, Hong Kong.

In this talk, we report a novel actuating material—nickel hydroxo-oxyhydroxide—that exhibits enormous actuation due to a volume change stimulated either electrochemically, or by illumination of visible light of low intensities. For electrochemical actuation, Ni(OH)2/NiOOH is capable of undergoing fast, reversible, and large actuation in alkaline electrolytes under potentials of less than 1 V, due to a redox reaction involving volume changes. On the other hand, the light actuation of Ni(OH)2/NiOOH is due to its turbostratic crystal structure which is capable of intercalating water molecules. It is shown that the intercalated water can be rapidly and reversibly desorbed into the environment under visible light of intensities lower than 1 sun, resulting in fast actuation driven wirelessly by light.

By electroplating the actuating material on passive substrates, we have fabricated film-actuators capable of undergoing reversible bending and curling with an intrinsic actuating stress of tens of megapascals at response rates in the order of tens to hundreds of degrees per second, which are comparable to mammalian skeletal muscles. Also, by intentionally electroplating the nickel hydroxo-oxyhydroxide on selected areas of the substrate, we have also fabricated actuation devices of various shapes and functions, e.g. a hinged actuator that can lift objects ~100 times of the weight of the actuating material is achieved, and other examples showing the potential use in robotic devices. The light-induced actuation mechanism reported here has the potential for realizing wirelessly powered micro-robotic devices.

2:30 PM CP01.02.03
A Highly Sensitive and Selective Relative Humidity Sensor Based on Mn Loaded Cubic Mesoporous SBA-16 Vijay K. Tomer1, Jasbir Sangwan1, Vijay Kiran1 and Ekta Poonia2; 1Department of Higher Education, Government of Haryana, Tau Devi Lal Govt. College for Women, Sonipat, India; 2Berkley Sensor and Actuator Center, University of California, Berkeley, Berkeley, California, United States; 3Chemistry, CRA College, Sonipat, India; 4Chemistry, D.C.R. University of Science and Technology, Sonipat, India.

The template assisted facile synthesis of 3-D cubic mesoporous silica comprised with in situ doping of metal oxides, immense surface to volume ratio, ordered network of long range porosity and ultrafine size was proposed in this study. The FE-SEM and HR-TEM studies indicated the novel morphology of hexagonal cubic channels with ordered network of porosity, X-ray diffraction study confirmed the 3-D cubic structure of silica with existence of anatase phase of in situ doped metal oxide species containing Im3m symmetry. N2-BET adsorption desorption isotherm displayed the immense surface area (768m2/g) of synthesized material which was decreased (715m2/g) after in situ doping of metal oxides due to decrease in mesoporous volumes. The sensing behavior of synthesized nanostructures was determined by measuring the change in impedance corresponding to different RH conditions. The in situ doped metal oxide silica samples specified a swift response time of 4.7 s and quick recovery time of 3.2 s exhibiting synergistic effect as compared to undoped silica. In addition, the long term stability, sensitivity, great recyclability and less hysteresis indicated the possible practical application of synthesized nanoparticles.

2:45 PM CP01.02.04
Nanoscale Dielectric Charging and Breakdown Mapping Thomas Moran1, James Steffles1, Keigo Suzuki2 and Bryan D. Huey3; 1University of Connecticut, Storrs, Connecticut, United States; 2Murata Manufacturing Co., Ltd., Yusa, Japan.

Dielectric thin films are crucial for counting, computing, wireless, and sensor systems. As their dimensions continue to diminish, and engineered microstructure becomes increasingly refined, it is crucial to be able to investigate charging, discharging, and breakdown at the nanoscale. Based on Atomic Force Microscopy several new approaches have been developed for such investigations, reported here for BaTiO3 as well as BaTiO3 and SrTiO3 superlattices. In this manner, the influence on charging and discharging can be mapped for grain boundaries as well as heterostructure interfaces. Furthermore, by applying voltages up to 150V, in a controlled environment, across films shallow-angle-polished to create thicknesses gradients from 200 down to 2 nm, scaling laws for breakdown become uniquely accessible on a single specimen. This is advantageous as the composition is reasonably consistent, as comparable to investigations with multiple films. Such methods are equally applicable for investigations of breakdown mechanisms with inorganic as well as polymeric dielectrics.

3:30 PM CP01.02.05
In Situ Raman Spectroscopy to Study Plastic Deformation in Silicate Glasses Shefford P. Baker1, Nicole Wiles1, Zachary Rouse1, Praveena Manimunda2, Thomas Wyrobek1 and S.A. Syed-Axil2; 1Cornell University, Ithaca, New York, United States; 2Bruker Nano Surfaces, Minneapolis, Minnesota, United States.

Understanding plastic deformation in silicate glasses is important in the development of glasses with improved resistance to mechanical failure. Plastic deformation under a point contact determines the stress state, which determines whether a surface flaw forms, which in turn determines the strength of the glass. Unfortunately, relatively little is known about the atomic scale mechanisms that control plasticity in silicate glasses. To date, most effort has focused on the continuum concepts of shear and densification. Raman spectroscopy has been used to study structure of glass glasses deformed by indentation and indentation. To investigate the structure of plastically deformed glass under load, we have developed an instrument in which the deformed material under the indenter can be investigated in-situ, while the load is being applied. Measured changes in spectra can be correlated to changes in ring size, bond angles, and other structural motifs with load. Transient structural changes which disappear after load is removed were identified.

3:45 PM CP01.02.06
Direct Observation of Conducting Channels in SrCoO3, Based RRAM Device Hung-Yang Lo, Juan-Min Huang and Wen-Wei Wu; National Chiao Tung University, Hsinchu, Taiwan.

Resistive random access memory (RRAM) has attracted considerable interest for next-generation non-volatile memory due to its fast switching speed, high storage density and excellent scalability. To effectively control the switching characteristic with considerable memory performance, a complete study of the switching behavior is essential. In this work,
we utilize SrCoO₃ (SCO) which grows on Nb-doped SrTiO₃ (Nb-STO) substrate as our dielectric layer since it exhibits large different resistance between SrCoO₂₋ₓ and SrCoO₂₋ₓ, where the value of SrCoO₂₋ₓ is higher than that of SrCoO₃. Based on this characteristic, we fabricated a Au/SCO/Nb-STO device, and measured the SET (~1.6 V) and RESET (~−5.3 V) process with more than 700 cycles. Meanwhile, the conducting filaments were observed via in-situ transmission electron microscope (TEM). From the HRTEM results and corresponding FFT-DP (Fast-Fourier-Transform Diffraction pattern), it is clearly demonstrated the formation of conducting filaments is from SrCoO₂₋ₓ to SrCoO₂₋ₓ. Accordingly, the formation/rupture of conducting path is due to the movement of oxygen vacancy, and hence its resistance is able to switch reversibly between low resistance state and high resistance state. This study not only revealed the switching mechanism of SrCoO₂, but also proved it to be the promising candidate for RRAM application.

SESSION CP01.03: Advances in Xtreme Experimentation I
Session Chairs: Arief Budiman and Ralph Spolenak
Tuesday Afternoon, April 23, 2019
PCC West, 100 Level, Room 101 A

4:00 PM CP01.03.01
Shining Light on Nanoscale Mechanical Properties Ralph Spolenak
ETH Zurich, Department of Materials, Laboratory for Nanometallurgy, Zurich, Switzerland.

When investigating films thinner than one hundred nanometers, X-ray diffraction at synchrotron sources has been the method of choice in order to achieve enough signal. When films, however, exhibit a nanocrystalline microstructure and consist of light elements also diffraction reaches its limits. Here we provide case studies on reflection anisotropy spectroscopy that is sensitive to elastic distortions of the lattice or the symmetry breaking of a crack pattern. Thin films only start reflecting less than their bulk counterparts, when their thickness reaches several tens of nanometers and thus experiments can be extended to the single digit nanometer thickness regime. The case studies focus on plastic deformation and fracture on the phase change media as well as colored and noble metal thin films for applications in wearable electronics.

4:30 PM CP01.03.02
Direct Observation of Metallic NPs Electrodeposition on Glassy Carbon (GC) and CNTs by In Situ and Operando TEM Flores L. Ileana 1, Mariam Ezzedine 1, Leandro Sacco 1, Mihai R. Zamfir 1 and Costel Cojocaru 1, 2; 1 Ecole Polytechnique, Palaiseau, France; 2 CNRS, Palaiseau, France.

Liquid electron microscopy is a new TEM-based characterization tool that allows us to apply the powerful capabilities of an electron microscope to probe image and understand real-time nanoscale morphological and structural evolution of nano-systems under certain electrochemical conditions (operando).[1] For in situ electrochemical experiments, the importance of using the liquid cell is related to the fact that experiments in liquid environments enable direct imaging of the key phenomena taking place during the battery operation, stage crucial for establishing a good correlation between the microstructure of nanocomposites and the performance of the device. The main challenge of our work is the assessment of the batteries performances when nanostructured electrode materials are considered for both the anode and the cathode. Nanostructured materials show great promise; they can open new possibilities for enhancing the energy density of Li-ion batteries. The present study is focused on the realization of the in - situ liquid TEM observation using a closed electrochemical cell [2] of the electrochemical technique that activate the nanoparticle nucleation/growth mechanism of under certain electrochemical conditions (operando) as the ionic solution is introduced into the cell(unit) [3, 4]. From the experimental point of view, two electrodeposition approaches have been used: the cycling voltammetry and pulsed chronoamperometry modes both under constant flow. The interpretation and the analyses of the recorded current versus time curves allowed us observing that the nucleation mode is strongly related to the deposition conditions. Thus we noticed when the pulsed chronoamperometry mode is used we have a homogeneous NP deposition on the working electrode. The NPs size is depending on the cycle number and the liquid flow rate within the cell. In contrast, under cycling voltammetry mode, we observe an inhomogeneous deposition of the NPs generated by the oxidation of different organic species that can be formed after the first cycle.

CP01.04.01
Synthesis and Interfacial Analysis of Carboxyl Functionalized Carbon Nanotube - MOF-808 Composite Using Scanning Transmission Electron Microscopy (STEM) Justin W. Hendrix; Naval Surface Warfare Center, Dahlgren Division, Dahlgren, Virginia, United States.

Carbon Nanotubes (CNTs) and Metal Organic Frameworks (MOFs) represent two of the most promising classes of emerging materials in engineering today. Together, they exhibit many useful properties such as high conductivity [1], catalytic reactivity [3], porosity [4], and strength [2]. Methods in integrating these materials towards electromagnetic and chemical applications is of strategic importance for defense. Innovative materials have often been designed by combining low and high dimension constituents, through compositing, as a means to improving the functionality. In this work, we were able to combine these nanomaterials by synthesizing novel MOF-CNT nanostructured composites, using zirconium containing MOF (MOF-808). MOF-808 is composed of zirconium (IV) nodules, connected by organic carboxyl linkers, to create a nanoporous octahedral 3D crystal structure. Carboxylated functional groups are believed to be an important surface modification, due to its ability to bridge the zirconium nodules. Multiwalled CNTs, surface functionalized with carboxyl end groups, were used as the reinforcing agent with MOF-808 to create a MOF-CNT composite. The functionalities were chosen to create a MOF-CNT composite, linked by primary bonds. Scanning transmission electron microscopy (STEM) and nanoarea electron diffraction are powerful techniques in identifying structural changes at atomic scale resolution. Using a NION UltraSTEM-200X and a JEOL 2200FS at the U.S Naval Research Laboratory, we are able to identify MOF-808 adhesion to the surfaces of functionalized CNTs. Analysis shows the existence of lattice defects at the interface of MOF-808, as synthesized with carboxylated CNTs. The disruption is believed to be caused by the carboxylated CNTs acting as heterogeneous nucleation sites, forming the MOFs around the nanotube center. In this work, STEM and electron diffraction are used as effective techniques to study the interface of surface modified nanostructure composites.

doi: 10.1109/MOCAST.2018.8375600
Development of Compound Melt Extruded Nanocomposite FDM Filament by Continuous Syringe Pumping of Dispersed Graphenes During the Extrusion

Dripping water on to the polymer melt did not lower the degradation temperature of any of the polymer, indicating it evaporates off immediately as intended. Mechanical strength was seen to improve by 20% in composites of PLA/EFG at 8wt%, and by 10% in dual filler composites PLA/EFG/LCGO at 2wt%. Direct solution addition mid extrusion has shown to generate average agglomerate size range from <500nm to 50μm. It is expected that the upper limit will lower to 25μm with a slower addition of filler. Powdered polymer (HDPE/LDPE/PLA) was added to the first port of the extruder. Once the polymer was molten, a dispersion of fillers (LCGO/EGF/laponite) in an aqueous solution was syringe pumped directly into the melted polymer in a second port along the extrusion screw. As each drop of solution was added, the water evaporated and the filler was taken in to the polymer. This method prevents a lot of the filler-filler contact that occurs in typical powder coating methods, which in turn keeps agglomerate size low. Solution concentrations were up to 10mg/mL, added at at 6mL/min. LCGO was made on site at UOW [4], to approximately 9mg/ml (aq. dispersion). EGF was made in house at UOW. Laponite was sourced from BYK Additives and Instruments (Germany). PLA was sourced from Filabot (USA), HDPE from Sigma-Aldrich (USA), LDPE from Visy (Australia). Each additive was diluted to 0.1, 0.5, 1, 2, 5 and 10mg/mL in an aqueous solution for both single and dual filler composites. Direct solution addition mid extrusion has shown to generate average agglomerate size range from <500nm to 50μm. It is expected that the upper limit will lower to 25μm with a slower addition of filler. Mechanical strength was seen to improve by 20% in composites of PLA/EFG at 8wt%, and by 10% in dual filler composites PLA/EFG/LCGO at 2wt%. Dripping water on to the polymer melt did not lower the degradation temperature of any of the polymer, indicating it evaporates off immediately as intended.

Photocatalytic Disinfection Using GO/TiO2 Nanocomposite Against Escherichia coli and Study on Effect of Reactive Oxygen Species (ROS) Christeena T. Thomas, Myriam Solis López, Roberto Hernández, Martha Barajas Aceves, Jose Tapia Ramirez, José Álvaro Chávez Carvayr, Antonieta García Murillo, Felipe de Jesús Carrillo, Eleicer Ching, and S. Velumani. 1, 2, 4CIVESTAV-IPN, Mexico City, Mexico; 3Programa en Nanociencias y Nanotecnología, Centro de Investigación y de Estudios Avanzados del IPN, Mexico City, Mexico; 4Genética y Biología Molecular, Centro de Investigación y de Estudios Avanzados del IPN, Mexico City, Mexico; 5Instituto de Investigaciones en Materiales, Universidad Nacional Autónoma de México, Mexico City, Mexico; 6Ingeniero Químico Industrial, Escuela Superior de Ingeniería Química e Industrias Extractivas – IPN, Mexico City, Mexico; 7Departamento de Ciencias Naturales, Universidad Tecnológica de Panamá, Panamá, Panamá; 8IEECS, Centro de Investigación y de Estudios Avanzados del Instituto Politécnico Nacional, Mexico City, Mexico.

Photocatalytic disinfection of Escherichia coli K12 was experimented with the synthesized Graphene oxide/ Titania (GO/TiO2) semiconducting nanocomposites. GO was functionalized with TiO2 to increase efficiency in the disinfection process. Characterizations by scanning electron microscope (SEM) and transmission electron microscopy (TEM) for the surface morphology and Ray diffraction (XRD) for the crystal structure, Raman spectroscopy for the structural Analysis and UV-Vis diffuse reflectance (DR) to determine the band gap in GO/TiO2; semiconducting nanocomposites were carried out. The photocatalytic disinfection was performed under visible light irradiation using a solar simulator. For the study of reactive oxygen species (ROS) in the photocatalytic disinfection of Escherichia coli K12, scavenger study was done. From the XRD results, partial reduction of GO to reduced GO was observed due to the increase in the concentration of GO. The SEM analysis shows the homogeneous distribution of TiO2 nanoparticles over GO. According to Raman results, the corresponding D and G bands were identified at 1342 cm\(^{-1}\) and 1600 cm\(^{-1}\) respectively showing the crystalline quality of the synthesized nanocomposites. All these characteristic techniques reveal the enhancement of photocatalytic disinfection by embedding TiO2 nanoparticles in GO. As a result, the electron – hole pair recombination rate was reduced, and photocatalytic inactivation efficiency was increased. ROS, which is responsible for disinfection was identified.

CP01.04.08
Graphene Reinforced Metallic Foam Through Electrochemical Co-Deposition Rui Dai and Qiong Nian; Arizona State University, Tempe, Arizona, United States.

Monolayer Graphene with extraordinary mechanical properties and super large specific surface area arouses extensive scientific interests as the potential reinforcement for fabrication of lightweight, high strength and stiffness metal-matrix composites. Previous experimental studies have demonstrated this reinforcement effect of graphene in a variety of metal matrix composites mainly in the shape of thin film or thick bulk, however, few talked about its reinforcement efficiency in the three-dimensional (3D) structure. Herein, to reveal the reinforcement effect of graphene in the 3D structure, a graphene-nickel composite foam has been fabricated through applying electrochemical co-deposition process. Specifically, a Polyurethane (PU) foam with the stochastic lattice structure is selected as the template, on which the graphene nano-foam and nickel matrix were co-deposited through adjusting the electrochemical deposition conditions. Afterwards, the PU template was removed by a thermal decomposition process and the lightweight nickel foam in consist of hierarchy open cells and hollow triangle ligaments was obtained. Computational simulations and theoretical modeling were utilized to understand the underlying mechanisms and provide a comparison to the experimental results. Our study on the 3D graphene-metal composite foam sheds light on fabricating novel high strength mechanical metamaterial.

CP01.04.09
Sintering Behavior in Thin Film of Ni Nanoparticle through In Situ Stress Analysis for MLCC Internal Electrode Mingjeong Choi, Wonhyo Joo, Cheol Kim, Kyungryul Lee and Young-Chang Joo; Seoul National University, Seoul, Korea (the Republic of).

Recently, the trend of miniaturization of electronic components is accelerated due to the spread of mobile devices. In particular, Multi-Layer Ceramic Capacitor (MLCC), made by stacking Ni paste layers and ceramic slurry layers alternately followed by a high-temperature sintering process, has a layer thickness of less than 1 μm. One of the biggest issue in MLCC is difference in sintering behavior between ceramic and metal layer and subsequent twisting or fracture due to that. In order to identify the origin of such problem and reduce it, a quantitative tool for analyzing the sintering behavior of the thin film form is required. However, at present, the analysis of sintering behavior of μm scale thin films is limited to indirect methods such as ex-situ microstructure change analysis. In this study, the sintering behaviors in thin film of Ni nanoparticle were successfully analyzed by measuring the stress variation of thin films using laser based optical analysis. First, a Ni paste of 80nm particles was applied evenly on a ceramic substrate by spin coating and it was heated up to 580°C in a chamber filled with N\(_2\) gas mixed with H\(_2\) gas for preventing oxidation. In this process, the stress curve versus temperature with 4 inflection points was obtained. Among them, the points related to the evaporation and decomposition of the solvents in the paste were excluded by comparison with the TGA data, and only one inflection point near 430°C remained. Then the microstructural analysis was carried out for the samples quenched at the temperatures below and above the point. Finally, it was found that the inflection point has a significant relation with the neck formation in the sintering process. The same results were obtained for Ni-alloy materials. This study suggests a method of in-situ analysis of the sintering behavior of metal nanoparticles through stress analysis, and it is expected to act as useful guide line for the study of materials requiring high-temperature sintering process.

CP01.04.11
In Situ Mechanical and Electromechanical Testing of Piezoresistive Nanowires During Scanning Electron Microscopy Sijia Ran and Steven T. Boles; The Hong Kong Polytechnic University, Hong Kong, Hong Kong.

The fundamental relationship between electronic transport properties and applied strain in piezoresistive materials permits their usage in a broad range of applications related to electromechanical systems. Furthermore, strain engineering has been demonstrated as a useful technique to improve the performance of electronic devices, as it allows for enhanced carrier mobility and direct control of the band gap of semiconductors. Quantitative characterization of the relationship between electrical properties and strain is essential to the development of piezoresistive-based devices and to the application of strain-engineered devices. To quantify fundamental piezoresistive properties and reach high strain levels, testing at the nanoscale is critical, as the size scales can fall below the threshold for external or bulk defects. However, proper characterization of the piezoresistivity is a challenge at the nanoscale due to the miniscule specimen size. In this work, in situ tensile tests inside a scanning electron microscope (SEM) are conducted to study the mechanical and electromechanical properties of tellurium (Te) and germanium (Ge) nanowires. The in situ tensile testing technique allows real-time observations of elastic/plastic behaviors and gives the resistance changes under different strains for the determination of the piezoresistivity. The reversibility and the repeatability of the observed piezoresistive properties can be confirmed from loading-unloading tests and measurements of multiple nanowires with different diameters. These tests offer accurate experimental data that yields insights into the fundamental mechanisms behind piezoresistivity, such as strain-induced changes in band structure.

CP01.04.12
Piezoelectric Response of Sn-Doped BaTiO\(_3\) Epitaxial Thin Film TaeYeon Kim, 1 Sanjith Unithrattil, 2 Jun Young Lee 1 and Su Yong Lee 1; 1Gwangju Institute of Science and Technology, Seoul, Korea (the Republic of); 2Pohang Accelerator Laboratory, Pohang, Korea (the Republic of).

Accompanying with doping of Ca, Zr, etc, BaTiO\(_3\)-based ceramics exhibited excellent dielectric behaviors. Especially, Sn has been found to increase the permittivity by 3 times in comparison with single BaTiO\(_3\) and to induce the relaxor-type behavior.1,2 Recent transmission electron microscopy studies3 have shown that polar nano region (PNRs) embedded in the matrix is responsible of relaxor behaviors. The lattice constant increases with the doping of Sn, and the PNR region expands due to the stress of the matrix which has a large effect on the ferroelectricity of materials. Through high-resolution scanning transmission electron microscopy and first order calculation[4], they confirm the unit cells of the PNRs expand by the stress, which indicates that there is more space between Ti atoms and the oxygen octahedra to allow larger off centre displacements. This result shows an extreme improvement in dielectric permittivity. In addition, experimental methods of applying the temperature and electric field to control the stress in the PNR region have been proposed, and simulation has confirmed that these elements increase the piezoelectricity of the relaxor ferroelectric materials.[5,6] However, the relationship between PNR and electric field of the Ba\(_{(1-x)}\)Sn\(_{x}\)TiO\(_3\) (BTS) film was not confirmed experimentally. Therefore, we use a combination of time-resolved micro-X-ray diffraction (TRXD), which is used to apply biaxial stress to the thin film in real time. As a results, we confirm the relationship between PNR with piezoelectric response through calculation of the correlation length in Ba\(_{(1-x)}\)Sn\(_{x}\)TiO\(_3\) (BTS) film.
Shear Banding and Fracture Behavior in Bulk Metallic Glasses Under Quasi-Static and Dynamic Shearing.

The (111)-oriented Nb:Si:TiO thin crystal substrates with a Nb concentration of 0.5% were used as substrates to grow the epitaxial Ba(Ti0.5Sn0.15)O3 thin films on top. The BaTiO3 film was deposited using pulsed laser deposition (PLD) in an oxygen atmosphere of 10 mTorr. After the deposition, the samples were cooled down in a high vacuum. The dielectric constant was 412, which is twice as high as that of the conventional BTO (about 200). In Pohang Light Source, an X-ray beam with energy of 8 keV was focused to a spot with a size of 11.5 μm onto a circular Pt top electrode with a diameter of 100 μm. With an application of electric field (364 MV/m), (111) reflections of film shifted to the lower q, value from 2.696 to 2.691 Å, which indicates the piezoelastic expansion with piezoelectric coefficient of 6.7 pm/V. We deposited the BTO thin film through PLD for the first time, and experimentally observed the piezoelectric properties as an electric field was applied. The change in the PNR region was confirmed from the results.

In the recent years, replacing the current Zr-alloy-based cladding with silicon carbide composites has gained traction in the Department of Energy (DOE) as well as in the industry. The most recent generation of SiC/SiC composites (III), defined by near-stoichiometric chemical composition and crystallinity with reduced oxygen content, has been extensively tested for nuclear applications. They are comprised of a SiC matrix (m) reinforced with long SiC fibers (f) that are woven or braided onto a tubular cladding configuration. The properties of SiC/SiC composites are greatly influenced by the matrix processing methods, fiber architecture and orientation, and interface materials. Oxidation reaction kinetics under steam attack is of critical importance under accident conditions. When exposed to steam, SiC exothermically forms silica, hydrogen and carbon monoxide releasing an energy of 223 kJ/mol, approximately. In general, a competition between a parabolic oxidation process and a linear volatilization process results in paralinear kinetics.

In this work, we capture the oxidation process in a model composite material using a combination of x-ray tomography and mesoscale phase-field simulations. First, the microstructure of the composites is faithfully extracted by x-ray tomography and a full three-dimensional reconstruction is performed. This nondestructive technique allows us to extract all the pertinent microstructural details. Starting with the digitized microstructure, we then simulate the evolution of the pores/pathways accompanying the transport of steam through phase-field modeling. Non-equilibrium chemical thermodynamic models are used to make accurate predictions on the pertinent chemical reactions. The evolution equations (Allen–Cahn and Cahn-Hilliard), which are fully coupled to heat conduction and deformation models, allow us to determine the extent of oxidation processes in the composites under anticipated accident conditions.

In Situ Growth of Nanodefects in Si

Nucleation and growth of oxygen precipitates in Czochralski Si crystals with different boron dopings has been investigated in-situ up to 1000°C to monitor their structural evolution from the very early stages to a stable configuration. Thickness-dependent Pendellosung oscillations as described by the dynamical theory of X-ray diffraction are extremely sensitive to strain fields from defects in a host crystal. Based on this, we initiated a novel approach to study the precipitation kinetics of oxygen in Si. A diffusion-limited model of growing spherical precipitates with two growth regimes interprets the data. An initial diffusion-driven progression is followed by a long time precipitation behavior, which is interpreted as Ostwald ripening.

Large Dielectric Constant Enhancement in MXene Percolative Polymer Composites

We demonstrate that poly(vinylidene fluoride) (PVDF)-based percolative composites using two-dimensional (2D) MXene nanosheets as fillers exhibit significantly enhanced dielectric permittivity. The poly(vinylidene fluoride-trifluoroethylene-chlorotrifluoroethylene) (PVDF-TrFE-CFE) polymer embedded with 2D Ti,C,T nanosheets reaches a dielectric permittivity as high as 10 near the percolation limit of about 15 wt % MXene loading, which surpasses all previously reported composites made of carbon-based fillers in the same polymer. Up to 10 wt % MXene loading, the dielectric loss of the MXene/PVDF-TrFE-CFE composite indicates only an approximately fivefold increase (from 0.06 to 0.35), while the dielectric constant increased by 25% times over the same composition range. Furthermore, the ratio of permittivity to loss factor of the MXene-polymer composite is superior to that of all previously reported fillers in this same polymer. The dielectric constant enhancement effect is demonstrated to exist in other polymers as well when loaded with MXene. We show that the dielectric constant enhancement is largely due to the charge accumulation caused by the formation of microscopic dipoles at the surfaces between the MXene sheets and the polymer matrix under external applied electric field.

Thermal Conductivity of 3D Graphene Reinforced Cu Composite Fabricated by a Simple Two-Step Process

Cu composite reinforced by three-dimensional (3D) graphene network was synthesized in a simple two-step process; (1) an axial compaction of Cu particles in a mold, and (2) CVD at an appropriate condition leading to a Cu composite reinforced with 3D graphene network. Cu composites with different contents of either graphite or graphene were obtained by controlling the processing parameters. 3D graphene network reinforced Cu composite is presented with a possible explanation for and characterization of the formation of graphene. Lastly, the thermal conductivity data of 3D graphene-Cu composite, which is currently about 450 W/mK in both perpendicular and parallel directions, is presented along with a possible mechanism to explain the high thermal conductivity.

Deformation and Failure Behavior of 3D Micro-Architected Lattice Materials
Wei Huang, Mark Wong, Arturo Mateos, Julia Greer and Yong-Wei Zhang; 1School of Aeronautics, Northwestern Polytechnical University, Xi'an, China; 2Institute of High Performance Computing, A*STAR, Singapore, Singapore; 3Division of Engineering and Applied Science, California Institute of Technology, Pasadena, California, United States.

3D micro-architected structural meta-materials are instrumental in light-weight, high-strength, and damage-tolerance engineering applications. The reliability of such materials is often dictated by the mechanical properties of their truss components such as nanowires and nanopipes and their defects, such as notches and voids and also structure-level defects that disrupt the connection of the lattices. An in-depth understanding on the effects of component-level factors such as grain boundaries, surface roughness, sizes, shapes and man-made notches and structure-level factors such as the sizes and shapes of the connection disruptions on the deformation mechanisms and failure patterns of 3D micro-architected meta-materials is of great importance to their fabrication and services with high reliability. In this talk, we will first report our recent progresses in the study of the effects of component-level factors such as grain boundaries, surface roughness, and the sizes, shapes and man-made notches on the plasticity and failure of the components using both computer simulations and mechanical testing. We will then report our recent work on the effect of temperature and component size on the deformation and failure of micro-architected meta-materials under compression and tension using both computer simulations and mechanical testing. Finally, we discuss the effect of structure-level defects (connection disruption) on the failure behavior of 3D micro-architected meta-materials under tension using both finite element modeling and mechanical testing. The present works explore the size effect, temperature and flaw sensitivity of 3D nanolattices and their components using both simulations and experiments, and demonstrates various interesting and unique features of the architected structural meta-materials.

Systematic Study of Electron-Beam Assisted Plasticity for Amorphous Silica Nanostructures
Sung-gyu Kang, Woonjin Cho, Heung Nam Han and In-Suk Choi; Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

In this study, we explore the effect of electron-beam irradiation on the mechanical behavior of amorphous silica nanostructures. It has been reported that amorphous silica exhibits ductile deformation behavior under the electron-beam irradiation during the in-situ compression testing. However, the dependency of electron-beam conditions such as acceleration voltages and beam currents has not been thoroughly investigated. Hence, we performed in-situ mechanical testing for amorphous silica nanostructures at various electron-beam conditions. By systematically changing acceleration voltages and electron-beam currents, we found the threshold electron-beam condition to induce plastic deformation of amorphous silica. Furthermore, our simulation study suggests that the electron-beam effect has clear correlation with the interaction volume of the electron-beam with the sample.

3D Printing and Mechanical Testing of Polymer-Graphene Composite Lattices
Kalaimani Markandan; Nanyang Technological University, Singapore, Singapore; 
Wei Huang, Mehrdad Kiani, Yifan Wang, Nicolas Bertin and Wei Cai; Stanford University, Stanford, California, United States.

3D printing has become a popular fabrication technique for rapid prototyping of complex structures in recent years due to its simplicity, relatively short production time and low material wastage. Despite these advantages, it remains difficult to fabricate structures out of composite materials, such as nanofiller-reinforced polymer resins, using 3D printing. Here, we investigate the factors influencing the stereolithographic synthesis of 3D structures, such as concentration of filler and post-fabrication baking temperature and duration, and demonstrated, for the first time, the successful fabricate graphene-polymer composite lattices. Quasistatic mechanical tests showed that the stiffness of a polymer, reinforced with as little as 0.02 wt. % graphene, can increase up to 70.2 % compared to a non-reinforced polymer. Furthermore, enhanced energy absorption was also observed for octet-truss lattices 3D printed from the polymer-graphene composite material. In situ microscopic deformation and failure of the 3D printed graphene-polymer composite during mechanical testing will be presented and discussed as well.

9:15 AM CP01.05.04
Strengthening Mechanisms in Bimetallic Core-Shell Nanocubes
Wendy Gu, Mehrdad Kiani, Yifan Wang, Nicolas Bertin and Wei Cai; Stanford University, Stanford, California, United States.

Strength, ductility and toughness are key attributes of precipitate strengthened alloys, but remain challenging to achieve in many metallic systems. A detailed understanding of dislocation dynamics at precipitates is necessary for controlling work hardening, localized plasticity, plastic reversibility (e.g. Bauschinger effect), fatigue and failure, as well as the development of high performance steels, lightweight alloys, and high-temperature superalloys. Progress in these areas has been hampered by the lack of direct experimental evidence of detailed deformation mechanisms at precipitates, which prevents the verification and calibration of physics-based predictive computational models. Here, we use bimetallic core-shell nanocubes as model systems in which single precipitates (core nanocrystal) are isolated, and colloidal chemistry is used to tailor precipitate size, composition and defect structure. Nanocrystals are compressed using in-situ scanning electron microscope to obtain stress-strain behavior at individual precipitates, and characterized before and after compression using transmission electron microscopy. Molecular dynamics and discrete dislocation dynamics simulations are compared to experiments in order to determine the dislocation mechanisms responsible for the mechanical response. Here, we compare the mechanical behavior at semi-coherent precipitates in Au@Cu core-shell nanocubes and coherent precipitates in Au@Ag nanocubes. Au@Ag nanocubes have misfit dislocations at the core-shell interface and threading dislocations within the Cu shell, while Au@Cu nanocubes are defect-free. Au@Cu core-shell nanocubes are found to have higher strength, and strain hardening that is absent in Ag and Au@Ag nanocubes. We determine that deformation in Au@Cu nanocubes is governed by the motion of threading dislocations that extend from the bimetallic interface to the nanocube surface, that operate as single-arm sources. Plastic deformation in Au@Ag nanocubes occurs through the nucleation of dislocations at free surfaces.

Plasticity and Fracture in Metallic Materials with Hierarchical Nano/Microstructures
Amit Misra; University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

This presentation will review the recent progress in the understanding of plastic deformation and fracture in metallic materials that have hierarchical composite structures across nano-to-micro length scales. Examples will be presented from different model systems such as laser-processed Al-Al2CuSi eutectics, and vapor deposited Cu-Mo thin films. The role of in situ straining experiments in TEM and SEM, and integration with atomistic modeling, dislocation theory and crystal plasticity in understanding mechanical behavior will be emphasized. The common aspects in interface-dominated mechanical behavior in hierarchical metallic composites such as unusually high flow strengths, high strain hardening rates, plastic co-deformability and suppression of shear bands will be highlighted.

10:30 AM *CP01.06.02
Indentation and Helium Implantation Response of TaTi/ZrTi Nanocomposites Fabricated Via Solid Metal Dealloying Michael Demkowicz; Texas A&M University, College Station, Texas, United States.

We use solid metal dealloying to synthesize TaTi/ZrTi nanocomposite thin films with widely differing morphologies of the constituent phases, ranging from particulate to bicontinuously interpenetrating, but comparable characteristic dimensions of microstructure features. We then investigate the indentation and helium implantation response of these composites. Our work shows a systematic dependence of indentation pile-up height on microstructure morphology, which we attribute to morphology-induced differences in strain hardening rates. We also find a reduction in the size and distribution of helium precipitates relative to un-dealloyed materials, which we relate to the characteristic dimensions of microstructure features of the composites. We conclude with a discussion of future prospects for tailoring mechanical and radiation response by changing microstructure morphology in dealloyed composites.

11:00 AM CP01.06.03 Unraveling the Material and Microstructural Features Prompting Sub-Crystalline Localization in Polycrystalline Ni-Based Superalloys Marat Latypov1, Jean-Charles Stinville2, Jason Mayeur2, Tresa Pollock1 and Irene J. Beyerlein1; 1University of California, Santa Barbara, Santa Barbara, California, United States; 2The University of Alabama in Huntsville, Huntsville, Alabama, United States.

Annealing twins can have a strong impact on the mechanical performance of Ni-base superalloys used in turbine disks. While they are recognized for helping to increase yield strength, annealing twins are also known to localize strain and initiate microcracks in high-cycle fatigue. Using a combination of in-situ deformation DIC and 3D crystal plasticity based computational modeling, we investigate the microstructural factors leading to strain localization and subsequent slip band initiation. The analysis focuses on the coupled role of elastic anisotropy, grain neighborhoods, and grain shape and size in determining the location of the exceptionally preferred points of high elastic strain concentration and localized slip, when the applied strain is under but near the macroscopic elastic-plastic transition. We find that the very few localized slip bands are correlated to the development of only the highest elastic strain concentrations. The latter develops in grains that have an outstandingly compliant orientation relative to its neighbors. We discuss some important microstructural features responsible for microcrack initiation as revealed by the model calculations.

11:30 AM CP01.06.04 An Analysis of the Deformation and Fracture Mechanisms of Cu/Nb Nanolaminates by In Situ TEM Mechanical Tests Javier Llorea, Zhihui Liu, Miguel A. Monclus, L. W. Yang, Miguel Castillo-Rodriguez and J. M. Molina-Aldareguía; IMDEA Materials Institute, Getafe, Madrid, Spain.

Nanoscale metallic multilayers formed by alternating layers of two dissimilar metals with layer thicknesses in the nanoscale range have very attractive properties including high hardness, strength and thermal stability. Nevertheless, most of the mechanical characterization of metallic nanolaminates has been carried out by means of nanoindentation or micropillar compression and very little information is available on the tensile behaviour of free-standing nanolaminates films. Thus, there is a lack of information on the deformation and fracture mechanisms of these systems in tension. In this investigation, the mechanical behaviour of Cu/Nb nanolaminates manufactured by accumulated roll bonding were studied by means of tensile tests carried out within a transmission electron microscope (TEM). Tensile specimens with the loading axis parallel and perpendicular to the laminate were milled using a focus ion beam gun and attached to a push-pull loading device which was introduced in the TEM. Load and deformation were recorded during the in situ tensile deformation, together with the mechanisms of deformation, crack propagation and crack arrest at the Cu/Nb interfaces. Evidence of plastic deformation by confined layer slip was found in both orientations for Cu and Nb, but important differences were found in the fracture mechanisms between both orientations. Crack nucleation and propagation was localized in the thickest Cu layer when the nanolaminates was perpendicular to the loading axis. In the parallel orientation, crack was nucleated in a Cu layer but was stopped at the Cu/Nb interface, leading to a rough crack path. The influence of the orientation on the deformation and fracture mechanisms was discussed to the light of the observations provided by the in situ mechanical tests.

11:45 AM CP01.06.05 In Situ TEM on Twinning Plasticity in Nano-Sized HCP Metals Scott X. Mao1, Yang He1 and Chongmin N. Wang2; 1University of Pittsburgh, Pittsburgh, Pennsylvania, United States; 2Pacific Northwest National Laboratory, Richland, Washington, United States.

Twinning is an essential carrier of plastic deformation and critically influences the mechanical behavior of materials. Due to its atomic-scale complexity, the atomic mechanism of twinning nucleation and growth in hexagonal close-packed (HCP) crystals remains theoretical contention to date, which largely impedes the design and processing of high strength alloys. Here, by using in situ transmission electron microscopy, twinning mechanism was directly captured in HCP crystals. In stark contrast to the classical twinning dislocation mechanism, it was found that {1 0 -1 2} twinning nucleation could be dominated by atomic shuffles which were manifested by the direct transformations between prismatic and basal planes; this process established the lattice correspondence of the {1 0 -1 2} twin. During the twin growth, the incoherent B│P-type twin boundaries transformed to coherent twin boundaries which propagated by the movement of classical twinning disconnections. The findings resolve long-standing controversies in twinning of HCP crystals, opened the way for twinning-based design and processing of high strength HCP alloys, and hold broad implication to the deformation in complex crystal structures.

SESSON CP01.07: Xtreme Materials Design—Nanolayers II Session Chairs: Irene Beyerlein, Arief Budiman, Michael Demkowicz and Jessica Krogstad Wednesday Afternoon, April 24, 2019 PCC West, 100 Level, Room 101 A

1:30 PM *CP01.07.01 Strength, Plasticity and Irradiation Properties of Amorphous Ceramics Containing Nano-Sized Metal Additions Jian Wang, Kaisheng Ming, Qing Su and Michael Nastasi; University of Nebraska–Lincoln, Lincoln, Nebraska, United States.

Radiation induced damage in the core structural materials that are made of crystalline materials are microstructural/crystal defects. Conceptually, these defects can be visualized as regions where there is either a deficiency of lattice atoms (voids, vacancies, edge dislocations, vacancy type dislocation loops) or an excess of lattice atoms (self interstitial atoms, interstitial type dislocation loops). All these defects lead to changes in the mechanical properties of the material. For example, radiation induced swelling (by vacancies and voids) causes dimensional distortion and embrittlement, and is a life-limiting materials issue for structural materials in nuclear power reactors. Austenitic steels were used in fast reactors but could not reliably serve beyond ~150 dpa. Ferritic and ferrite-martensitic (FM) steels have been found to swell much less than austenitic steels. Nano-structuring of both austenitic and FM steels appears to be a promising avenue for further improvement of swelling resistance, providing such structures are stable under ion irradiation. Advanced oxide dispersion strengthened alloys were found to be a promising core structural material, but amorphization and dissolution of oxide particles under high dpa irradiation challenges potential applications. Interfaces (interphase boundaries and grain boundaries) between the metal matrix and nanoscale oxides in oxide dispersion strengthened (ODS) steels systems prove to benefit swelling resistance and creep stiffness. Nanoscale metallic interfaces have shown strong defect sink strength and the ability to suppress He bubble formation. However, all of these do not change the intrinsic issue — radiation induced damage in crystalline materials. Compared to crystalline solids, amorphous materials possess no translational symmetry, and amorphous materials do not contain conventional crystal defects such as vacancies, interstitials, or dislocations.

There are two unique radiation effects which must be considered for the irradiation response of amorphous materials: thermal spike formation associated with damage cascades. Our work shows a systematic dependence of indentation pile-up height on microstructure morphology, which we attribute to morphology-induced differences in strain hardening rates. We also find a reduction in the size and distribution of helium precipitates relative to un-dealloyed materials, which we relate to the characteristic dimensions of microstructure features of the composites. We conclude with a discussion of future prospects for tailoring mechanical and radiation response by changing microstructure morphology in dealloyed composites.

2:00 PM *CP01.07.02 Radiation induced damage in the core structural materials that are made of crystalline materials are microstructural/crystal defects. The Influence of 3D Interfacial Structure and Morphology on the Mechanical Behavior of Nanocomposites

Nathan Mar|1, Youxing Chen|1, Kevin Schmalbach|1, Justin Cheng|2, Zhao Wang|2, Nan Li|1, Jon Kevin Baldwin|2, David Poerschke|1, R. Lee Penn|1 and Andreas Stein|1

1University of Minnesota, Twin Cities, St. Paul, Minnesota, United States;
2Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Two-dimensional (2D) sharp interfaces with distinct boundaries demarcating an abrupt discontinuity in material properties in nanolayered composites have been studied for almost twenty years and are responsible for enhanced behaviors such as strength, radiation damage tolerance, and deformability. However, 2-D interfaces have their limitations with respect to deformability and toughness. 3D interfaces are defined as heterophase interfaces that extend out of plane into the two crystals on either side and are chemically, crystallographically, and/or topologically divergent, in three dimensions, from both crystals they join. Here, we present the mechanical behavior of three different classes of nanocomposites:

1) nanolayered Cu/Nb containing interfaces with 3D character and 2) Tungsten-based 3D ordered nano/mesoporous composites consisting of a porous W scaffolding with silicon carbide or silicon nitride infill. Micropillar compression results show that the strength of Cu/Nb nanocomposites containing 3D interfaces is significantly greater than those containing 2D interfaces. Shear banding in 3D Cu/Nb is observed during pillar compression with retention of continuous layers across the shear band. We will present our recent results on deformation of such 3-D interfaces and structures, and describe this evolution mechanistically through the use of atomistic simulations.

Cyclic Plasticity and Damage Behavior of Metals at the Nanoscales

Xue-Mei Lau|1, Hong-Lei Chen|2, Li-Xue Zheng|1 and Guang-Ping Zhang|1

1Institute of Metal Research, Chinese Academy of Sciences, Shenyang, China; 2School of Materials Science and Engineering, University of Science and Technology of China, Shenyang, China.

Fatigue of metals at the nanoscales has drawn extensive attention due to not only the long-term service reliability of nanoscale metallic components in micro/nano-devices, but also the fundamental understanding of the mechanical fatigue mechanisms at the materials at the nanoscales. It has been demonstrated that the decrease in the length scale from micron scales to submicron scales strongly constrains the formation of typical dislocation structures (dislocation walls and cells), and thus suppresses cyclic strain localization, leading to the enhancement of fatigue strength. In this talk, we will present ex-situ TEM investigations on cyclic plasticity and damage behavior of metals at the nanoscales, such as nanocrystalline metal films and metallic multilayers. For nanocrystalline metal films with a thickness ranging from 20 to 930 nm, we found an evident transition of cyclic plasticity from full dislocation-dominated to partial dislocation-controlled behavior, meanwhile grain boundaries exhibit the unstable behavior related to the film thickness. Furthermore, the fatigue damage behavior was characterized, and slip irreversibility was estimated theoretically based on the observations of dislocation activities. For the nanoscale metallic multilayers, we found that the heterogeneous layer interface in the Cu/Ta multilayers with different layer thicknesses exhibits different stability under cyclic loading. The fatigue damage mechanism and the scaling effect on the slip irreversibility, grain boundary as well as heterogeneous layer interface instability of the metal films and multilayers at the nanoscales will be discussed.

Advances in In Situ Microfracture Experimentation Techniques—Enabling Enhanced Fracture Properties of Cu/Nb Nanolayers via Interface Interaction Engineering

Hashina Parveen Anwar Ali|1, Nan Li|2 and Arief S. Budiman|1

1Xtreme Materials Laboratory, Engineering Product Development (EPD), Singapore University of Technology and Design (SUFTD), Singapore, Singapore; 2Center for Integrated Nanotechnologies (CINT), Materials Physics and Applications Division, Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Plasticity and fracture of materials at the nanoscales can deviate significantly from the same phenomena in bulk properties, which may have important implications if the materials are to be used in real-world engineering systems. Nanoscale metal-metal multilayered materials, where interfaces can be created and modulated in a highly controlled manner and with relative ease, provide a model material system platform to understand plasticity and fracture based on their interactions with other microstructural features at the nanoscales. Recently, there is a growing trend to understand fracture of multilayered materials to see the interactions between the crack and multilayered interface through novel experimentation techniques. In this review, we will introduce the rationale behind this trend and the current microfracture testing methods to test and analyze multilayer fracture behavior. Four examples of in situ fracture techniques are highlighted in this work – the in situ observation upon tensile testing of film on a substrate, the in situ microfracture clamped beam bending technique across the multilayers for accumulative roll bonded as well as physical vapor deposited multilayers and the in situ delamination of metal-metal multilayers along the multilayered interface.

Advanced In Situ X-Ray Diffraction Strategies for the Evaluation of Structure, Strains and Defects in Functional Materials

Olivier Thomas|1,2,3

1Aix Marseille Universite, Marseille, France; 2Université de Toulon, Toulon, France; 3IM2NP, CNRS, Marseille, France.

In present synchrotron radiation facilities, the trend towards fast on-the-fly experiments [1,2], made possible in particular thanks to faster low noise hybrid pixel area detectors, opens many avenues for in situ evaluation of structure, strain and defects in various nano-materials. Pole figure measurements can now be performed fast enough to follow intriguing texture changes during phase transformations [3]. Combination of curvature measurement with x-ray diffraction allows for a detailed understanding of strain evolution during crystallization of phase change materials [4]. Thanks to focused beams strain mapping in devices can be performed in situ as a function of temperature [5]. I will also show how small x-ray beams may be used for investigating the mechanical behavior of nano-objects in situ during mechanical testing [6,7]. All these recent evolutions will benefit a lot from the development of new and even more brilliant sources which will appear in the coming years.

In Situ Study on the Strain Partitioning in a Duplex Stainless Steel by Synchrontron X-Ray Diffraction, SEM, µ-DIC and EBSD

Xiao Zhang|1,2, Pei Wang|1, Dianzhong Cheng|1, Nan Li|2, Si-Xue Zheng|1 and Guang-Ping Zhang|1

1Institute of Metal Research, Chinese Academy of Sciences, Shenyang, China; 2School of Materials Science and Engineering, University of Science and Technology of China, Shenyang, China.

Advanced
The strain partitioning between austenite and ferrite, and grain rotation in a duplex stainless steel are studied in situ during uniaxial tensile loading by a method combining synchrotron X-ray diffraction with SEM, μ-DIC and EBSD. The multi scale results show that at the elastic stage, austenite strain partitioning happens. As the sample comes into the plastic stage, when austenite deforms plastically and ferrite deforms elastically, strain partitioning between phases and grains with different orientations happens. At this time austenite undertakes more strain, and strain accumulates within austenite grains around the phase boundaries and grain boundaries. As the applied stress increases further, both austenite and ferrite strain partitioning plastically. Strain accumulates within the entire austenite grains and ferrite grains around the phase boundaries. Strain gradient exists in both austenite grains and ferrite grains which causes significantly grain rotation at this stage. The research makes up for the disadvantage of the synchrotron X-ray diffraction by applied in the in situ SEM, μ-DIC and EBSD, which gives a new sight on the studying of the micro deformation of multi-phase materials.

8:45 AM *CP01.08.03
In Situ Full Field Diffraction X-Ray Imaging of Buried Tilt and Strain Fields in Light Ion-Implanted Si Wafers Antoine Peulin,1 Samuel Tardif2, Tao Zhou3, Frédéric Mazen3, Joël Eymery4 and François Rieutord2; CEA-LETI, Grenoble, France; 2CEA-INAC, Grenoble, France; 3ESRF- The European Synchrotron, Grenoble, France.

The Smart CuTM technology, which is based on the implantation of light ions in a crystalline matrix, is well-suited for the production of Silicon-On-Insulator (SOI) substrates used in electronics. Under annealing the gas implanted in the crystal forms defects that evolve into micro-cracks, which eventually leads to a subsurface fracture and the delamination of a thin crystalline layer. Bonding the implanted crystal to an oxidized substrate prior to the splitting, allows one to obtain a SOI substrate with a nanometer-thick top silicon layer.

However, the physics leading to delamination is still not fully understood and it is difficult to selectively measure the brittle, implanted layer when a wafer is bonded on top. The aim of this study was to find a way to measure in situ the effect of these buried micro-cracks in terms of lattice strain and tilt on the crystalline matrix under annealing.

A new method called Full Field Diffraction X-ray Microscopy (FFDXM) has been used to observe the deformation induced by the gas-filled micro-cavities in the Smart CuTM technology. This method has been developed at the European Synchrotron Radiation Facility (ESRF) at the ID01 beamline. It consists in using a well-collimated X-ray beam to diffract on the sample and post-sample lenses to obtain a real space image on a two-dimensional detector of the Bragg reflection, quite similar to dark-field imaging in electron microscopy. It allows direct imaging of crystalline domains with a space resolution of some hundreds of nanometers over hundreds of microns, with possible orientation and/or strain contrast. Using hard X-rays (10 to 20 keV), it is possible to image buried features, e.g. at the interface of two bonded wafers.

The acquisition time of FFDXM (on the order of the minute) is compatible with the annealing times in the Smart CuTM technology (on the order of the hour). Thus it has been used in situ to follow the evolution and the movement of the micro cavities coalescence mechanism and the spatial extent of their tilt/strain fields during annealing, a key point to improve understanding of silicon fracture mechanisms after light ion implantation.

9:00 AM *CP01.08.04
In Situ Nano X-Ray Tomography for High-Resolution Imaging of Cracks in Composites and Integrated Circuits During Mechanical Loading Kristina Kutukova1, Juergen Gluch1, Izabela Zglobicka1, Christoph Sander2, Andre Clausner1 and Ehrenfried Zschech4; 1Fraunhofer Institute for Ceramic Technologies and Systems, Dresden, Germany; 2Bialystok University of Technology, Bialystok, Poland.

The imaging of crack propagation in mechanically stressed bulk samples and thin film stacks with high spatial resolution is essential for the validation of models based on materials physics and chemistry as well as on fracture mechanics, and eventually for the design of advanced materials with tailored mechanical properties. Information about the kinetics of crack evolution is needed for ensuring the in-service mechanical performance and reliability of advanced products. Laboratory X-ray microscopy and nano X-ray computed tomography (nano XCT) offer intrinsic advantages for 3D in-situ imaging of cracks in multi-component materials and structures, since they are nondestructive, i.e. the material itself and the local strain state are not modified by sample preparation. We will present experiments that combine nano XCT and mechanical loading for visualization of crack evolution in composites and in 3D patterned microchip structures.

The combination of nano XCT with micro-mechanical experiments merges the advantages of high-resolution 3D imaging of the microstructure of materials with the observation of phenomena like crack propagation during mechanical loading. The application of in-situ mechanical loading of multi-component materials is demonstrated. A customized micro-mechanical test setup is designed for in-situ nano-indentation experiments in such a way that it fits into the limited space of the nano XCT tool and that the indenter tip and the sample fit into the field of view of the X-ray microscope. Cracks in carbon fibre reinforced aluminum matrix composites along interfaces are imaged using XCT, to evaluate the fracture behavior of MMCs.

A miniaturized double cantilever beam test in an X-ray microscope is used for in-situ imaging of crack evolution in microchips. High-resolution 3D image sequences based on nano XCT are acquired during mechanical loading to visualize crack opening and propagation in on-chip interconnect structures of integrated circuits with about 100 nm resolution [2]. As a result, the weakest layers and interfaces are identified and the robustness of the Cu/low-k interconnect stack against chip-package interaction, a serious reliability concern for microelectronic products, is evaluated. This setup can be used to study the dynamic response of samples during low-cycle fatigue too.

Perspectives to overcome three major limitations of state-of-the-art nano XCT tools, i.e. the need of sample preparation (typically less than 50 mm thickness, depending on the material composition, if 8 keV photons are used), limited space for microelectronic products, is evaluated. This setup can be used to study the dynamic response of samples during low-cycle fatigue too.

This talk will highlight recent advances with in situ Transmission Electron Microscopy (TEM) nanomechanical testing and imaging techniques that provide insight into small-scale plasticity and the evolution of defect structures in materials. With the advent of fast direct electron detectors, it is possible to perform strain mapping during in-situ deformation in a TEM with the precision of a few nanometers using the 4DSTEM technique. This talk will describe our recent results from in situ TEM nanomechanical testing that provide insight...
into multiscale metallurgical phenomena using these techniques, such as the role of short range ordering in Ti alloys and deformation phenomena in metallic glasses.

Advances in Nanomechanical Throughput for Extreme Materials Design

Douglas D. Staufner, Eric Hintzula, Ude Hangen and Oden L. Warren; Bruker Nano Surfaces, Eden Prairie, Minnesota, United States.

Advances in materials design often begins with a hypothesis or simulation, and ends with a structure/process/property correlation. In between is synthesis and characterization, often with a very limited sample size necessitated by either the production of a large numbers of samples (e.g. combinatorial studies) or expense (cost of base materials plus synthesis). It is important to get as many structural parameters with that small volume of material as possible, therefore correlative and in situ studies are of primary interest. Here the authors present a nanomechanical testing technique which is capable of very large throughput, capable of collecting more than one million mapped data points on a damascene steel sample in the cm^2 dimensions. The mechanical property map is correlated to both chemical and structural mapping that can be used to generate a full structure/property/process/understanding. This indentation mapping technique can also be compared with in situ microbeam bending tests, for example the transition in a BMG to Ti dissimilar weld from ductile Ti rich, to a ductile BMG with Ti lamella, to fully brittle BMG.

Annealing of Metal Films at Room Temperature Using Electron Wind Force and Elastic Strain Energy—An In Situ TEM Study

Zahabul Islam1, Huaqian Gao2 and Aman Haque1; 1The Pennsylvania State University, University Park, Pennsylvania, United States; 2Brown University, Providence, Rhode Island, United States.

Grain growth in metallic thin films is commonly achieved with high temperature (greater than 30% of the homologous temperature) annealing. In this study, we explore an alternate route that is non-thermal in nature. Specifically, we study the synergy of electrical current and tensile strain instead of temperature. Our approach involves passing electrical current in the specimens at much lower current density than the electro-migration damage limit. This directly causes Joule heating, which is eliminated by both passive and active heat removal techniques to keep the specimen temperature at or near ambient conditions. We then study the role of mechanical strain on the grain growth at room temperature. In-situ Transmission electron microscopy (TEM) shows more than 10 times grain growth under the application of elastic strain (about 0.1%) dramatically increased the grain size by more than 10 times in a few seconds at the room temperature regions. This suggests that the synergy of elastic strain energy and electrical current density may achieve grain growth in metallic materials even at room temperature. We investigated this phenomenon using molecular dynamics simulation, which reveals that externally applied strain is localized at the grain boundaries in nanocrystalline metals, which promote the effects of electron wind force on the grain boundary atoms. We conclude that synergy of two or more stimuli can achieve grain growth at low or even room temperature.

Our experimental study begins with fabrication of a micro-electro-mechanical system (MEMS) device with 100 nm thick Palladium thin film. Palladium melts at 1555 °C and is used in catalysis and electronics applications. It is therefore an attractive specimen for room temperature annealing. To decouple the contributions from the electrical current, temperature and stress, we developed a unique experimental setup, where the same specimen could be divided into two regions. The center region experiences high temperature and the applied current density. The two edges of the freestanding thin film specimens remain at the same current density, but at around room temperature. The negligible grain growth at the edges suggests the dominant role of temperature on grain boundary mobility. The initially nanocrystalline (5 nm grain size) specimens were exposed to various levels of current density with and without tensile strain inside a TEM. Transmission electron microscope (TEM) images and diffraction patterns show that even elastic strain energy can not only strongly influence the grain growth, but also lower the required electrical current density. The resulting microstructure showed very high density of nano-twins compared to the purely thermally annealed ones.

In addition to the experimental study, we employed classical molecular dynamics (MD) simulation to investigate the underlying mechanism on grain growth using embedded atomic model (EAM) potential. We model the electron flow by imposing an additional equivalent wind force on each atom at room temperature. This equivalent electrical wind force enhances the atomic motion and diffusion at defective regions (grain boundaries), which in turns facilitates the grain growth. The role of mechanical stress is to promote this mechanism through localization at the grain boundaries. Displacement vector analysis of individual grain from molecular dynamics simulation reveals that grain grows due to the grain boundary sliding and rotation during tensile straining accompanied by AC current.

In Situ Nanoindentation Tests to Investigate Plastic Deformation and Recovery of Thin 3C-SiC and Change of Mechanical Properties Due to Ion Irradiation

Xuying Liu, Chaiyapat Tangpatjaroen, Izabela Szulifarska and Paul Voyles; University of Wisconsin-Madison, Madison, Wisconsin, United States.

We have used in situ TEM to investigate deformation and failure of 3C-SiC as synthesized and after irradiation with carbon ions. Radiation-induced embrittlement is a significant problem in all kinds of nuclear materials (e.g. [1]). 3C-SiC has shown severe embrittlement and loss of strength under high fluence at relatively low temperature [2]. Our in situ nanoindentation tests on as-synthesized 3C-SiC show that this brittle ceramic can show some plasticity at room temperature. The continuous load-displacement curves confirmed that no fracture happened during indentation, which is also reflected in the TEM videos. Bend contours moved away from the surface during loading, representing the stress field inside the sample under applied force. SEM observation post indentation shows metal-like extrusion around indents, which demonstrates that samples experienced some plastic deformation. In dark-field TEM images after indentation, there are bend contours left in the sample, which is further evidence for residual strain, and thus plastic deformation of the samples. In addition, during unloading, after the force dropped to zero, the contours were still moving backward, which is an indicator of plastic deformation recovery. Very small sample size can decrease the brittle-to-ductile transition temperature to room temperature for some brittle materials [3][4], and room-temperature plasticity has been observed previously in different polytypes of SiC with different geometries due to phase transition [5], gliding of existing dislocations [6], amorphization [7], and other mechanisms.

In situ TEM nanoindentation tests of 3C-SiC irradiated at 600°C with 3.15 MeV carbon ions up to up to 5 displacements per atom (dpa) in the first one micron show different fracture behavior. In situ indentation along the irradiation profile probes different levels of radiation damage. Indenting at deeper irradiation depth with more irradiation damage (high dpa and larger diameter defects) causes quick and sharp crack and a small residual indent, while indenting at non-irradiation effected area causes a larger residual indent and more debris. These preliminary results suggest that irradiation induced defects make the sample more brittle and reduce its fracture toughness.

In Situ TEM Studies of Mechanical and Electromechanical Properties of Individual InAs Nanowires

Lunju Zang1, Christoph Gammer2, Burak Ozdo1, Thomas Nordqvist3, Peter Krostrup4, Andrew Minor1,5, Wolfgang Jäger6 e and Eva Olsson7; 1Chalmers University of Technology, Gothenburg, Sweden; 2Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Leoben, Austria; 3Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 4University of Copenhagen, Copenhagen, Denmark; 5Department of Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 6Institute of Materials Science, Christian-Albrechts-University Kiel, Kiel, Germany.

Strain engineering of the electrical and optical properties of semiconductor nanomaterials is an effective way to tailor the performance of nanowire-based devices such as high-
InAs nanowires, both bare InAs nanowires and InAs/Ga$_2$O$_3$As core-shell nanowires, were used in the investigation. Simultaneous stress and current-voltage (I-V) measurements were enabled by an electrical push-to-pull (EPTP) device in a Hysitron P95 nanindentation TEM holder. In situ nanoscale lattice strain mapping within the nanowire was performed using scanning transmission electron microscopy (STEM) combined with nanobeam electron diffraction (NBED). Direct and quantitative stress, strain and electrical transport measurements were carried out on individual nanowires. The results showed that the resistivity of the InAs nanowires decreased continuously with uniaxial tensile stress. Large piezoresistance effect was found in InAs nanowires. However, bare InAs nanowires and InAs/Ga$_2$O$_3$As core-shell nanowires show different electromechanical behavior. The large piezoresistance effect is partly due to the small Young’s modulus of the nanowires (~11 GPa), but band gap narrowing of InAs is considered to be the main reason for the resistivity change. Moreover, despite apparent elastic deformation of the nanowires, significant inhomogeneous strain distribution within the InAs/Ga$_2$O$_3$As core-shell nanowires was unveiled by STEM-NBED strain mapping at different tensile stress levels. The inhomogeneous strain distribution at nanometer scale can increase the resistivity of the nanowire by enhancing electron scattering. The findings demonstrate unique mechanical and electromechanical properties of the nanoscale InAs wires and provide new insights of the correlation between mechanical strain and electrical transport properties in free-standing nanostructures [1].

In Situ TEM MEMS-Based Tensile Nanomechanical Testing of Ultrathin Films Saurabh Gupta, Brad Boyce, Olivier Pierron and Sandra Stanoev; 1Georgia Institute of Technology, Atlanta, Georgia, United States; 2Sandia National Laboratories, Albuquerque, New Mexico, United States.

A MEMS based technique for in-situ TEM nanomechanical tensile testing of ultrathin films has been developed which allows for high magnification TEM observations of the deformation mechanisms in the thin film at the nanoscale while simultaneously measuring the macroscale behavior of the thin film quantitatively. Consecutive stress relaxation transients were performed in-situ in the TEM on ultrathin grained 100-nm-thick gold and 200-nm-thick aluminum films using this MEMS device. The plastic deformation in the gold films was observed to be mediated via intragranular dislocations originating from grain boundaries and was very localised. Local grain growth was also observed in the aluminium films in regions of severe plastic deformation along with dislocation pile-ups in some grains. The physical activation volume of the gold films was obtained around 3-15b$^3$ while activation volumes between 5-40b$^3$ were measured for aluminum films. The observed plastic deformation mechanisms are consistent with the low activation volumes calculated for these ultrafine grained thin films.

SESSION CP01.10: Materials in Extreme Design

High-Velocity Impact Ignition of Pre-Stressed Micron-Scale Aluminum Powder Compacts Michelle Panova and Kevin Hill; Texas Tech University, Lubbock, Texas, United States.

Pre-stressing aluminum (Al) particles is linked to increased reactivity by altering the physical and mechanical properties at the core-shell interface of the Al-Al$_2$O$_3$ particle. Changes in quenching rates during pre-stressing have been shown to change the reaction mechanism of micron Al particles. Faster quenching rates (i.e., 900 K/min) lead to shell delamination and a reduced oxidation barrier. Slower quenching rates (i.e., 200 K/min) result in increased hoop stress in the shell. To examine the effects of pre-stressing under high velocity (850-1200 m/s) impact conditions, 3-4.5 micron diameter Al particles were annealed to 573 K, then quenched at different rates (200 and 900 K/min), mixed with 1 wt. % polyvinylidene fluoride (PVDF), and formed into pellets. The projectiles were fired from a High-velocity Impact-ignition Testing System (HITS) into a steel anvil. Data for flame spreading and pressure in the impact chamber were collected for two stages of ignition and reaction corresponding with impact and rarefaction due to after blast. Results show that shell delamination in the faster quenched Al samples contributes to faster reaction rates during impact as well as during rarefaction in the after blast for both impact velocities. In contrast, increased hoop stress in the shell from slower quenching significantly delays energy release at the lower impact velocity by delaying shell failure. At the higher impact velocity, the increased stress in the slower quenched particles contributes to more rapid energy release than untreated particles during impact and after blast, but the alumina diffusion barrier is not removed as effectively from the particles compared to the delamination present in the faster quenched particles. These results establish a link between altering mechanical properties of fuel particles towards influencing fuel particle reactivity under the extreme loads of high velocity impact ignition and reaction.

Mechanical Characterization of Quartz Tuning Fork Coupled Oscillator for Quantitative Measurement of Nanoscale Forces at sub-10 nm Gap Separations Cedric Shaskey, Amun Jarzembski and Keunhan Park; University of Utah, Salt Lake City, Utah, United States.

Quantitative nanoscale force measurement using atomic force microscopy (AFM) has been well established [1]. However, these measurements are limited to cantilever-based AFM which suffers from a snap-to-contact when tip-sample separations are on the order of 10 nm. In order to probe forces when the tip-sample separation is in the sub-10 nm range, a force sensor which has vertical rigidity orders of magnitude larger than conventional AFM cantilevers is required. Quartz tuning forks (QTFs) satisfy this condition while also achieving higher sensitivity due to the coupled oscillation of their tines which produces a resonant Q-factor that is typically an order of magnitude larger than conventional AFM cantilevers. However, the coupled oscillation complicates the mechanical modeling and characterization. QTFs exhibit multimodal resonances: although previous models have accurately described the fundamental resonance [2, 3, 4], no model has been able to explain other observed resonant modes. The present study aims to create a lumped model capable of explaining all of the mechanical resonances of a QTF and extracting the relevant parameters. The QTF spectrum is measured electrically (via piezoelectric effect) and simultaneously measured optically (via Fabry-Perot interferometry). Electrical measurements are performed with two different lead configurations to separately extract the in-phase and anti-phase oscillations of the tines. Optical measurements are performed in two orthogonal directions to extract the true amplitude of the in-plane and out-of-plane oscillations. By combining these measurements with an in-plane model and an out-of-plane model, the lumped parameters can be extracted. Preliminary measurements indicate that the coupling is an order of magnitude larger than previously reported [3]. Complete characterization of the QTF will enable predictions of the behavior of the QTFs when a tip-sample interaction is present. This will allow quantitative extraction of the interaction force at sub-10 nm gap separations.

Crack Nucleation in a 3C-SiC Nanowire and Its Atomistic Origin Fazle Flahi and Zubaer M. Hossain; Mechanical Engineering, University of Delaware, Newark, Delaware,
It is very important to predict the crack nucleation site to eliminate the probability of failure of a material. A thorough analysis of stress distribution on 3C-SiC (111) nanowire is done by Molecular Dynamics calculation to find out the atomistic origin of a crack nucleation. Stillinger-Weber interatomic potential is used to predict the stress on different locations of the hexagonal cross-section. In thin nanowires with a diameter (d) less than 1.0 mm has their highest stress concentration on core site. For the smallest nanowire considered in this work (d=0.32 nm), the difference in stress between the edge atoms and the core atoms is around 50 GPa. But as the diameter increases, the stress concentration moves to the immediate vicinity of the edge. For, d>1.0mm, core region is not subjected to highest load and crack nucleates in the immediate bond to the corner atom. The surface is a result of terminated material from the bulk structure and it is least stressed in larger nanowire when the external load is uniaxial along the (111) direction. Heterogeneity in stress on the cross section of NW is the sole contributing factor to the variation in crack nucleation site. As the nucleation of crack is directly related to toughness, we also get d-dependent toughness in nanowire due to stress heterogeneity. The concluding statement of this work is, the location of crack nucleation in 3C-SiC (111) nanowire and corresponding energy absorption rate is governed by stress heterogeneity, not the surface to volume ratio of the structure.

Coherent Diffraction for a Look Inside Nanostructures—Catalysis and Defects
Marie-Ingrid Richard1, 2, 3; IM2NP, Marseille, France; 1Aix-Marseille University, Marseille, France; 2ESRF, Grenoble, France.

Characterising the structural properties (strain gradients, chemical composition, crystal orientation and defects) inside nanostructures is a grand challenge in materials science. Bragg coherent diffraction imaging (Bragg CDI) can be utilised to address this challenge for crystalline nanostructures. A resolution of the structural properties of less than 10 nm is achieved up to-date [1]. The capabilities of the Bragg CDI technique will be demonstrated on single nanoparticles for enhanced catalysis.

As an example, the Bragg CDI technique allows understanding the interplay between shape, size, strain, facetting [2], composition and defects at the nanoscale. We will demonstrate that Bragg CDI on a single particle model catalyst makes it possible to map its local strain/defect field and directly images strain build-up close to the facets. The localized strain modfies sorption energies of the reactants. In situ [3] and operando Bragg CDI was also performed: it was possible to track a single particle in liquid and gas phase environments, to monitor its facet changes and to measure its strain response to gas or electrochemical reaction.

This technique opens pathways to determine and control the internal structure of nanoparticles to tune and optimise them during catalytic and other chemical reactions.

Financial support to this work by ANR Charline (ANR-16-CE07-0028-01) is gratefully acknowledged.

Mechanical Strengthening of Nickel Continues Down to 3 nm
Bin Chen1, Xiaoling Zhou1,2, Qiong Xu1, Z.Q. Feng1, L.L. Zhu1, X.X. Huang1, and X.X. Huang1, 2, 3

Because of unique sensitivity to lattice, Bragg coherent x-ray diffraction imaging (BCDI) has been employed on various nanoscaled materials such as metal, metal oxide, and mineral, to image three dimensional map of strain distribution and lattice distortion with non-destructive measurements. In-situ and operando imaging became a major driver for BCDI to address scientific questions on physics, chemistry, and materials science in recent years.

In this talk, I will introduce current state-of-art of BCDI and recent experimental results on in-situ and operando BCDI. High temperature BCDI reveals annealing effect on gold grain on thin film and relaxation of strain inside quantum materials such as nanodiamond and silicon carbide. Strain and dislocation development has been observed on palladium during phase transition under hydrogen flow and on gold-silver alloy for dealloying process. In addition, some estimates of BCDI in the future will be discussed.

Novel Functional Nanocomposites of 2D MXenes and Light-Weight Metals
Vladislav Karnyshayev1, Babak Anasori2, Yury Gogotsi2 and Dmitri Talapin1; 1The University of Chicago, Chicago, Illinois, United States; 2Drexel University, Philadelphia, Pennsylvania, United States.

Nanocomposites of light-weight metals and ceramic Nanocrystals (NCs) as reinforcements are an important class of structural materials. Compared to other ways of fabricating these materials, liquid metal route results in nanocomposites with superior mechanical properties, greater industrial compatibility and chemical versatility. From thermodynamic
point of view, introducing ceramic NCs directly into liquid metal is challenging because surface tension of liquid metals greatly exceeds that of ordinary solvents. Hence, in order to satisfy the wetting condition, strong chemical bonding between NCs and liquid metal is required. At the same time, the interfacial reaction should not compromise thermodynamic stability of the NCs. Among existing ceramic NCs, the recently discovered 2D transition metal carbides (MXenes) offer a unique solution to fabricating next generation light-weight nanocomposites due to their high-strength (Young Modulus 0.33 TPa), metal-like conductivity, solution-processability and surface group tunability. Here we demonstrate that 2D sheets of titanium carbide (Ti$_3$C$_2$Tx, where T stands for surface groups such as =O, -OH and -F) can be successfully integrated into ultra-light-weight Mg-Li alloy (final density $\rho \approx 1.8$ g/cm$^3$) via the liquid metal route. 2D sheets are uniformly distributed throughout the Mg-Li alloy matrix as evidenced with FIB-SEM and TEM analysis. The recovered NCs retain 2D morphology and ultrathin thickness of the starting MXene sheets ($\approx 1$ nm) and can be preliminarily indexed as a face-centered cubic Li alloy (final density $\rho \approx 1.8$ g/cm$^3$).

PARC has recently invented a novel composite, Chemically Linked Graphene Networks, wherein graphene sheets are chemically bonded to each other by flexible polymer linkers. Inter-particle chemical bonding restricts their movement under stress. This feature cannot be achieved with conventional particle-filled polymer composites in which the dispersed particles can move easily within the polymer network on impact or load. Chemically linked graphene networks produced cured architectured structures with remarkably high strength when compared with the base polymers or with conventional graphene composites. These structures are enabled by a new, low cost synthetic approach to highly dispersible, chemically reactive functionalized graphene particles. In addition to enhanced mechanical strength, we have found that this material possesses additional valuable properties including outstanding gas barrier performance and high thermal conductivity. The technology is targeted for direct 3D printing of multifunctional lightweight load-bearing structural parts that may be used as a direct carbon-fiber reinforced polymer replacement, or as a replacement for some metal parts in industries such as aerospace and automotive.

Studies of MOFs and Their Complexes by High Resolution "Conventional" and Novel Solid-State Synchronous Fluorescence Spectroscopy

Nc metals have been reported to exhibit an extended microplastic regime during loading unlike in case of the cg metals that show a macroscopic yielding already at 0.2% strain [3]. In addition, these materials have been shown to exhibit Bauschinger effect (BE) during unloading, where a pronounced reverse plastic deformation is observed [4]. So far, such an effect has been explained by stress gradients developing between differently sized grains or by back stresses that develop due to piling up of dislocations at grain boundaries that aids their reverse motion during relaxation [5,6]. However, in case of nc metals it is still a subject of open discussion whether the deformation processes are mainly dislocation or grain boundary mediated. Thus, in the context of cyclic loading-unloading, we intend to explore the deformation mechanisms that contribute to the BE in these class of materials.

We performed in situ cyclic loading-unloading experiments on 100 nm thick sputtered nc Pd thin films inside a TEM. The stress strain curves show a nonlinear unloading deviating from ideal elastic unloading behavior, which is a characteristic of the BE reported in case of thin metal films. The corresponding bright field TEM (BFTEM) series show local contrast changes in the grains, which are partly reversible during unloading. Aiming towards a quantitative un-parsing of these events, we used automated crystal orientation mapping in STEM mode (ACOM-STEM) in conjunction with quasi static loading-unloading experiments. Analyses of series of HAADF-STEM images that were acquired along with the ACOM series indicated reversible contrast changes in several grains indicating changes in crystal orientations. This was confirmed from the quantitative analyses of the ACOM series consisting of a large number of grains that indicated grain rotation. The average rotation was found to progressively increase during loading while a significant number of grains showed complete or partially reversible rotations on unloading. Local analyses of the STEM series also shows that the contrast changes traverse multiple grains in direct vicinity indicating that these rotations are likely to be operating in a co-operative manner. Relating these effects to the observed mechanical response of the sample, we conclude that grain rotation is a potential mechanism contributing to the BE in nc metals. With our in situ ACOM approach, we are developing a closer link of the competing deformation mechanisms and the microstructural heterogeneity in terms of grain size, crystallographic texture and grain boundary character to further elucidate on the observed mechanical response of nc metals.

8:45 AM CP01.12.03

Imaging Reversible Topotactic Phase Transitions in Strontium Ferrite Thin Films by In Situ TEM Zhenzhong Yang, Le Wang, Endong Jia, Zihua Zhu, Chongmin N. Wang, Peter V. Sushko and Yingge Du; Pacific Northwest National Laboratory, Richland, Washington, United States.

The creation, clustering, and ordering of oxygen vacancies (VOs) in perovskite-structured oxides (ABO3, B being a transition metal) give rise to a special class of materials, such as Brownmillerite (BM) structured SrCoO2-x SrFeO2-x and rhombohedral structured SrCrO2. A topotactic phase transition (e.g., SrFeO2-x ↔ SrFeO3) can occur as a result of oxygen content variation, which leads to dramatic changes in their functional properties, such as electronic conductivity, ionic conductivity, and electrocatalytic reactivity. Understanding the detailed structural and phase transition processes is critical for the rational design of functional energy materials that are used in batteries and solid oxide fuel cells. In this study, using in situ environmental transmission electron microscopy (ETEM), we directly imaged the oxygen diffusion and phase transition processes in epitaxial BM-SrFeO2-x thin films at elevated temperatures. The high spatial and temporal resolution of the TEM allowed us to correlate the onset of phase transition, reaction rate, and transition pathways with the annealing temperature. The phase transformation from BM-SrFeO2-x to perovskite SrFeO3.6, triggered by the intercalation of O ions, exhibited a clear reaction front, indicating the oxidation of FeO tetrahedra to FeO octahedra occurs preferentially at the phase boundaries, which is supported by our density functional theory calculations.

9:00 AM CP01.12.04

Studies of MOFs and Their Complexes by High Resolution “Conventional” and Novel Solid-State Synchronous Fluorescence Spectroscopy Cole Grinnell1, Jun Dai2, Michael L. McKee1 and Alexander Samokhvalov1; 1Chemistry Department, Morgan State University, Baltimore, Maryland, United States; 2Chemistry Department, Rutgers University, Camden, New Jersey, United States; 3Department of Chemistry and Biochemistry, Auburn University, Auburn, Alabama, United States.

High resolution optical spectroscopy and, specifically, fluorescence spectroscopy provides valuable information on both vibrational and electronic phenomena. This is of significant interest to understand from vibrionically resolved optical emission spectra the mechanisms of intermolecular interactions of functional groups in advanced nanoporous solid-state materials, in particular metal-organic frameworks (MOFs), and their complexes with small molecules. First, we will describe our recent studies of vibrionically resolved solid-state “conventional” fluorescence emission spectra of naphthalene at room temperature. Distinct vibrionic transitions 0-0, 0-1, 0-2, etc. are facely observed in the near-UV range, and assigned to specific vibrations of isolated naphthalene molecules. In addition, naphthalene forms excimers, which is clearly seen in well-resolved vibronic structure in the near-UV/visible range of fluorescence spectrum. Further, naphthalene forms the stoichiometric sorption complex with MOF Basolite F300. In this research, we utilized naphthalene molecule as the fluorescent “self-probe” confined in the nanocavity of MOF, which shows: a) a loss of excimer emission, b) the decrease of area ratio A(0-2)/A(0-1) of respective vibronic peaks, and c) non-polar environment. The complementary characterization of chemical bonding in the complex has been conducted using UV-Vis DRS and DFT calculations. However, “conventional” fluorescence emission spectra of most solids are very broad and diffuse under ambient conditions, therefore their vibronic structure is not observed. For chemical compounds in diluted solutions, strong narrowing of emission peaks is routinely achieved by synchronous fluorescence spectroscopy (SFS). In the experiment by SFS, the excitation λexc and emission λem wavelengths are scanned simultaneously (“synchronously”) at the constant offset Δλ = λexc - λem. In contrast, studies of solid materials by the SFS are very rare. We present novel high resolution in-situ instrumental method, solid-state synchronous fluorescence spectroscopy, which has recently been developed in our lab. This method has been applied for studies of electronic photoexcitation/relaxation transitions and molecular interactions within MOFs and their sorption complexes. The MOF Basolite A100, which is similar to the benchmark MIL-53(Al), shows the unprecedented and sharp, “molecular-style” resonances in solid-state synchronous fluorescence spectra. Basolite A100 forms the stoichiometric sorption complex with an archetypal polar molecule of dimethyl sulfoxide (DMSO). The peaks in the solid-state SFS of the sorption complex are shifted to the shorter wavelengths, due to the interactions of the linker in this MOF with DMSO adsorbate molecule. The complementary experiments by powder XRD, FTIR and differential scanning calorimetry (DSC) provide an additional insight on the nature of bonding in the complex. The described novel high resolution spectroscopic method, solid-state SFS shows strong potential to become a useful experimental technique for studies of electronic levels in solids, the pathways of excitation and relaxation, and for understanding intermolecular interactions in composite functional nanostructured materials well beyond MOFs and their sorption complexes.

9:15 AM CP01.12.05

Synthesis and Mechanical Behavior of Freestanding, Nanocrystalline NiTi Films Under Cyclic Tensile Deformation Paul Rasmussen and Jagannathan Rajagopalan; Arizona State University, Tempe, Arizona, United States.

Controlling the micro/nanostructure of thin films would enable us to explicitly tailor their mechanical behavior. Here, we describe a new process to synthesize thin films with precise microstructural control via systematic, in-situ seeding of nanocrystals, and subsequent crystallization of amorphous precursor films. Using this process, we synthesized austenitic NiTi films with submicron grain sizes. We then co-fabricated freestanding samples of the films with MEMS testing stages and performed cyclic tensile load-unload experiments. Samples seeded with Cr showed a high phase transformation stress (> 700 MPa) during the first cycle that increased even further during subsequent cycles. More interestingly, the film showed a continuous decrease in stress-strain slope during unloading rather than the pseudo-elastic behavior typically observed in nanocrystalline NiTi. Preliminary in-situ TEM straining studies suggest that this unusual loading behavior is caused by a combination of reverse phase transformation and reverse plasticity.

9:30 AM BREAK
In Situ Studies of Surface Effects on the Mechanics of Metal Network Structures

Joerg Bagdahn; Anhalt University of Applied Sciences, Köthen (Anhalt), Germany.

The topic of soiling of photovoltaic module (PV) and concentrated solar power (CSP) collectors has recently gained increasing attention due to its impact on solar power production, especially in arid and semi-arid areas with high concentrations of airborne dust. Soiling describes the deposition of dust and other contaminants on surfaces, reducing solar irradiation by absorbing or reflecting the sunlight, causing energy yield losses which can exceed 1% per day. The amount of soiling is influenced by complex interactions of many factors which can vary significantly from site to site. Dust accumulation and corresponding soiling rate is determined by the interaction of particle deposition, rebound and resuspension, which are strongly influenced by particle adhesion forces and removal forces.

A focus is made on soiling mechanisms that increase particle adhesion such as cementation, particle caking and capillary aging. A detailed analysis and model of dew-driven soiling mechanisms of cementation, particle caking, and capillary aging are given on the basis of microstructural material and dust characterization of outdoor exposed glass samples. To identify the underlying physical and chemical processes of cementation, glass samples were exposed to outdoor conditions in various locations (Qatar, Chile, Morocco) and investigated at microstructural level using electron microscopy (SEM and TEM) and elemental analysis with energy-dispersive X-ray spectroscopy (EDX). For samples from Qatar, the formation of nanoscopic needle-like structures was observed, which can be attributed to the clay minerals and somehow contradicts the common perception that cementation occurs via the precipitation of salt.

Overall the study aims to provide a useful, in-depth but also global overview and fundamental understanding of soiling processes on PV modules down to the microscale, which could be used to develop appropriate soiling mitigation strategies.

Stress and Fracture of Crystalline Silicon Cells in Solar Photovoltaic Modules—A Synchrotron X-Ray Microdiffraction Based Investigation

Sasi Kumar Tippahothla1, Wenjian J. Song1, Ihor Radchenko1, Camelia V. Star1, Nobumichi Tamura2, Andrew A. Tay2 and Arief S. Budiman1; 1Singapore University of Technology and Design, Singapore; 2Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Fracture of crystalline silicon solar cells in photovoltaic modules is a big concern to the photovoltaics (PV) industry. Cell cracks cause performance degradation and warranty issues to the manufacturers and hence, they are a limiting factor to the applicability of silicon PV as a main stream power source with high long-term reliability. In such a scenario, it is important to evaluate and quantify the fracture of the crystalline silicon cells to address it. The roots of the cell cracking process lie in the manufacturing and integration process of the cells and modules as they go through a series of elevated temperature and pressure processes, involving bonding of dissimilar materials, causing thermomechanical stresses, thus leading to cell fractures. Evaluation of the mechanics of these thermomechanical stresses and the role of different materials and processes in a sequential manner is highly essential to quantify these stresses and optimize the PV modules to address them and hence, the cell fractures. We present a novel synchrotron X-ray microdiffraction based techniques combined with finite element modelling to evaluate and characterize the stress and fracture in the crystalline silicon PV modules. Our results show that the thermomechanical stress builds up over the module integration processes such as soldering and encapsulation. We show the detailed stress evolution at each step of the lamination process, using the finite element simulations, validated by the synchrotron X-ray microdiffraction results. We further show the effects of the material and process parameters which affect the cell stress and thus, could be used to reduce the cell fractures and pave the way for the next generation crystalline silicon solar PV modules with enhanced fracture resistance.

Advances in X-Ray Microscopy for the Study of Battery Reactions in Single Particles

Joeri Cabana; University of Illinois at Chicago, Chicago, Illinois, United States.

The existing performance limitations of Li-ion batteries can be tracked to slow transport and irreversibilities in the changes undergone by the electrode materials, often coupled with mechanical events such as fracture. Tools that provide insight into the onset and propagation of these transitions are critical to identify the mechanisms of electrochemical function. This information must be generated at the level of single particles, where irreversibilities trigger degradation of the electrode architecture. Synchrotron-based X-ray microscopy combines morphological observations at high spatial resolution with a suite of chemical probes, such as diffraction and spectroscopy. Therefore, it is ideally suited to relate electrochemical observations with changes in nanoscale chemistry, linked to mechanical degradation. In this talk, we will justify the need for sophisticated connections between these phenomena, and we will proceed to discuss recent developments in X-ray microscopy aimed at visualizing them in single particles of battery electrodes. The talk will highlight the new fundamental insight generated by the tools, involving local dynamics of heterogeneity and, where relevant, their relationship with fracture events. While significantly valuable insight will be gleaned from samples harvested at relevant points of the electrochemical reaction, these measurements create uncertainty due to the possibility of relaxation of components from the kinetically controlled functional state to one that is more stable under open circuit conditions. Therefore, we will introduce our latest efforts to carry out time-resolved measurements simultaneous to the electrochemical reaction.

Creep Behavior of Nanocrystalline Al Alloys

Sung Eun Kim, Nisha Verma, Pascal Bellon and Robert S. Averback; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Nanostructured alloys are currently of much interest for their potential applications in extreme environments. Most research has focused on their high strength and ductility, however, for high temperature applications, their susceptibility to creep damage is also important, and much less work has been performed on this topic. Creep may be significant in these materials as diffusional creep scales inversely with grain size, e.g., Coble creep varies as 1/r3, and in situ creep measurement is one of the techniques highly demanded these days.

In the current work we have examined grain growth and creep behavior in Al alloys- Al5Si, Al5Si5 and Al5Si7- using our in-situ creep measurement apparatus. We prepared our alloys as thin films using magnetron sputtering. These films were stabilized at a grain size ~150 nm by first annealing them at 250°C. Creep measurements were performed using a bulge test (JJ Vlassak and WD Nix, J. Mats. Res. 7, 3242, (1992)); the grain size and precipitate structure were examined by transmission electron microscopy. The creep measurements revealed that the creep rate increased linearly with applied stress, while the temperature dependence showed approximately Arrhenius behavior with an activation enthalpy of 0.2 – 0.5 eV, which is somewhat lower than that of grain boundary diffusion in large grained Al.
small scale has been linked to interfacial effects, as there are observations of stiffening or enhanced compliance in nanoscale objects. Yet, the underlying mechanisms remain under investigation. While numerical studies provide a wealth of suggestions, meaningful experimental verification is more elusive. This talk discusses experiments designed to verify the suggested contribution of capillary forces to the plastic and elastic response of small bodies. Dealluying-made nanoporous metals provide model systems in the form of homogeneous metal networks with struts or ligaments at the nanoscale. The mm-size nanoporous bodies are highly deformable in compression and can be tested with reliable macroscopic methods. In-situ tests of such samples in electrolyte and control of the electrode potential afford variations of the surface state during ongoing deformation processes. Typically, the variation of surface state tension and surface stress are known; the response of the mechanical behavior then affords robust conclusions on the role of capillary forces in small-scale mechanics, including their impact on strength, compression-tension asymmetry, and size-dependent stiffness. At the same time, electrochemical cycles can be tuned to provide a stringent control over the purity of the surface, which is rarely available in experiments in the field.

2:15 PM *CP01.14.02
Deformation and Failure of CuZr Gradient Nanoglasses Paulo Brancicio; University of Southern California, Los Angeles, California, United States.
The intricate deformation and failure of seamless gradient nanoglasses are investigated with tensile loading large-scale molecular dynamics simulations. Cu55Zr45 metallic glasses are used as parent alloys for the construction of functionally graded nanoglasses with grain sizes from 3 to 15 nm. Tensile loading simulations are used to characterize the mechanical behavior of the heterogeneous metallic glass and shed light on the plastic deformation mechanisms. Results indicate a strong localization of the plastic deformation beyond the yield point for loading parallel to the gradient direction in soft regions with high concentration of reduced grain sizes. Loading perpendicular to the gradient direction indicates overall significant delocalization of plasticity throughout the sample. Results indicate a synergy of the gradient design and a superior combination of strength and ductility for gradient nanoglasses with a hard core (large grain size) compare with gradient nanoglasses with soft core (small grain sizes), in agreement with reports for gradient nanocrystalline systems.

2:45 PM CP01.14.03
Electrical and Mechanical Tuning of 3D Printed Photopolymer-CNT Nanocomposites Through In Situ Dispersion Jaime E. Regis1, 2, Luis Chavez1, 2, Luis C. Delfin1, 2, Carlos Garcia Rosales1 and Yirong Lin1, 2, 1Department of Mechanical Engineering, University of Texas at El Paso, El Paso, Texas, United States; 2W.M. Keck Center for 3D Innovation, The University of Texas at El Paso, El Paso, Texas, United States; 3Department of Electrical and Computer Engineering, The University of Texas at El Paso, El Paso, Texas, United States.
In recent years, polymer matrix nanocomposites have gained an increased amount of interest due to the scalability and manufacturability provided using polymers and the highly desirable properties from their fillers. The incorporation of ceramic, metallic, and/or organic fillers have given way to a variety of applications by enabling the improvement of thermal, electrical, mechanical, and dielectric properties. Such applications include, but are not limited to, energy storage materials, piezoelectric pressure sensors, and self-healing materials. Due to their high electrical conductivity and mechanical properties, carbon nanotubes (CNT) have attracted a great amount of attention for use as nanocomposite reinforcement; however, the fabrication of composites of this nature through additive manufacturing is a concept that has not been explored thoroughly. CNT have the tendency to agglomerate and become points of failure for composites rather than the reinforcements. For this reason, additive manufacturing of CNT-polymer nanocomposites typically uses low percentages of CNT. In this study, the synthesis and fabrication of multi-walled carbon nanotubes (MWCNT) composites was realized through stereolithography additive manufacturing with in situ, electric field-assisted dispersion. With the introduction of MWCNTs into the polymer, a 77% increase in elastic modulus was observed. Furthermore, in situ dispersion through electric field improved the average elongation at break of the samples with MWCNTs by 32%. An increase in ultimate tensile strength of the MWCNT from in situ dispersed composites of 42%, more than 20% over the pure polymer material, was also observed when applying an electric field. Engineering of the magnitude and direction of electrical conductivity in MWCNTs was accomplished through the application of in situ electric fields during the 3D printing process. The electrical conductivity of the material saw an increase of 50% with the introduction of MWCNTs which improved further by 26% with electric field induced dispersion. The feasibility using in situ electrical field in 3D printing to tune electrical and mechanical properties of MWCNT reinforced, polymer nanocomposites was demonstrated.

SESSION CP01.15: Advances in Novel and Extreme Materials Design—Polymer/Fibre-Based Nanocomposites
Session Chairs: Paulo Brancicio and Arief Budiman
Friday Afternoon, April 26, 2019
PCC North, 100 Level, Room 121 A

3:30 PM CP01.15.01
3D Architectural Design Enabled by Electrospinning to Fabricate Strong and Tough Fibers Komal Agarwal1, Rahul Sahay2, Aviniah Bajir3 and Arief S. Budiman1, 2 Singapore University of Technology and Design (SUTD), Singapore, Singapore; 3Department of Engineering, School of Engineering and Mathematical Sciences, La Trobe University, Melbourne, Victoria, Australia.
Advances in material science and engineering has bolstered technological advancements of the twenty first century. Nature constantly provides solutions to overcome materials and structures related obstacles. Cuticle of Mantis shrimp dactyl club, scarabaeus, lobster, and epicarp of diplazium crenatoserratum and pollia condensata fruit, have inspired scientists to mimic their microstructure for enhanced optical and mechanical properties. The structural arrangement of the fiber layers plays crucial role in enhancement of toughness of the composite. In past, attempts have been made to design helicoidal structures at macroscopic levels. We have successfully fabricated helicoidally oriented fibers in microns range (20-25 microns) using near field electrosprinning. For our first study, melt near field stage-controlled electrosprinning was used to assemble dense Polyacryloplactone (PCL) fibers (150-200um) stacked helicoidally at 15° angle offsets. The toughness of the surface-treated helicoidal PCL was found to be two times higher than the surface-treated unidirectional sample and five times higher than the helicoidal sample without surface treatment. Alternatively, in our second study, near field solution electrosprinning was used to fabricate much smaller (av. ~22μm) Polyvinylidene fluoride (PVDF) fibers fused together and oriented at angle offsets of 15°. Numerous interface changes between different planes and directions, arrests crack propagation in helicoidal layers, allowing material to absorb more energy before fracture. These fibers show superior tensile characteristics, impact resistance and toughness as compared to its bulk counterparts. Near field electrosprinning provides a promising future pathway to fashion helicoidal architectures in nano range increasing the toughness and impact resistance of the materials furthermore.

3:45 PM CP01.15.02
Multi-Phase Graphene-Polymer Nanocomposite Fibers—Design, Fabrication and Characterizations Weiheng Xu, Sayli Jambhulkar and Kenan Song; Arizona State University, Mesa, Arizona, United States.
Polymer fibers usually possess high tensile strength, anti-corrosion, and heat resistance properties. Combining them with “nanofillers”, such as graphene, would further introduce and enhance properties including mechanical reinforcement, energy dampening, electrical conductivity and thermal dissipation. Most of the previous works in this area involved homogeneously mixing graphene or graphene oxide (GO) dispersions in polymers, following by chemical or thermal reduction. However, the finalized graphene nanoparticles are not, strictly speaking, single-layered due to their tendency to aggregate during the mixing process and forming defects and unoxidized functional groups during post reduction. Besides, graphene particles are not always continuously bridged and their orientations are not anisotropic, leading to the limited mechanical strength, thermal and electrical conductivity in composite fibers. We are currently working on a cost-efficient method suitable for mass production of single-layered graphene-included polymer composite (GPC) fibers through an in-situ graphite exfoliation method. During the fabrication process, spinnertet was designed and fabricated to include polymers and original graphite in different channels. The relative molecular movements on two sides of the graphene channel can initiate and promote graphene exfoliation and orientation in a higher degree than those composite fibers with only polymers appearing on one side of the graphite. Upon stretching the spun fibers, polymer channels separated by the graphene channel will generate shear stresses, the degree of which will depend on polymer-graphene interfacial bonding and relative displacements of molecular chains on both sides of graphene layers, along with the graphene channel direction. Mechanical tests showed an increase of both modulus and strength (>200%) as comparing multi-phase composite fibers with pure polymer fibers. Scanning electron microscopy
3D Printable High-Performance Cyanate Ester Resins for Additive Manufacturing and hematite nanomaterials and in understanding processes controlling iron mineral transformations in the environment. The findings provide detailed new insights into processes controlling phase transformation outcomes among iron (oxyhydr)oxides, and should help in the design new maghemite larger particles during heating, allowing us to discover and observe the size effect among individual nanowires. Both transformed into hematite. For the sized β-FeOOH nanowires. In this case diameters larger than 20 nm, the final product depends on the heating temperature, time, and pressure. Maghemite was the final product at transformation temperatures less than 300 °C, whereas hematite was the final product above 300 °C. The transformation of maghemite to hematite appeared to be by direct topotactic atomic rearrangement in the solid state. Imaging was complemented by in situ XRD, in situ XPS and TGA-mass spectrometry measurements. In situ XRD showed amorphization of the β-FeOOH nanowires quickly upon approaching 200 °C and then maghemite was observed, consistent with the in situ TEM observation. However, the recalcitrance of maghemite conversion to hematite when starting from smaller β-FeOOH nanowires did not manifest in the XRD measurements upon increasing the heating temperature to 500 °C, which occurred readily for all different sized β-FeOOH nanowires. In this case ex situ TEM indicated the smaller β-FeOOH nanowires merged into larger particles, which allowed the maghemite to be readily transformed into hematite. For the in situ TEM experiments, because the β-FeOOH nanowires were mounted on a copper grid, this appeared to inhibit nanowire coalescence into larger particles during heating, allowing us to discover and observe the size effect among individual nanowires. Both in situ XPS and TGA-MS measurements showed the loss of water and HCl upon heating. The findings provide detailed new insights into processes controlling phase transformation outcomes among iron (oxyhydr)oxides, and should help in the design new maghemite and hematite nanomaterials and in understanding processes controlling iron mineral transformations in the environment.

4:30 PM CP01.15.05
3D Printable High-Performance Cyanate Ester Resins for Additive Manufacturing Seyed Mahmoud Hosseini and Walter E. Vott; Chemistry, The University of Texas at Dallas, Richardson, Texas, United States.

Cyanate ester resins (CER) are a class of high-performance thermosetting resins with low dielectric constants, high glass transition temperatures (~250°C), and very low water absorption. Cyanate ester polymer’s strength, rigidity, chemical resistance, and ability to withstand extremely high temperatures make them ideal for use in applications in which long-term stability is essential. For instance, cyanate ester polymers are used in the development of electronic devices, under-the-hood automobile parts, and in aerospace applications and vehicles. However, the bottleneck of pure CE resins is their brittleness due to limited strain tolerance. One of the ways to overcome this problem is copolymerizing cyanate esters with epoxy resins, which improve the flexibility and decrease the curing temperature. One current method to prepare 3D structures of cyanate ester-epoxies is a molding process that involves casting monomers into a mold and then heating up the mold gradually. This study shows the synthesis and development of resins for the 3D printing of cyanate ester with different thiol-based monomers. We could overcome obstacles that had been preventing the field from efficiently using three-dimensional printing to create cyanate ester polymers. We could improve the brittleness of cyanate ester polymers with tunable glass transition temperature. Additional additives (initiators, inhibitors, and dyes) and monomers containing photo-cross-linkable groups provide control of chemical crosslinking for spatial control during network gelation.
Growth of single crystals via assembly of colloidal nanocrystals is widespread phenomenon in both synthetic and natural environments. In mineral systems, this process exhibits a range of styles including face-specific oriented attachment of like phases, attachment of a nanoscopic phase to a bulk phase followed by transformation, and mis-oriented aggregation followed by coarsening to a single crystal. While descriptions of assembly in these systems must share a commonality with continuum-based DLVO-type theories for simple colloids, mineral systems present additional complexities, including face-specificity of dielectric properties, the presence of structured nanoscale interfaces, and the consequent solvent-responses that are expected to be of a comparable length scale. To understand the relationship between nanocrystal structure, interparticle forces and consequent motion leading to assembly, we are investigating colloidal assembly in the titanium, iron and zinc oxide systems. We use in situ TEM to observe assembly dynamics, force spectroscopy with custom-made single crystal tips to measure face-specific interparticle forces, AFM to probe interfacial structure, and molecular simulations to understand the origins of these features. For both ZnO and the iron oxhydroxide ferrhydrate, TEM demonstrates that direction-specific forces align randomly diffusing particles prior to contact and that attachment occurs on lattice matched faces via a sudden jump to contact followed by coarsening to produce compact single crystal structures. Direct measurements of the forces between both TiO$_2$ and ZnO surfaces reveal orientation dependent attractive interactions that exhibit the symmetry of the underlying lattice. A combination of molecular dynamics and classical DFT simulations indicate a combination of hydration, ion correlation and dispersion forces are responsible for orienting the particles and that the barriers caused by hydration layers, which scale with surface hydrophobicity, cannot be overcome by simple Brownian motion in the absence of fluctuations in those layers. Addition of organic ligands, like oxalate, to the ferrhydrate system produces a dramatically different pathway and outcome: Nanoparticles of hematite nucleate sporadically from the ferrhydrate and, once formed are covered with oxalate and drive all new hematite particles to nucleate within about 1 nm of the surface, after which they jump to contact. The oxalate inhibits growth and coarsening of the particles, leading to spindle-shaped aggregates of coaligned particles with a fixed and constant aspect ratio. Thus the random assembly process seen in the pure ferrhydrate system is replaced with one that is deterministic. Classical DFT calculations show that gradients in Fe$^{2+}$ chemical potential created by the ligands drive this interfacially driven bias towards growth by oriented attachment.

SESSION CP02.01: Crystal Nucleation and Growth, Nanoparticle Superlattice

10:30 AM • CP02.01.01
Understanding the Relationship Between Interfacial Structure, Interparticle Forces and Assembly Dynamics During Oriented Attachment of Colloidal Crystals

James L. De Yoreo$^1$, Lili Liu$^1$, Guomin Zhu$^1$, Xin Zhang$^2$, Dongsheng Li$^1$, Sebastian Kerstel$^1$, Maria Sushko$^1$, Jaehun Chun$^1$, Elias Nakouzi$^1$, Chongmin N. Wang$^1$, Greg Schenter$^1$, Kevin Rosso$^1$ and Christopher Mundy$^1$: 1Pacific Northwest National Laboratory, Richland, Washington, United States; 2Materials Science and Engineering, University of Washington, Seattle, Washington, United States; 3Chemical Engineering, University of Washington, Seattle, Washington, United States.

The directed assembly of nanoscale building blocks into complex superstructures is of widespread scientific and technological interest. Scientists and engineers have been intrigued by the prospects of tailoring self-assembled processes to create materials whose properties and function can be tuned through the interaction between constituent particles. In particular, recent reports of epitaxially connected colloidal quantum dot superlattices with long-range atomic coherence have generated significant interest as a platform for novel, quasi 2D ‘designer materials’. Experimental protocols for the formation of high quality superlattices in which constituent quantum dots are registered to within a single atomic bond length have been established; however, significant gaps persist in our fundamental understanding of several aspects of the underlying mechanism by which these structures form.

Our approach to gain mechanistic insights into the assembly and subsequent attachment leverages unique in-situ multiprobe characterization techniques including TEM and X-ray scattering. The combination of in-situ wide- and small-angle X-ray scattering informs the temporal evolution of nanoparticle orientation and assembly at the fluid interface. We will present recent advances with in-situ analysis TEM analysis of quantum dot solids deposited on a heating chip to gain atomic-level insights into the formation of the interdot bond. In-situ TEM experiments at varying temperatures and ramp rates hold significant potential to provide new mechanistic insights into the temporal evolution of interdot bridge width and structure.

11:45 AM • CP02.01.04
In Situ Cooling TEM Study on Structure Phase Transition in LaNiO$_{3-\delta}$

Xue Rui$^1$, Bixia Wang$^2$, Daniel Phelan$^1$, John Mitchell$^1$ and Robert Klue$^1$; 1Materials Science and Engineering, University of Illinois at Chicago, Chicago, Illinois, United States; 2Argonne National Laboratory, Lemont, Illinois, United States.

In the past decades, rare-earth nickelate perovskite RNiO$_3$ (R=rare earth) have been demonstrated to exhibit rich phase diagram concomitant with complicate magnetic property. It has been found that these nickelates can undergo a structure transition from Orthorhombic to Monoclinic (Pnma to P2$_1$/c) accompanied with metal-insulator transition (MIT) upon cooling process. Currently, atomic-resolution scanning transmission electron microscopy (STEM) equipped with a cooling holder can enable imaging with picometer resolution at cryogenic temperature, providing an intuitive method to analyze the change of atomic structure at low temperature. In this work, we will use aberration-corrected STEM combined with in-situ cooling to analyze the phase transition found in LaNiO$_{3-\delta}$. During in-situ cooling experiment, we have found the reversible disappearance/appearance of superlattice peak from diffraction pattern of LaNiO$_{3-\delta}$ as a function of temperature. Electron energy-loss spectroscopy (EELS) will be used to examine the change in local electronic structure as a function of temperature.
1:30 PM *CP02.02.01

**Self-Assembly of Electrostatically and Sterically Stabilized Colloidal Nanocrystals—The Roles of Topology, Image Charges and Non-Classical Nucleation**

Erik Janke, Igor Coropceanu, Michael Boles and Dmitri Talapin; Department of Chemistry, University of Chicago, Chicago, Illinois, United States.

Colloidal nanocrystals offer a route toward engineering new classes of materials by acting as discrete units that can be assembled to construct composite solids. The self-assembly of two sizes of spherical nanocrystals has revealed a surprisingly diverse library of structures. To date, at least fifteen distinct binary nanocrystal superlattice (BNSSL) structures have been documented. The stability of the observed binary phases cannot be fully explained using the traditional conceptual framework treating the assembly process as entropy-driven crystallization of rigid spherical particles. We evaluate new theoretical models treating the co-crystallization of deformable spheres and to formulate new hypotheses about the factors affecting the nucleation and growth of the binary superlattices. The deviation from hard sphere behavior can be explained by specific topological textures developed within deformable layers of surface ligands. Our results also suggest that the relative abundance of BNSSL phases is determined not only by their thermodynamic phase stability but also by a postulated pre-ordering of the binary fluid into local structures with icosahedral or polytetrahedral structures prior to nucleation. 

Strong electronic coupling between individual nanocrystals within a superlattice is an important prerequisite for the emergence of non-additive physical properties. However, a simultaneous realization of strong electronic coupling and dense ordered packing of nanocrystal solids has remained elusive. We report a method for growing all-inorganic highly ordered solids of electrostatically-stabilized nanocrystals with the interstitial space filled with a glassy metal chalcogenide matrix which, combined with the short separation between particles leads to very strong electronic coupling. Temperature-dependent conductivity measurements show metallic transport across our supercrystals. The formation of strongly-coupled all-inorganic nanocrystal assemblies represents an important step toward the bottom-up design of functional nanostructured composites.

**Multicomponent Nanocrystal Self-Assembly for the Creation of Multifunctional Materials and Devices**

Christopher Murray1, 2; Jennifer D. Lee1; Natalie Gogotsi2; Katherine C. Elbert1; Austin A. Keller1; Daniel J. Rosen1; Chenjie Zeng1; Prashant Ramesh2 and Jungmi Park1; Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 1Materials Science and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Monodisperse shape-controlled nanocrystals (NCs) are ideal building blocks for the assembly of new thin films and devices. These NCs can be thought of as "artificial atoms" with tunable electronic, optical, magnetic properties that are allowing the development of a new periodic table for design at the mesoscale. In this talk, I will briefly outline the current state of the art in synthesis, and integration of multiple NC phases and core-shell (heterostructures) NCs emphasizing the design of semiconductor building blocks with tunable shapes (spheres, rods, cubes, discs, octahedra, etc... I will then share how these tailored NCs can be directed to assemble into single-component, binary, ternary NC superlattices providing a scalable route to the production of multi-functional thin films. The in situ studies of NC organization and transformation will be carried out using a combination of X-ray scattering and electron microscopy/tomography. The modular assembly of these NCs allows the desirable features of the underlying quantum phenomena to be retained and enhanced even as the interactions between the NCs allow new delocalized properties to emerge. Synergies in electronic, optical coupling between NCs will be emphasized as we push toward the realization of artificial solids with a new 3D and structure and high mobility device integration. I will share specific case studies in thin film transistors, thermo-electric materials and solution-processable photovoltaic devices build with these strongly coupled nanocrystal solids highlighting the recent developments in wafer scale NC superlattice design and patterning may provide a path to scalable fabrication. In a final example of hetero-integration, I will present our progress in the co-assembly of plasmonic resonators together with nanoscale emitters as a route to the scalable self-assembled MetaMaterials with novel linear and non-linear optical properties. Progress toward the design of micron-sized 3D superlattice composed NC building blocks will also be shared.

2:30 PM *CP02.02.03

**Prescribing Self-Assembly of Nanoscale Architectures Through Valence Control**

Oleg Gang1, 2; Columbia University, New York, New York, United States; 2Brookhaven National Laboratory, Upton, New York, United States.

The challenges of creating designed materials via self-assembly of nanoscale blocks require establishing robust yet highly tailorable methods for directing nanoscale interactions. While it has been recognized that anisotropic bonds allow for the coordination control and, consequently, for the regulation of formed structures, the development of practical realizations was notoriously difficult. We have developed an assembly platform that through a regulation of nano-object valence allows to design a coordination symmetry. That approach permits an assembly of prescribed nanoscale architectures and complex lattices. Moreover, a variety of nano-object types can be integrated into these self-assembled hetero-architectures. This new assembly methodology requires direct 3D nanoscale visualizations, both in-situ and ex-situ, in order to probe the imperfections, a structure formation and assembly pathways. Our advances in the development of suitable x-ray- and electron- based methods for 3D characterizations will be also discussed.

3:30 PM *CP02.02.04

**Polymer Nanoreactors—Vehicles to Control and Observe Nanoparticle Formation**

Chad A. Mirkin; Northwestern University, Evanston, Illinois, United States.

Polymer nanoreactors have novel chemical and physical properties, which make them promising for a wide range of fields spanning catalysis, plasmonics, and electronics. However, the combinations of elements that have thus far been studied in these systems are limited by a lack of methods for preparing and analyzing multiplexed nanoparticle systems. To explore the vast number of elemental and structural combinations possible, we developed scanning probe block copolymer lithography (SPBCL), a method for synthesizing polyelemental nanoparticle arrays from polymer nanoreactors that contain metal precursors in defined amounts and ratios. Through heat treatments or electron irradiation, small nanoparticles nucleate, grow, and coarsen inside each nanoreactor eventually resulting in a single nanoparticle. The structure and formation of these spatially encoded nanoparticles can be studied using electron microscopy, both in situ and ex situ, as a function of their composition and thermal treatment. Although metal species aggregate at different rates, the final structures of the nanoparticles attain thermodynamic equilibrium. Additionally, by utilizing the fluidic polymer nanoreactors as windowless liquid "cells," the motion and interaction of ~1 nm nanoparticles during electron beam-induced solvent evaporation can be tracked in real time using an electron microscope. Taken together, SPBCL serves as a novel method for synthesizing polyelemental nanoreactors in a combinatorial manner, and the polymer nanoreactors provide a versatile platform for studying the structural evolution and final structure of complex, polyelemental systems.

4:00 PM *CP02.02.05

**Peering into the Self- and Directed-Assembly of Nanoparticles**

Hongyou Fan; University of New Mexico/Sandia National Laboratories, Albuquerque, New Mexico, United States.

Self-assembly of synthetic nanocrystals enables the positioning of nanoparticles into one to three dimensional ordered arrays, facilitating integration of nanoparticle lattices into nanophotonic and nanoelectronic architectures. The functional properties of these particle materials are expected to be highly sensitive to structural factors such as coordination number, degree of long-range order, or nanoparticle separation distance, requiring the development of robust self- and directed-assembly pathways for precise control of structural parameters to improve optical and electronic properties of functional nanoparticles. In this presentation, I will review our past efforts in development of self-assembled nanoparticles thin film arrays and in situ structural evolution at ambient conditions extend my presentation to our recent progress in development of a new Stress-Induced Fabrication method in which we applied high pressure or stress to nanoparticle arrays to induce structural phase transition and to consolidate new nanomaterials with precisely controlled structures and tunable properties. By manipulating nanoparticle coupling through external pressure, a reversible change in their assemblies and properties can be achieved and demonstrated. In addition, over a certain threshold, the external pressure will force these nanoparticles into contact, thereby allowing the formation and consolidation of one- to three-dimensional nanostructures. Through stress induced nanoparticle assembly, materials engineering and synthesis become remarkably flexible without relying on traditional crystallization process where atoms/ions are locked in a specific crystal structure. Therefore, morphology or architecture can be readily tuned to produce
System-Level Control of Structural Hierarchy in Nanoparticle Superlattices

Supramolecular chemistry is an ideal means to dynamically program structural hierarchy in both polymer and composite materials, as it uses reversible interactions between atomically precise building blocks to create well-defined nano- to macroscopic structures. Simple synthetic adjustments in molecular composition can alter how polymers bind to one another in three-dimensional space, and this in turn can modulate the nanoscale morphology of the assembled material. Conversely, once assembled, these larger-scale structures can act as scaffolds that allow multiple supramolecular binders to behave as a collective unit. Because the shape of these larger length scale motifs can affect the ability of individual supramolecular motifs or polymer chains to coordinate their binding, material form at the nanoscale could potentially be used as a design handle to tune the supramolecular groups’ collective behavior. Understanding how to holistically control structural hierarchy in this manner therefore necessitates the development of a synthetic building block whose nanoscale morphology can be tuned without significantly altering the chemical structure of the individual supramolecular binding groups themselves.

We have recently demonstrated a new polymer brush-particle building block capable of directed assembly via complementary hydrogen bonding motifs, called the Nanocomposite Tecton (NCT). NCTs consist of an inorganic nanoparticle core coated with a dense polymer brush, where each polymer chain terminates in a supramolecular bonding group; interparticle interactions drive particle assembly by creating dynamic nanoscale bonds consisting of multiple supramolecular linkages. NCT assembly is distinct from other materials synthesis methods reliant on paired hydrogen bonding motifs, as each NCT-NCT connection consists of multiple supramolecular interactions that behave collectively not because individual groups are closely linked via covalent bonds, but rather because they are geometrically confined to a localized volume at the NCT surface. An NCT’s nanoscale geometry (as dictated by the particle core size, polymer length, and polymer morphology) therefore has a strong influence on its assembly behavior, and can be used to tune NCT-NCT bond strength without changing molecule-molecule bond strength. Here we show how nanoscale structure can be used to manipulate material morphology in a holistic manner, where structural features at the molecular, nano, and mesoscopic length scales influence one another in a programmable manner, and each can be used to dictate material behavior.

SESSION CP02.03: Poster Session: Liquid-Phase TEM and Assembly
Session Chairs: Qian Chen, Liang Hong, Jianbo Wu and Xingchen Ye
Tuesday Afternoon, April 23, 2019
5:00 PM - 7:00 PM
PCC North, 300 Level, Exhibit Hall C-E

CP02.03.01
Synthesis of Cs-Pb-Br Colloidal Crystals
Liang Zhou, Ling-Dong Sun and Chun-Hua Yan; College of Chemistry and Molecular Engineering, Peking University, Beijing, China.

Owing to their unique collective properties, colloidal crystals are attracting more and more attention. They offer us a novel method to fabricate functional materials. Nucleation and growth processes are two key factors for us to obtain colloidal crystals. Here, by changing the reaction temperature, we realized precise control of nucleation and growth rates of colloidal crystals. For the saturated solution of Cs-Pb-Br nanoparticles, a relevantly fast cooling led to nucleation of colloidal crystals, and then a very slow cooling was applied to grow colloidal crystals. Through this method, we acquired ordered cubic colloidal crystals, which was made up of 10 nm cubic Cs-Pb-Br nanoparticles. The size of those uniform colloidal crystals was about 2 μm. We found out that precursors concentration, solvents, which would influence the nucleation and growth processes, had a great influence on the final product. Through time sequence experiment, we briefly described the growth dynamics of colloidal crystal, and built the relationship between quality of colloidal crystals and nucleation/growth rates.

CP02.03.02
Observation of Carbon Nanotube Diameter via Metal Catalysts and Precursor Ratios on Carbon Foam Substrates
Nicholas Roskopf, Fabian E. Villalobos and Pedro A. Pena; Chemistry, University of California, Riverside, Riverside, California, United States.

Polyacrylilde derived carbon foams/sponges were synthesized via oxidation of simple sugars by metal nitrates leading to embedded metal particles within the carbon foam. Ni and Co in three different sugar (Xylose) to metal concentrations (20:1, 200:1, 2000:1) were varied to produce metal particles of different sizes. Carbon nanotubes (CNTs) were then grown on these carbon foams using metal catalysts, both which have favorable carbon solubility properties, as catalytic substrates. Using two different metals, and three different precursor concentrations, undergoing the same synthesis process allows for six comparable CNT diameters. Deviations in particle size and therefore CNT diameter may be a result of differences in carbon solubility, precursor concentration, among other controlled variables such as processing temperature and time. SEM micrographs allow for accurate measurement of CNT diameters and sufficient sample size for statistical analysis to reliably identify significant trends in CNT sizes based off varying metal substrates and substrate concentrations. This data may provide insight into control of CNT diameters in addition to properties such as chirality towards applications pertaining to capacitors, gas sensors, hydrophobic or oleophilic coatings.

CP02.03.03
Solution Phase Behavior of Polymer-Grafted Nanoparticles—Improving Assembly and Processability
Sarah N. Izor1,4, Tony Dagher1, Chris Grabowski1, Ali Jawaid1,4, Kyoungwoen Park1, Larry F. Drummy4 and Richard A. Vaia1, 4; 1USC, Inc., Dayton, Ohio, United States; 2Duke University, Durham, North Carolina, United States; 3SABIC, Selkirk, New York, United States; 4Air Force Research Laboratory, Dayton, Ohio, United States.

Self-assembling polymer-grafted nanoparticles (PGNs) are advancing roll-to-roll manufacturing of photovoltaics, microsystems, optoelectronics, memory, and multifunctional coatings. Architectural features of the polymeric canopy (e.g. grafting density, chain length) not only determine processability and assembly, but also robustness, such as mechanical toughness and dielectric breakdown strength. To control PGN assembly, and therefore tailor properties, a detailed understanding of solution phase behavior is imperative. However, while phase properties of macromolecules have been extensively explored, comparable knowledge of PGN solution phase behavior is lacking and fails to elucidate the role of the PGN constituents. Here we map the phase space of polystyrene-grafted gold-nanoparticles in cyclohexane by establishing the upper critical solution coexistence curve via UV-vis spectroscopy, dynamic light scattering, and small angle X-ray scattering. Increasing the molecular weight of the polystyrene graft (20 → 50 kDa) advances the coexistence curve to higher temperatures (T_C ~ 12 → 20 °C @ 10 nM (φ ~3e-5)) and increases the estimated theta temperature (θ ~ 25 → 27 °C). Considering the well-established phase behaviors of structured macromolecules, the coexistence curves and theta temperatures of PGNs are less than those of polystyrene stars (θ ~ 30 °C) and linear chains (θ ~ 33 °C). Using a TEM solution cell the impact of the proximity to the coexistence curve (e.g. spinodal decomposition θ. nucleation and growth) on the assembly process is demonstrated. Such insight refines processing techniques for slot-die coating techniques, allowing for rapid self-assembly of large-area ordered PGN monolayers directly on solid substrates.

New Generation Liquid Cell for Controllable Electrochemistry Experiment in the Transmission Electron Microscope
We present the design and development of a MEMS (Micro ElectroMechanical System)-based liquid cell that enables in-situ liquid electrochemistry inside the TEM (Transmission Electron Microscope). The presented device, referred to as the Nano-Cell, enables the user to work in liquid conditions with a three-electrode configuration (i.e. reference, working and counter electrodes) in order to trigger and measure chemical reactions as a function of an electrical stimulus. The design of the Nano-Cell has been done in such a way that a thin liquid layer (to minimize electron scattering and maximize resolution) is guaranteed. Furthermore, the patented on-chip inlet and outlet combined with the design of the fluidic channel offer unrivalled control of the liquid flow. As a result, the complete system gives new insights on materials characterization at the nanoscale with applications in corrosion, Lithium batteries, electroplating and materials science.
Here, we present results showing good agreement between experimental cyclic voltammetry of Ferrocenemethanol, a one-electron redox molecule in an aqueous solution and finite element modeling, allowing to characterize mass transport to the electrode and to extract reaction rates and other material properties. We demonstrate the superior fluid flow control through the MEMS based microfluidic channel. Using a pressure-based pump, both the pressure and the flow can be accurately controlled in the sample area. The resulting liquid layer thickness, in hundreds of nanometers, allows to maximize spatial resolution in TEM: while diffusion is impeded by this thin liquid layer, it mimics diffusion-limited mass transport observed in classical macroscopic electrochemistry. With additional controlled fluid flow, faster mass transport can be achieved in a similar way to other classical approaches using a rotating disc electrode or a flow cell, showing the relevance of this approach. Finally, we demonstrate experimentally controlled flow and increased mass transport to the electrode and its influence in tuning electrodeposition of copper crystals.

Watching Nanoparticle Growth with Tandem Self-Assembly of Nanocrystals in Solution—Insights from Real Time Analysis and Interpretation of Au Nanoparticle Self-Assembly and Its Driving Sources
Jinhui Tao; Department of Chemistry & Biochemistry, Northern Illinois University, DeKalb, Illinois, United States; 1,X-Ray Science Division, Argonne National Laboratory, Lemont, Illinois, United States.
Nanoparticles have been used in a variety of applications such as catalysts, pharmaceuticals and sensors. Controlling their growth and assembling them into a hierarchical structure is critical for the application. Current understanding of the nanoparticle growth and its assembly is mainly derived from their post-synthesis characterization. An atomic level understanding of the mechanism of nanoparticle formation and assembly during the synthesis process will be interesting and important. Tandem in-situ small angle X-ray scattering (SAXS) X-ray Absorption Spectroscopy (XAS) will be a unique way to achieve this goal. In this presentation, I will discuss the growth of nanoparticles using SAXS-XAS.

8:30 AM CP02.04.03

Real Time Analysis and Interpretation of An Nanoparticle Self-Assembly and Its Driving Sources
Jaewon Lee, Elias Nakouzzi, Miao Song, Bin Wang, Jaehun Chun and Dongheng Li; Pacific Northwest National Laboratory, Richland, Washington, United States.
The self-assembly of nanoparticles (NPs) into superlattice structures attracts great attention due to their unique optical, thermoelectric, magnetic, energy storage and catalytic properties. Understanding of and mechanisms of particle assembly and interaction between active species can help to establish conditions to control the assembly process and superlattice structure, which are closely tied to the physical and chemical properties. However, little is known about the driving forces and controlling factors during the process of particle self-assembly. In this work, we analyzed dynamic information of the process and investigated the Van der Waals force, Brownian force, and the hydrodynamic force, based on measured particle positions and velocities by directly observing the process of 2-dimensional self-assembly of nanoparticles and tracking individual particles as a function of time via in situ TEM. In addition, we studied the steric hindrance factor between particles due to the polymer attached on particle surface. We estimated the most stable conditions based on our calculations and measurements of all process self-assembly during the nanoparticle process. Experimentally, we analyzed and simulated the process of all self-assembly using in situ analysis of particle assembly.

9:00 AM CP02.04.04

Probing Crystallographic Evolution of Gibbsite Nanocrystals Using In Situ High-Field 27Al NMR Spectroscopy
Xin Zhang1, Ying Chen1, Jianzhi Hu1, Nancy Washton1, Carolyn I. Pearce1, Katharine Page1, Zhenming Wang1, James J. De Yoreo1, Sue Clark1,2 and Kevin Rosso1; Pacific Northwest National Laboratory, Richland, Washington, United States; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Washington State University, Pullman, Washington, United States.
Gibbsite (α-Al(OH)3) is important hydrosilicate of aluminum in nature that also play diverse roles across a plethora of industrial applications. In addition, it’s prominent component in high-level nuclear waste stored in large quantities at the Hanford Site, Washington and at the Savannah River Site, South Carolina. Future processing of these waste materials depends on an understanding of the behavior gibbsite crystalization, dissolution, and transformation. As a consequence, precise synthesis of the gibbsite nanocrystals with controlled particle size, shape and properties is important. Mechanisms of crystalization of gibbsite nanocrystals still remain poorly understood, particularly in complex industrial systems, which can include concentrated sodium hydroxide at low water activity. In this work, in situ magic angle spinning nuclear magnetic resonance (MAS-NMR) combine with high resolution atomic force microscopy (AFM), scanning electron microscopy (SEM), transmission electron microscopy (TEM), Raman, and X-ray Pair Distribution Function (PDF) techniques were conducted to investigate the crystalization of gibbsite nanocrystals from amorphous aluminum hydroxide gel precursors and also aluminum (II) based cluster solutions. By focusing on the dynamics of aluminum coordination change from tetrahedral in solution or clusters to octahedral in solids, and the intermediate pentacoordinate state, some unifying principles governing these transformation emerge, which are important for controlling morphology of gibbsite, and management of nuclear waste.

9:15 AM CP02.04.05

Self-Assembly of Nanocrystals in Solution—Insights from In Situ Electron Microscopy
Eli Sutter; University of Nebraska–Lincoln, Lincoln, Nebraska, United States.
Solution-phase self-assembly of nanocrystals into mesoscale structures is a promising strategy for creating functional materials from nanoscale building blocks. Liquid environments are key to self-assembly since they allow suspended nanocrystals to diffuse and interact freely, but they also complicate experiments. Existing approaches for studying self-assembly have until recently been limited to assessing the final product ex-situ, or tracking long-range order in-situ in solution by reciprocal space methods. In-situ liquid electron microscopy is the only technique that provides access to real-space dynamics, especially at small scale, and is capable of probing self-assembly processes in real space in the native liquid environment. Here I will illustrate the power of in-situ liquid-cell electron microscopy to probe self-assembly of nanocrystals in solution from monomers to extended assemblies with nanometer scale resolution, and extracting fundamental information on assembly pathways and forces. Examples include self-assembly of polyhedral nanoparticles and highly anisotropic nanocrystals controlled by non-specific interactions, and programmable crystallization of DNA-nanoparticle conjugates and their real-time reconfiguration in response to external stimuli. Our results demonstrate that real-time electron microscopy can advance our understanding of solution phase self-assembly processes as a basis for designing materials with tailored functionality.

Interfacially-Driven Nanoparticle Nucleation Biases Hematite Crystallization Towards Oriented Attachment
Guomin Zhu1,2, Maria Sushko2, John Loring2, Jennifer Solits2, Jinhui Tao2, Benjamin Legg3, Chongmin N. Wang3 and James J. De Yoreo3,4; 1University of Washington, Seattle, Washington, United States; 2Pacific Northwest National Laboratory, Richland, Washington, United States.
Spatial and Shape Control of Soft Patches on Anisotropic Nanoparticles

A diverse class of materials exhibit characteristics of mesocrystals: single crystals composed of distinct nano-sized domains that are atomically aligned. The formation of such structures is often attributed to crystallization through oriented attachment (OA). However, many unanswered questions about the fundamental drivers and dynamic progression of this phenomenon remain. Here we focus on the crystallization of hematite (hem, Fe$_2$O$_3$) mesocrystals from ferrihydrite (fh) nanoparticles. In pure solution the resulting hem crystals can grow densely packed spherical caps, faceted plates, and core-shell structures. We investigate the effects of nucleation and assembly kinetics and addition of small molecule and polymer capping to direct the synthesis of monodisperse plasmonic NPs intimately and permanently capped with stimuli-responsive polymers. The size and shape of hairy NPs can be precisely tailored by modulating the length of inner hydrophilic block of star-like diblock copolymers. The perpetual anchoring of stimuli-responsive polymers on the NP surface captures the attractive feature of self-assembly and disassembly of NPs on demand using stimuli of different wavelengths or temperature, as revealed by tunable surface-plasmon resonance absorption of NPs and the reversible transformation of NPs between their dispersed and aggregated states. By extension, the star-like block copolymer strategy enables the crafting of a family of stable stimuli-responsive NPs (e.g., pH-sensitive polymer-capped magnetic, ferroelectric, upconversion, or semiconducting NPs) and their assemblies for fundamental research in self-assembly and crystallization kinetics of NPs as well as potential applications in optics, optoelectronics, magnetic technologies, sensory materials and devices, catalysis, nanotechnology, and biotechnology.

In the co-existing crystal and dispersed nanoparticles fluctuates due to thermal agitation, which defines the final shape of the superlattice. The tracked interface profile at the single particle resolution allows us to decompose an otherwise complicated interface into a series of Fourier components based on the capillary wave theory. Characteristics such as the interfacial stiffness at different lattice orientations and the lateral fluctuation correlation lengths are measured for the first time from real-time electron imaging. Our experiments can provide insights into the engineering the crystallization pathways and growing defect-free superlattices from solution.

To decipher the growth mechanism and quantify the kinetic parameters controlling rates, seed-free and seed system were examined in soft aqueous solution at room temperature, and the spindles grow by creation of new particles in the solution near the hm interface. Based on ATR FTIR measurements of the relative binding strength of oxalate to the (001) and (012) faces and calculations of chemical potential gradients near the interface, we propose that oxalate plays the role of inhibiting classical monomer-by-monomer growth of the hematite particles while promoting the nucleation of new hm particles at the hm/solution interface by creating a gradient in Fe$^{3+}$ chemical potential. In this way, the oxalate ligands bias the growth process away from classical mechanisms and towards oriented attachment.
Despite splendidous synthetic achievements in anisotropic nanoparticles, spatial control of their surface chemistry remains primitive. Here we demonstrate a single-pot site-specific polymer coating on anisotropic nanoparticles due to the local nanoparticle surface curvature difference. No post-coating manipulation is needed to induce the spatial patterning. Surface characterization and three-dimensional morphology of these patchy nanoparticles under scanning transmission electron microscopy and atomic force microscopy reveal the full geometry of regiospecific functionality. Mechanistic insights gained in this study via quantitative analysis on thickness, local surface curvature, and confined area on surface of patchy nanoparticles may be applicable to design hybrid anisotropic nanoparticles with directional and “soft-interaction” between themselves, which can be further expanded to bottom-up reconfigurable assembly.

SESSION CP02.05: Self-Assembly, Shape Anisotropy and Multifunction II

Wednesday Afternoon, April 24, 2019
PCC West, 100 Level, Room 101 B

1:30 PM *CP02.05.01
Revealing of Intermediate States During Nanocrystal Superlattice Transformations Using In Situ Liquid Phase TEM Haimei Zhong1,2; Lawrence Berkeley National Laboratory, Berkeley, California, United States; Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States.

Nanocrystal superlattices experience structural transformations due to ligand exchange, where each individual nanocrystal acts as an artificial atom. Drastic changes of the electronic properties have been observed resulting from the superlattice transformations. For example, the electron transfer characteristics for PdSe nanocrystal superlattices are drastically different before and after PostTreatments. We report our study of PdSe superlattice structural transformations due to ligand exchange with in situ liquid cell TEM. Direct observations reveal the rare behavior of individual nanocrystals and intermediates during superlattice structural transformations. Assisted with theoretical calculations/computations, we are able to develop an understanding of the particle-particle interactions modified by ligand displacement from nanoparticle surfaces. This work also demonstrates that in situ liquid cell TEM is an indispensable approach for revealing of the pathways of superlattice transformations at the single nanoparticle level.

Acknowledgements: This work was funded by Department of Energy, Office of Science, Office of Basic Energy Sciences, Materials Sciences and Engineering Division under Contract No. DE-AC02-05CH11231 within the KC22ZHI program. The collaboration and program support through the UC Lab Fees project are also acknowledged. Dr. Yu Wang and Xinping Peng performed the in situ TEM experiments.

2:00 PM *CP02.05.02
Self-Assembly of Nanoparticle Superlattices and Their Post-Assembly Transformations Rafal Klajn, Weizmann Institute of Science, Rehovot, Israel.

Self-assembly of nanoparticles has been used to fabricate structurally diverse colloidal crystals, including binary, ternary, and quasicyristalline superlattices, many of which were found to exhibit unanticipated optical, electronic, and catalytic properties. In this talk, I will describe how these nanoparticle superlattices can be further (post-assembly) subjected to chemical reactions and transformed into novel classes of materials. I will focus on non-close-packed nanoparticle arrays, which we created through the selective removal of one of two components comprising binary nanoparticle superlattices. I will also discuss the importance of the liquid on the structure of binary superlattices assembled at the liquid-air interface and the choice of the liquid can lead to the fabrication of superlattices featuring previously unknown types of packing of the constituent nanoparticles.

2:30 PM BREAK

3:30 PM *CP02.05.03
Visualizing Self-Assembly—From Atoms to Nanostructures Utkar Mirsaidov, National University of Singapore, Singapore, Singapore.

The assembly process of nanoparticles from individual atoms, and nanostructures from nanoparticles in solution is fundamental for materials engineering and “bottom-up” fabrication of functional nanodevices. Using dynamic in situ TEM imaging [1-3] in liquids, I will describe how inorganic and organic nanoparticles form in solution and how these nanoparticles interact with each other. First, I will discuss how phase separation of a solution containing Au ions into solute-rich and solute-poor phases leads to the formation of Au nanocrystal through a pathway that does not follow classical nucleation theory (CNT). Namely, I will show that there are multiple steps that lead to the formation of nuclei from which nanocrystal grow [4]. These steps are: 1) phase separation of the liquid solution into solute-poor and solute-rich phases, from which 2) amorphous nanoparticles which serve as a precursor for nuclei emerges. This is followed by 3) crystallization of amorphous nanoparticles into crystalline nuclei. I will show that similar is true for more complex structures such as MOFs Next, I will highlight the role of intermolecular forces between nanoparticles in solution and describe their role in the assembly of nanostructures from individual nanoparticle building blocks (bottom-up approach) [5]. Specifically, I will show how the balance between repulsive hydration force and attractive van der Waals (vdW) force results in a metastable nanoparticle-pair which promotes their subsequent attachment to each other [6]. I will also briefly discuss the effect of other interactions such as electrostatic, H-bonding [7,8], and capillary forces [9] and hydrophobic interactions [10] in the context of their effect on the nanoparticle self-assembly dynamics. These findings highlight the role of solvent-mediated physical and chemical forces in material synthesis and self-assembly of nanoparticle superlattices. Our observations also emphasize the importance of direct nanoscale observation in uncovering previously unknown intermediate states that are pivotal for synthesis and self-assembly.

4:00 PM *CP02.05.04
Transmission Electron Microscopy Investigation on Pt-Based Nanocrystals for Electrocatalysis Dong Su, Brookhaven National Laboratory, Upton, New York, United States.

For metallic electrocatalysts for energy applications, understanding of structure-performance relationship can only be built on the precise characterization on the phase, interfacial and surface structures. Advanced (scanning) transmission electron microscopy (STEM) techniques have been widely applied to investigate the structure of catalysts at atomic scale. With the help of multimodal characterization techniques, it is possible to establish a direct link from the composition and surface structure to the performance of electrocatalysis. In this talk, I will discuss the recent progresses in the Pt-based catalysts for proton exchange membrane fuel cells. The first case is on how the strain and ligand effects affect the surface electronic structure and then the overall performance. In case of PtPb/Pt(110) faceted core-shell nanoplates, the biaxial strain from PtPb to Pt may help to drastically different before and after PbCl treatments. We report our study of PbSe superlattice structural transformations due to ligand exchange with in situ liquid cell TEM. Direct observations reveal the rare behavior of individual nanocrystals and intermediates during superlattice structural transformations. Assisted with theoretical calculations/computations, we are able to develop an understanding of the particle-particle interactions modified by ligand displacement from nanoparticle surfaces. This work also demonstrates that in situ liquid cell TEM is an indispensable approach for revealing of the pathways of superlattice transformations at the single nanoparticle level.

Acknowledgements: This work was funded by Department of Energy, Office of Science, Office of Basic Energy Sciences, Materials Sciences and Engineering Division under Contract No. DE-AC02-05-CH11231 within the KC22ZHI program. The collaboration and program support through the UC Lab Fees project are also acknowledged. Dr. Yu Wang and Xinping Peng performed the in situ TEM experiments.

4:30 PM CP02.05.05
Polyomorphous Self-Assembly of Nanoarrows Chang Liu1, Qian Wang2, Binbin Luo1, Limin Qi1 and Qian Chen1; 1University of Illinois at Urbana-Champaign, Urbana, Illinois,
The shape details of nanoparticle building blocks are critical to the dynamics and packing symmetry of their self-assembly process. Using liquid-phase transmission electron microscopy, we observed dynamic assembly and transformation of arrow-shaped gold nanoparticles in multiple geometric configurations. In-situ monitoring of the individual nanoparticles shows that they follow side-to-side, face-to-face or closed packing units directed by the convex or concave shape details with different relative orientations. The aspect ratio of these nanoparticles can be precisely tuned to achieve structural complexity and tunability, which can also be illustrated by the solvent evaporation-driven self-assembly. Our study provides guidance for future works of anisotropic particle self-assembly with complex structural details to have good controls in shape-oriented interaction and to enrich the library of self-assembly structures and properties.

Liquid-liquid phase separation (LLPS) of proteins into concentrated microdroplets (also called coacervation) is a phenomenon that is increasingly recognized to occur in many biological processes, both inside and outside the cell [1]. While it has been established that LLPS can be described as a spinodal decomposition leading to demixing of an initially homogeneous protein solution, little is known about the assembly pathways by which soluble proteins aggregate into dense microdroplets. Using a recently developed technique enabling the observation of matter suspended in liquid by transmission electron microscopy (TEM), we observed how a model intrinsically disordered protein (IDP) phase-separates in liquid environment. The model protein used in these experiments is Histidine-rich Peak Proteins 2 (HBP-2), a protein present in the beak of squids that can be reconstitutively obtained [2]. Our observations reveal for the first time dynamic mechanisms by which soluble proteins self-organize into condensed microdroplets, with nano-scale and milli-second space and time resolution, respectively. With this method, and the initial and natural growth steps of the LLPS could be captured, opening the door for a deeper understanding of other biomacromolecular complexes exhibiting LLPS ability.

8:00 AM CP02.06.01
Size Dependency of the Ferroelectric Properties in Single Nanocrystals of BaTiO₃: Locally Investigated by HRTEM and PFM
Hortense Le Ferrand, Martial Duchamp, Bartosz Gabryelczyk, Cai Hao and Ali Miserez; Nanyang Technological University, Singapore, Singapore.

Despite the study of BaTiO₃: for more than a half of a century, the physical and functional properties of this material at the nanoscale are still poorly known. This is due to the presence of multiple concomitant factors that are difficult to disentangle from macroscopic experiments. One of the distinctive characteristics of BaTiO₃ is the ferroelectricity, which is associated to the coherent and collective displacement of Ti ions that give origin to an electrical charge separation at the surface. However, at reduced crystals size (tens or couple hundred of nanometers) the polar ordering of this material changes significantly from the bulk. From commonly employed experimental techniques used to study the crystal structure and phase transitions, such as XRD, Raman, DSC, and dielectric spectroscopy; the reorientation of the crystal size results in peaks broadening and higher signal to noise ratio. Therefore, the crystal structure, phase transition temperature, and polar ordering of perovskite nanocrystals at the nanoscale is still unclear. To overcome these issues, PFM and HR-STEM have been employed to study the ferroelectricity and the atomic columns displacement of single nanocrystals of BaTiO₃, with sizes of 15 nm, 30-50 nm, and 100 nm. The results demonstrated that the 100 nm nanocrystals show behavior similar to bulk BaTiO₃, with a sharp ferroelectric to paraelectric phase transition around 110 °C. By decreasing the size of the nanocrystals at around 40 nm, it has been observed from HR-STEM images that the polarization was not anymore along the [001] axis and could be either [011] or [111] direction. In support to the HR-STEM data, the PFM hysteresis loops have shown a shape variation while increasing the temperature that has reorientably obtained [2]. Our observations reveal for the first time dynamic mechanisms by which soluble proteins self-organize into condensed microdroplets, with nano-scale and milli-second space and time resolution, respectively. With this method, and the initial and natural growth steps of the LLPS could be captured, opening the door for a deeper understanding of other biomacromolecular complexes exhibiting LLPS ability.

8:15 AM CP02.06.02
Design and Characterization of Chemically and Mechanically Tunable Room-Temperature Liquid Metal Colloids Zachary Farrell1, 2, Nicholas J. Morris1, 2 and Christopher Tabor1; 1AFRL, WPAFB, Ohio, United States; 2AFRL, WPAFB, Ohio, United States.

Exeutic Gallium-Indium alloy (EGaIn), a room temperature liquid metal, is of interest for components which leverage its liquid state and rapid alloying behavior for application such as reconfigurable and self-healing electronics. Additionally, its tendency to rapidly self-passivate by production of native gallium oxide allows for simple production of EGaIn colloids which resist spontaneous recoalescence. Although EGaIn has been used in applications such as these, to date, most approaches in this area have an ad hoc character due to a lack of fundamental knowledge on the chemical and mechanical nature of the native gallium oxide and the process by which it develops. To provide insight in these areas, we demonstrate the production and functionalization of EGaIn colloids with the aim of carefully tuning the gallium oxide shell thickness and thus the derivative chemical and mechanical properties of the particles. To accomplish this, orthogonal ligand chemistries consisting of thiols or phosphonic acids are chosen to selectively bond to either elemental gallium, native gallium oxide, or both. Characterization with XPS and nanoprinting of the resultant particles shows that not only can the gallium oxide shell thickness be tuned over nearly a full order of magnitude, but the particles also show good adherence to Reissner’s scaling theory which is commonly applied to other core-shell particles. We anticipate approaches such as these to find application in devices such as self-healing electronics where fine control over particle mechanical properties is desirable to ensure a robust and reliable response to an initiating stimulus.

8:30 AM *CP02.06.03
Direct Observation of Chemical and Mechanical Nanoscale Forces Matthew R. Jones; Chemistry, Rice University, Houston, Texas, United States.

Chemical and mechanical processes occurring at nanoparticle surfaces underlie ligand binding, intraparticle ripening, and particle deformation, to name a few. The ability to directly observe the time evolution of these systems would provide unprecedented mechanistic insight to these important fundamental systems. In this work, we leverage liquid-phase transmission electron microscopy techniques to monitor the chemical and mechanical nature of noble metal nanoparticles as they respond to external stimuli. More specifically, we track molecular binding events on immobilized nanoparticle templates to reveal ligand binding preferences for certain inorganic crystal facets. In addition, we
show the ability to controllably deform single nanoparticles in response to liquid-phase stimuli and use imaging data to understand the spatiotemporal dissipation of strain in confined crystalline materials. Finally, we look at the interplay between chemistry and mechanics at the nanoscale to influence how external stimuli can drive reconfigurable nanoparticle-based materials and devices.

9:00 AM CP02.06.04 Liquid Phase Imaging of Dynamic Biological Systems—A Multifaceted Approach Madeline J. Dukes¹, A. C. Varano², William J. Deanaley² and Deborah F. Kelly³; ¹Protochips, Inc., Morrisville, North Carolina, United States; ²Virginia Tech Carilion Research Institute, Virginia Tech, Roanoke, Virginia, United States.

State-of-the-art in situ and operando transmission electron microscopy (TEM) applications have skyrocketed in recent years, permitting scientists to observe dynamic processes at the nanoscale. As the techniques evolved, so have the designs for liquid cell specimen holders. New advanced holders are capable of controlling liquid environments while simultaneously delivering external stimuli [1]. Samples encapsulated in liquid retain their freedom to move as real-time analysis provides new insights for protein aggregation, diffusion, particle interactions, and mechanistic changes [1]. Thus, researchers can gain a more complete understanding of individual systems beyond static snapshots acquired by traditional TEM methodologies.

Combining liquid-phase TEM (LP-TEM) with low-dose imaging and down-stream computational procedures provides unique quantifiable data of biological entities. Recent work to determine aggregation properties of a protein-based therapeutic reagent, PEGylated Interferon α2a, revealed diffusion and growth behaviours as a function of time [3]. Understanding these aggregation steps is beneficial for developing effective drugs with low side-affects. Such studies represent a new means to improve our understanding of aggregation dynamics under physiologically relevant conditions.

Using the same techniques, we were able to correlate the nanoscale motion of actively transcribing double-layered rotavirus particles (DLPs) with cryo-EM reconstructions. A side-by-side comparison of the two techniques showed increased internal disorder in actively transcribing DLPS versus those in a resting state (not actively transcribing). These correlative applications advance our ability to quantify molecular dynamics in the context of three-dimensional structural information.

Finally, a new exciting path for LC-TEM involves tomographic data collection of samples in liquid. In closed cell specimen holders, measurements are limited by a reduced ability to tilt the holder to higher angles. To address this issue, we developed a sandwich approach that utilizes a conventional carbon TEM grid in combination with a silicon nitride microchip having integrated microwells to enclose liquid specimens. Tomographic data from this work proved useful for microbiology studies and the technique is currently in development to monitor host-cell pathogen interactions in real-time.

Collectively, these results demonstrate the wide variety of fundamental processes that benefit from in situ and in situ-adjacent imaging strategies to visualize/cooperate biological systems that inhabit the nanoworld around us.

9:30 AM CP02.06.05 Mechanistic Study of Galvanic Replacement of Chemically Heterogeneous Templates Alexander Chen, Sophia McClain and Sara Skrabalak; Indiana University, Bloomington, Indiana, United States.

Galvanic replacement is a useful method for synthesizing architecturally complex bimetallic nanomaterials from monometallic templates. The oxidation of a monometallic template by ions of a more noble metal is well studied; however, chemically heterogeneous templates offer more than one type of reaction site and potentially structurally more complex materials. Yet, mechanistic studies with such templates are limited. Here, the reactivities of Ag and Pd in Janus-style AgPd dimers are compared when Au ions capable of oxidizing both metals are introduced, revealing (1) the selectivity of an oxidant in galvanic replacement for oxidizing one of two available reductants, (2) the interaction between galvanic replacement and solid-state diffusion, and (3) the similar replacement mechanisms for different redox pairs. Specifically, when in the presence of Ag and Pd nanocrystals, Au ions with various reduction potentials and oxidation states almost exclusively replace Ag first and Pd second, and when Ag and Pd are physically joined in dimers, Ag oxidation facilitates diffusion of the remaining Ag toward the Pd domain. These results provide mechanistic insight into the kinetically linked processes involved in the galvanic replacement of complex multimetallic templates, and demonstrate the importance of understanding these interactions in order to achieve structural and compositional control over the resulting nanomaterials.

9:45 AM CP02.06.06 Synthesis and Characterisation of Calcium Carbonate-Based Nano- and Micro- Structural Materials Fearghal C. Donnelly¹, Yurii K. Gurko¹, ² and Finn Purcell-Milton¹; ¹School of Chemistry, Trinity College Dublin, Dublin, Ireland; ²School of Chemistry, ITMO University, Saint Petersburg, Russian Federation.

Calcium carbonate is a ubiquitous material, which has a high commercial importance and a variety of important applications. For example, calcium carbonate has traditionally found uses in the construction industry in the production of lime mortar and cement while its whiteness and high refractive index leads to its use in the manufacture of high-gloss paper and as a white pigment in the paint industry. In addition, CaCO₃ demonstrates excellent biocompatibility, enabling its biomedical applications such as in antacid tablets, bone regeneration and drug delivery systems.

The main goal of our work is the development of new CaCO₃ based nano- and micro-structural materials using various synthetic techniques. Here, we present our work on CO₂ bubbling, precipitation-based syntheses, and a novel dry ice carbonation method for the preparation of nano- and micro-particles of CaCO₃. CO₂ bubbling, which is the preferred method for industrial carbonation, was studied and the parameters affecting its synthesis were subsequently refined. Precipitation reactions were used to finely control the synthesis of unique CaCO₃ materials, and subsequently their chiral and luminescent properties. Finally, a unique dry ice carbonation method was developed enabling us to produce CaCO₃ morphologies which are not typically attainable using standard preparation approaches. We believe that this work will contribute to further development of CaCO₃ based materials with a range of potential applications.

10:00 AM BREAK

10:30 AM CP02.06.07 Poly(N-vinylpyrrolidone) Influences Shape-Control of Ag Nanocubes Through Reduction Kinetics Instead of Preferential Binding to Specific Facets Supriti Jharimune¹, Robert M. Rioux¹, Zhiqiang Chen¹, Rudeben Pldwa², Ji Woong Chang¹ and Bert Klumperman¹; ¹Department of Chemical Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States; ²Department of Chemistry and Polymer Science, Stellenbosch University, Matieland, South Africa; ³Department of Chemistry, The Pennsylvania State University, University Park, Pennsylvania, United States; ⁴Department of Chemical Engineering, Kumoh National Institute of Technology, Gumi-si, Korea (the Republic of).

Poly(N-vinylpyrrolidone) (PVP) is ubiquitously used in shape-controlled polyol synthesis of metal nanoparticles (NPs). Among the various systems using PVP, Ag nanocubes (NCs) synthesis has emerged as one of the most robust systems, where PVP is considered as the structure-directing agent and ethylene glycol (EG) as the reducing agent for Ag⁺ at
elevated temperature. While several reports indicate molecular weight ($M_w$) and monomer concentration ($C_m$) of PVP impact the final shape of NPs, a general consensus on the role of PVP during the synthesis of Ag NCs using polyol method is thus far lacking. Recent experimental studies from our group indicate the differential heat of adsorption of PVP to (100) versus (111) facets is too small to predict a cube over an octahedron via a thermodynamic Wulff construction. We further demonstrate that chloride (Cl$^-$) added as HCl is the structure-directing agent in synthesis of Ag NCs. However, it has been observed that PVP can impact the final shape as its $C_m$ or $M_w$ is changed, suggesting PVP may influence the rate of nucleation, leading to kinetically-preferred shapes even in the presence of Cl$^-$. We demonstrate PVP acts both as stabilizer and the dominant reducing agent in the synthesis of Ag NCs owing to displacement of the capped PVP molecules, thereby demonstrating the stabilizing role of PVP. Optimal studies of Ag$^+$ reduction at different PVP $C_m$ and $M_w$ shows faster reduction rate at higher $C_m$ for the same $M_w$ of PVP and at lower $M_w$ for the same $C_m$, suggesting PVP rather than EG plays a dominant role in the reduction of Ag$^+$ and the reducing effect originates from the end groups of PVP. We constructed an experimental phase diagram for the formation of Ag NCs by varying the PVP $C_m$ and $M_w$ at constant temperature. Between the high and the low boundaries of the phase diagram, any combination of PVP $C_m$ and $M_w$ can yield uniform Ag NCs. The lower boundary is related to a required minimum amount of PVP for stabilization, while the upper boundary is related to the role of PVP in Ag$^+$ reduction. Finally, in order to bridge the gap over existing arguments regarding the identity of end functional groups in commercial PVP (–OH or –CHO) and the functional group in PVP molecule responsible for Ag$^+$ reduction, we synthesized PVP with modifiable end-groups and a precise control over the average $M_w$ for a systematic comparative study of Ag NC synthesis. Experiments suggest end groups are indeed responsible for Ag$^+$ reduction kinetics; PVP with –OH end groups are more potent reducing agent than those with –CHO end groups. This work provides key insights into understanding the role of PVP in controlling reduction kinetics of Ag$^+$ and thereby influencing the shape of Ag NPs during polyol synthesis.

10:45 AM CP02.06.08
Study of Charge Effect on Nanoparticle Self-Assembly by Liquid Transmission Electron Microscopy

Yuzi Liu; Argonne National Laboratory, Lemont, Illinois, United States.

Self-assembly of nanoparticles into mesoscopic structures is a proposed concept in material science and technology for the fabrication of hybrid systems with collective properties for different purposes. Liquid cell TEM provides a direct imaging approach that enables to watch the movement of nanoparticles in real time. Here, it was employed to study the self-assembly process of nanoparticles with different charges to unravel the charge effect on self-assembly. It was found that the positively charged nanoparticles can assemble to quasi one dimensional structures when the electron beam intensity exceeds a threshold, while negatively charged particles do not move under the e-beam. We also found size select assembly. The high energy electron beam effect is the driven factor on the self-assembly process. The individual particles show a preference to attach to the ends of existing dimers, trimers to form trimer and tetramer. The long distance dipolar interaction and short distance Van der Waals are the dominant control interaction in the formation of anisotropic one dimensional structure. We further investigate the self-assembly of Au nanoparticles (positively charged) under biased conditions in liquid environment. The different biased voltage was applied to nanoparticle suspension. It was found that the nanoparticles start moving at certain biasing condition. By statistics, the nanoparticle displacement is roughly the same under different biased voltage. But the number of moving nanoparticles is increasing along with the higher biased voltage. We also studied the self-assembly of non-charged nanoparticles. The fractal structure was formed and the hierarchical assembly was observed.

This work was performed at the Center for Nanoscale Materials, a U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences User Facility under Contract No. DE-AC02-06CH11357.

11:15 AM CP02.06.09
Probing Synthesis, Bandgaps and Stability of a Family of Cs₂AgMX₆ Lead-Free Double Perovskite Nanocrystals (M = Sb, Bi, In; X = Cl, Br)

Jakob Dahl; 1 Emory M. Chan; 1 and Paul Alivisatos; 1, 2 Chemistry, University of California, Berkeley, Berkeley, California, United States; 1Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Lead toxicity has sparked interest into alternative halide nanomaterials with properties similar to CsPbX₂ perovskites. A promising alternative suggested from bulk studies is the family of double perovskites of the form Cs₂AgMX₆. Here, we report the robust and tunable synthesis of colloidal nanocrystals of Cs₂AgInCl₆ and Cs₂AgSbCl₆ via injection of acyl halides into a metal acetate solution under atmospheric conditions and relatively mild temperatures. We demonstrate the synthesis of single crystalline cubic nanocrystals of Cs₂AgMX₆ for a systematic comparative study of Ag NC synthesis. Experiments suggest end groups are indeed responsible for Ag$^+$ reduction kinetics; PVP with –OH end groups are more potent reducing agent than those with –CHO end groups. This work provides key insights into understanding the role of PVP in controlling reduction kinetics of Ag$^+$ and thereby influencing the shape of Ag NPs during polyol synthesis.

11:30 AM CP02.06.10
Visualizing Electrochemical Reactions at the Nanoscale by In Situ TEM

Huolin L. Xin; 1 Ruqian Lin; 2 Mingxing Gong; 2 and Nikhilendra Singh; 1 University of California, Irvine, Irvine, California, United States; 2Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, California, United States; 2Huazhong University of Science and Technology, Wu Han, California, United States; 2Toyota Research Institute of North America, Ann Arbor, Michigan, United States.

Over the past five years, we have witnessed a rapid growth in liquid and gas flow holders for TEM and X-ray microscopes. These holders have enabled direct imaging of material transformations in liquid and gaseous environments with submicron-scale to atomic-scale spatial resolution. In particular, research regarding electrode materials in lithium ion batteries and nanocatalysts in heterogeneous catalysis has greatly benefited from the emergence of these capabilities. Despite their initial success in in-situ battery studies, similar transformations in liquid and gaseous environments with submicron-scale to atomic-scale spatial resolution. In particular, research regarding electrode materials in lithium ion batteries and nanocatalysts in heterogeneous catalysis has greatly benefited from the emergence of these capabilities. Despite their initial success in in-situ battery studies, similar challenges remain for the in-situ study of electrocatalysts using an operando TEM liquid holder and I will also discuss existing challenges that the in-situ EM field need to address.

SESSION CP02.07: Other Colloidal Assembly
Session Chair: Qian Chen

PCC West, 100 Level, Room 101 B

1:30 PM CP02.07.01
Self-Assembly of Anisotropic Nanocrystals

Qiu Chen; Chemistry, Brown University, Providence, Rhode Island, United States.

Anisotropic nanocrystals with defined surface patchiness represent a unique class of building objects for constructing high-order architectural nanomaterials. When utilizing in assembly, on the one hand, anisotropic nanocrystals can display strong asymmetric interactions induced by the patchiness that may complicate the formation of ordered structures compared to the assemblies of isotropic building blocks. The same asymmetric interactions, on the other hand, can not only result in novel translational orderings, but also induce correlations between the atomic orientations of HNCs upon crowding, thus possibly dictate and control the atomicic lattices within the assembled superstructure. In this talk, I will use several types of anisotropic 'patchy' nanocrystals as examples to demonstrate how they assemble into the unprecedented superstructures through the directional interactions among the building blocks under an enthalpy-driven condition. Both translational periodicities and orientational ordering of the final superstructural materials will be discussed. The dominating driving forces lead to the obtained architectures will be identified through molecular dynamics computer simulations and experimental results.

2:00 PM CP02.07.02
Assembly and Rheology of 2D Colloids and Their Role in 3D Printing

Andrew Corker; 1, 2 Henry Ng; 2, Rob Poole; 2 and Esther Garcia-Tunón; 1, 2, 3 Materials Innovation Factory, University of Liverpool, Liverpool, United Kingdom; 3School of Engineering, University of Liverpool, Liverpool, United Kingdom.

Additive manufacturing (AM) techniques have undergone enormous growth in the past couple of decades and have already revolutionised the process of rapid prototyping and
manufacture of multfunctional, complex architectures. Due their interesting structure and surface chemistry, 2D colloids can be used in additive manufacturing to create complex structures with many unique characteristics, or can be used in composite formulations for a wide range of applications including: photovoltaic electronics, flexible transparent electrodes for energy storage to water purification.

Extrusion-based 3D printing, also known as Direct Ink Writing (DIW) or robocasting, provides a unique approach to introduce advanced and high-added-value materials with limited availability into lab-scale in manufacturing. Robocasting involves continuous extrusion of colloidal pastes or gels through a fine nozzle to create 3D structures layer-by-layer. Formulation design aims to ensure “printability” through careful control of rheology. The inks or pastes must be shear thinning to easily flow through the nozzle at modest shear rates and then immediately set into a non-flowing structure once printed. They must also be able to support multiple layers on top and retain the shape across spans without deformation. “Printability” however is still a broad concept due to the diverse range of applications within the field. This work compiles different rheology methodologies combining shear, extensional and oscillatory rheology that will enable quantifying the printability of soft materials.

2D colloids of graphene oxide (GO) exhibit a fascinating rheology and can aid the processing of different materials to develop ‘printable’ formulations. GO colloids in water form printable networks at relatively low concentrations and can behave as multifunctional additives. Due to unique surface chemistry GO, can be used to act as a rheology modifier that imparts a strongly shear-thinning and yield stress (ey) to suspensions of other materials even when is used in small concentrations. This work provides an in-depth rheological study of GO suspensions with a wide range of behaviours from Newtonian-like to viscoelastic ‘printable’ soft solids. The combination of extensional shear rheology reveals the network formation process as GO concentration increases from <0.1 vol% to 3 vol%. Results from the extensional tests showed how the GO transitions from a Newtonian-like liquid (<0.1vol%) to weakly (<0.8vol%) and then strongly-established structural network as concentration is increased. Our results also demonstrate that the quantification of ‘printability’ can be based on three rheology parameters: the stiffness of the network via the storage modulus (G’), the solid-to-liquid transition or flow stress (σf), and the flow transition index, which relates the flow and yield stresses (FTI=σf/ey).

2:15 PM CP02.07.03 Self-Assembly of Non-Spherical Nanoparticles into Functional Supercrystals Zewei Quan*; Chemistry, Southern University of Science and Technology, Shenzhen, China.

Nanoparticles are fascinating in many ways. Self-assembly of various building blocks into macroscopic structures with desired features and functions, is an interesting theme that runs through chemistry, biology and material science. In this talk, I will first show our recent progress in the self-assembly of non-spherical nanoparticles including nanocubes, nanorods, and nanodumbbells. The roles of non-spherical nanoparticle shape during this self-assembly behavior are of great interest, and different solvents have been demonstrated to modulate the individual particle interactions to control the final nanoparticle assembly pattern. Additionally, the stability of different nanoparticle superlattice polymorphs has also been provided with dedicated solution calorimetric measurements. Last, I will talk about how to use self-assembly technique to prepare ordered Au mesoporous nanosheets with plasmonic hotspots.

2:30 PM CP02.07.04 Direct-Write Freeform Colloidal Assembly Alvin Tan, Justin Beroz, Mathias Kolle and A. John Hart; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Assemblies of colloidal particles exhibit complex collective behaviors based on particle geometry, composition and arrangement, which enables tailored design of novel materials for diverse applications. Methods to deposit and self-assemble ordered particle solids from suspension are typically limited to fabrication of films and patterns, and commonly utilize surface tension to confine particles against substrates. In contrast, direct-write methods to build 3D structures rely on cohesion between particles in high-density suspensions to achieve structural rigidity, but this precludes particle ordering. Here, we present a method to build freestanding structures from self-assembled colloidal particles. The structures have mm-cm scale dimensions and can be built in freeform with aspect ratios greater than 10, yet retain polycrystalline order. We derive a scaling law that governs the rate of assembly, show how macroscopic structural color can be tailored via the size and crystalline ordering of polystyrene particles, and build exemplary freestanding functional structures. Owing to the diversity of colloidal building blocks and means to control their interactions, direct-write assembly could therefore enable novel composites, photonics, electronics, and other materials and devices.

2:45 PM CP02.07.05 Colloidal Crystals Engineered from Anisotropic Nanoparticles and DNA Haixin Lin, Lin Sun, Jinghan Zhu and Chad A. Mirkin; Northwestern University, Evanston, Illinois, United States.

DNA-mediated programmable assembly is a promising route for synthesizing novel materials. This strategy has been successfully used to synthesize crystalline structures with more than 35 different symmetries and over 500 structures. However, most of the properties of these colloidal crystals are dictated by the identity of the building blocks, instead of their structural arrangements. In contrast, crystal structure plays a crucial role in determining the properties of several traditional molecular/atomic crystals such as porous (e.g. MOFs, clathrates, zeolites) and anisotropic crystals (e.g. uniaxial crystals, biaxial crystals). Analogous porous or anisotropic colloidal crystals are difficult to fabricate given that the most commonly used building blocks are highly symmetric spherical particles. Unlike spherical particles, anisotropic particles can directionally guide the formation of DNA bonds with specific angles, which affects the lattice symmetry and crystal habit of the resulting colloidal crystals. In this work, we show two examples of how low symmetry nanoparticles assemble into either porous or anisotropic crystals.

3:30 PM CP02.08.01 Superhydrophilic Wrinkle-Free Cotton Fabrics via Plasma and Nanofluid Treatment Lihong Lao, Liling Fu, Genggeng Qi, Jintu Fan and Emmanuel P. Giannelis; Cornell...
For more than two decades in the apparel industry, there has been a consistently high demand for wrinkle-free cotton garments for easy care and comfort. Conventional wrinkle-free finishing is based on the crosslinking reaction between molecular chains of cellulose via formaldehyde derivatives such as dimethyldihydroxyethyleneurea (DMDHEU).

DMDHEU introduces hydroxyl (-OH) groups in cotton, which increases wrinkle-resistance and shape retention. However, the finishing reduces the hydrophilicity of the fabric due to the reduction of the number of OH groups; consequently, the moisture sorption capacity and wicking properties are reduced, resulting in a deterioration in the comfort of the cotton fabric. Therefore, recovering the hydrophilicity of wrinkle-free finished cotton has very significant practical value.

We demonstrate in this study, a wrinkle-free, superhydrophilic, cotton fabric (contact angle 0°) by attaching specially engineered nanoparticles to plasma pre-treated cotton fabric. Because of their charged nature, the nanoparticles are firmly anchored on the fabric via electrostatic interactions; the surface structures were confirmed by image and chemical analyses. The durability of wetting behavior and wrinkle-free property of the NP-coated fabric was evaluated via aging, laundering and abrasion tests. The strongly attached coatings are stable maintaining their superhydrophilic nature even after 60 days’ aging and 50 laundering cycles. The nanoparticle-coated fabric also combines superhydrophilicity with very good wrinkle-recovery property, tensile strength and abrasion resistance (25,000 abrasion cycles) performance.

3:45 PM CP02.08.02
High Performance Unpoled Piezoelectric Device Comprised of Surface Modified 3D Li-ZnO into PVDF Polymer Incorporated with MWCNT Aminur Rashid Chowdhury, Jared Jaksic, Istita Hussain, Phong Tran and Jasmir M. Uddin; The University of Texas at Rio Grande Valley, Edinburg, Texas, United States.

In last few years piezoelectric materials have found its position as one of the leading stress sensing element in real life applications. Hence the demand for developing highly effective and sensitive piezoelectric devices is the all-time high. We present an unpoled high performance flexible piezoelectric nanogenerator comprising of three-dimensional(3D) surface modified Lithium doped Zinc Oxide (Li-ZnO) with Multwallared carbon nanotube (MWCNT) in bulk matrix of Polyvinylfluoride (PVDF). 3D Li-ZnO was synthesized hydrothermally followed by surface modification by polyethylene glycol (PEG-20000). The polyethylene glycol coating served as an effective solution for avoiding electrical poling and enhanced the proportion of the PVDF β-phase while MWCNTs acted to increase conductivity and to reinforce the composite during mechanical stressing. This also acted as a cost-effective multifunctional piezoelectric device. The piezoelectric nanocomposite was tested with different body motions to assess this piezoelectric device's efficiency in real-world application. The piezoelectric device was found with promising a linear response to a gradual increase in normal stresses. This device also shows a promising use for biomedicine as PVDF, ZnO is FDA approved.

4:00 PM CP02.08.03
Chirality Inversion on the Carbon Dot Surface via Covalent Surface Conjugation of Cyclic α-Amino Acid Capping Agents Fatemeh Ostadhossein, Gururaja Vulpugundam, Santosh Misra, Indrajit Srivastava and Dipanjnan Pan; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Manipulating the chiroptical at the nanoscale is of great importance in stereoelectronic reactions, enantioseparation, self assembly and biological phenomena. In recent years, carbon dots have garnered great attention due to their favorable properties such as tunable fluorescence, high biocompatibility, and facile, scalable synthetic procedures. Herein, we report for the first time the unusual behavior of cyclic amino acids due to the surface of carbon dots prepared via microwave-based carbonization. Various amino acids were introduced on the surface of carbon dots via EDC; NHS conjugation at room temperature. Circular dichroism results revealed that although most of the surface conjugated amino acids can preserve their chirality on negatively charged, ‘bare’ carbon dots, the ‘handedness’ of cyclic α-amino acids can be flipped when covalently attached on carbon dots. Moreover, these chiral carbon dots were found to interact with the cellular membrane or its mimic in a highly selective manner due to their acquired asymmetric selectivity. Comprehensive inhibitor study was conducted to investigate the pathway of cellular trafficking of these carbon dots. Overall, it was concluded that chirality of amino acid on the surface of carbon dots could regulate many of the cellular processes.

4:15 PM CP02.08.04
Colloidal Cs\textsubscript{x}FAP\textsubscript{1-x}\textsubscript{A}\textsubscript{B}\textsubscript{x}\textsubscript{X}\textsubscript{1-x} Perovskite Nanocrystals with Full Range of A-Site Composition Tuning for High Voc Solar Cells Abhijit Hazarika\textsuperscript{1}, Qian Zhao\textsuperscript{1, 2}, Ashley Gaulding\textsuperscript{1, 3}, Jeffrey Christian\textsuperscript{1}, Benjia Dou\textsuperscript{1, 3}, Ashley Marshall\textsuperscript{1}, Taylor Moot\textsuperscript{1}, Joseph Berry\textsuperscript{1}, Justin Johnson\textsuperscript{1} and Joseph Luther\textsuperscript{1}; National Renewable Energy Laboratory, Lakewood, Colorado, United States; \textsuperscript{2}College of Chemistry, Nankai University, Tianjin, China; \textsuperscript{3}University of Colorado Boulder, Boulder, Colorado, United States.

Due to their amazing optoelectronic properties, colloidal lead halide perovskite nanocrystals (NCs) are receiving increasing attention in recent times. Perovskite NCs possess properties that are not accessible in their bulk or thin-film counterparts. For example, perovskite phase of CsPbI\textsubscript{3} is unstable in ambient condition in bulk or thin-film, but they are phase stable in their quantum confined form. This particular material has shown to have record efficiency for quantum dot (QD) solar cells. Another interesting advantage of these QD materials is that their compositions can be tuned without changing the crystal framework either by direct synthesis or by post-synthetic ion exchanges. Particularly, X-site ion exchange in the perovskite NCs with general formula A\textsubscript{x}B\textsubscript{1-x}FAP\textsubscript{x} can be achieved both in QDs and thin films, and it has been shown that only compositions with 1-x<0.4 can be realized in the pure usable perovskite phase. This is due to thermal instability of FAPbI\textsubscript{3} (crystallizes at around 130 °C) at temperatures required to crystallize CsPbI\textsubscript{3} (above 300 °C). Here, we present a simple post-synthetic cross-cation exchange reaction between colloidal solutions of CsFAPbI\textsubscript{1-x} and FAPbI\textsubscript{x} nanocrystals just by mixing them at temperatures slightly above the room temperature that enables us to achieve compositions in the whole range of 0<x<1. This helps us to realize compositions that were not known previously. The photoluminescence (PL) kinetics studies reveal that the activation energy required to inter-exchange the Cs\textsuperscript{+} and FA\textsuperscript{−} ions is around 0.65 eV, higher than that for X-site exchange in lead halide perovskites. We use these alloyed colloidal perovskite quantum dots to fabricate photovoltaic devices. We applied these alloyed NC ink in solar cell and demonstrated that they exhibited high open circuit voltage (V\textsubscript{OC}) of ~90% of their Shockley-Quiesser maximum and have lower losses than the thin film perovskite devices of similar compositions.

Tuning the Optical Properties of Pulsed Laser Synthesized Nitrogen Doped Graphene Quantum Dots Muhammad Shehzad Sultan\textsuperscript{1}, Vladimir I. Makarov\textsuperscript{1}, Muhammad Sagjad\textsuperscript{1}, Frank Mendoza\textsuperscript{2}, Wojciech M. Jadwisiencka\textsuperscript{2}, Brad R. Weiner\textsuperscript{1} and Gerardo Morell\textsuperscript{1}; \textsuperscript{1}Department of Physics, University of Puerto Rico, San Juan, Puerto Rico, United States; \textsuperscript{2}Department of Physics and Astronomy, Austin Peay State University, Austin, Tennessee, United States.

The graphene quantum dots (GQDs) have attracted the attention of researchers due to their excellent properties and potential applications in biomedicines, energy storage devices and photocatalysts. Photoluminescence is one of the most important characteristics of GQDs. The doping of GQDs with Nitrogen atoms is one of the most effective ways to tune their photoluminescence emission and to increase quantum yield. In this work, high-quality Nitrogen-doped graphene quantum dots (N-GQDs) were synthesized by using pulsed laser synthesis method at various irradiation powers of pulsed laser and changing the concentration of nitrogen doping to effectively tune the photoluminescence emission and improve the quantum yield (QY) of as synthesized N-GQDs. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. To observe optical properties of as synthesized N-GQDs, the UV-vis and Photoluminescence measurements were carried out. The as-synthesized N-GQDs exhibit high quality crystalline structure of graphene. A high quantum yield was exhibited by the obtained N-GQDs as compare to the pristine GQDs. The obtained N-GQDs with oxygen-rich functional groups exhibit a strong emission. This work may be helpful to expand the
In this presentation, we will describe the colloidal synthesis of phase-pure nanocrystals (NCs) of a highly abundant mineral, chalcopyrite (CuFeS₂). The steady state optical extinction spectrum of these NCs offers few surprises due to Fe which introduces deep energy levels in the electronic band structure, as supported by our density functional theory (DFT) calculations. The spectrum is characterized by absorption bands centered at around 480 and 930 nm, spanning almost the entire visible and near infrared regions. These are ascribable to electronic transitions from the valence band (VB) to the empty intermediate band (IB), located in the so-called fundamental band-gap and composed predominantly of Fe 3d orbitals. We further demonstrate, through spectroscopic measurements and ab initio calculations that these NCs actually sustain metal-like quasi-static optical resonances despite the absence of free carriers in the NC ground state owing to this unique band structure. Laser-irradiation (at 808 nm) of an aqueous suspension of these CuFeS₂ NCs exhibited significant heating, with a photothermal conversion efficiency of 49%. Such efficient heating is most likely due to the carrier relaxation within the broad IB band, as corroborated by transient absorption measurements and further described by DFT calculations. The intense absorption and high photothermal transduction efficiency (PTE) of these NCs in the so-called biological window (650–900 nm) make them suitable for photothermal therapy as demonstrated by tumor cell annihilation upon laser irradiation. We intend to put forward the chemistry behind the synthesis of these low band-gap ternary semiconductor NCs and describe the optoelectronic properties using experimental and theoretical points of view, through this presentation. A suite of spectroscopic techniques, which include visible-infrared transient absorption, x-ray absorption and emission, resonant inelastic x-ray scattering (RIXS) were used in our analyses. The subsequent use as a photothermal agent is an offshoot of this understanding. The presence of the deep Fe levels constituting the IB is the origin of such enhanced PTE, which can be used to design other high performing NC photothermal agents.

Local Symmetry Breaking in Functional Materials: A Tour from Quantum to Energy to Strange Emil Bozin; Brookhaven National Laboratory

The total-scattering-based PDF approach has been instrumental to understanding the local and intermediate range structure of complex functional materials. From standard to more advanced techniques, such as time resolved, dynamic, magnetic, thin film, and computed tomography approaches, the PDF method enables exploration of a diverse class of problems in contemporary material science. These include sustainable energy materials (e.g. battery and hydrogen storage materials, thermoelectrics), soft materials (e.g. drugs, polymers, sugars, cellulose), soft hard materials (e.g. strongly correlated electron systems, nanoparticles, catalysts), as well as materials displaying “strange” properties (e.g. negative thermal expansion, amorphization and amorphous materials, negative linear compressibility). This part will highlight the power of X-ray and neutron total scattering and PDF applications through selected illustrative examples. Focus will be placed on exploring dynamic local symmetry breaking in novel materials, emphasizing that this local symmetry breaking is the key for understanding devices from energy conversion to superconductivity. We will demonstrate that local, fluctuating broken symmetry states are widespread in functional materials.

SESSION CP03.01: Fast Transmission Electron Microscopy
Session Chair: Chengjun Sun
Tuesday Morning, April 23, 2019
PCC West, 100 Level, Room 101 C

10:30 AM *CP03.01.01
Development of a Dynamic Environment Transmission Electron Microscope for the Study of Ultrafast Light-Induced Phenomena in Nanoscale Materials Renske M. van der Veen1, 2; 1Department of Chemistry, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

In situ transmission electron microscopy has become a powerful technique to study functional nanomaterial dynamics in response to electrical, chemical, electrochemical, thermal, and/or electromagnetic fields prevalent under operating conditions. The time resolution, however, is typically limited by the maximum frame rate of the detector, which is at best in the kHz regime. Ultrafast transmission electron microscopy combines the high time resolution of laser spectroscopy with the excellent spatial resolution of electron microscopy techniques. The structural and electronic changes in the material are initiated by short (fs, ps, ns) laser pulses, which are followed by similarly short photoelectron pulses for probing the dynamics by means of imaging, diffraction, or energy-loss spectroscopy (EELS) within the electron microscope. In this talk I will present our dynamic environment transmission electron microscope (DETEM) at the University of Illinois. This versatile instrument enables time-resolved in situ studies of fast (fs-ms) material processes in gaseous and liquid environments that are triggered by light, heat, chemical flux, electrical bias or strain. I will give examples of studies using light excitation as the trigger, including nanosecond-resolved single-nanoparticle electron diffraction and real-space imaging of spin crossover phase transitions and ultrafast (fs, ns) EELS of light-induced dynamics in graphite thin films.

An Open Cell System for Probing Nanoparticles Under Illumination in Aqueous Solutions in an Environmental Transmission Electron Microscope Barnaby D. Levin1, Diane Haiber1, Qianlang Liu1, 2 and Peter Crozier1; 1Arizona State University, Tempe, Arizona, United States; 2Intel Corporation, Portland, Oregon, United States.

Nanoscale and atomic scale interactions between light and matter in water govern a number of important processes. One example is photocorrosion, which negatively impacts many areas including energy conversion technologies and structural materials. The process takes place in aqueous environments and, for semiconductors, is driven by electron-hole
pair generation from photon illumination[1-3]. For example, cadmium sulphide (CdS) based photocatalysts, undergo severe photocorrosion during photocatalytic water splitting[4]. Understanding the nano- and atomic scale changes induced by photocorrosion may offer new insights into fundamental questions regarding the initiation and evolution of photocorrosion and the impact of factors such as the presence of solute ions.

To probe photocorrosion and other light/matter interactions in solution, we have developed an open cell method for condensing liquid water around nanoparticles and illuminating them inside an environmental transmission electron microscope (ETEM). To facilitate liquid water formation, nanoparticles are dispersed on a TEM sample grid alongside ball milled sodium chloride (NaCl), which are strongly hydrophilic[4]. Samples are loaded into the ETEM in a cryogenic holder held at ~5°C, and are then exposed to 4–10 Torr of water vapor in the ETEM column, causing water droplets to form and dissolve the NaCl, and enveloping neighbouring nanoparticle clusters in NaCl solution. To illuminate particles immersed in solution, we have modified an earlier in situ light system[5] to use a 405 nm laser connected to the TEM with an optical fibre inserted through the objective aperture port of the microscope.

Aberration corrected TEM imaging before and after exposure to light and water will allow us to characterize changes that occur in clusters of particles. We apply this technique to CdS photocatalyst nanoparticles in a variety of light and solute conditions.

Composition Analysis by EDS at Elevated Temperatures in STEM and SEM Meiken Falke and Igor Nemeth; Bruker Nano GmbH, Berlin, Germany.

Energy dispersive X-ray spectroscopy (EDS) experiments at elevated temperatures up to the range of 1000°C, will be used to discuss challenges in in situ spectroscopy and element mapping. Heat radiation at elevated temperatures changes the low energy part of EDS spectra. Still, low energy element ID and chemical phase analysis are available in STEM and SEM within certain limits. The agglomeration and evaporation of material in a Pt-Au-nanoparticle test structure during heating in a conventional STEM were evaluated using statistical methods and phase analysis for. The results demonstrate the capabilities of in-situ EDS. The heating holder and its stability at changing temperatures plays a crucial role for successful experiments[1].

Further options of using EDS for in situ analysis are explored. One certain request is speed. Optimum photon detection geometry is crucial for efficient EDS in the electron microscope. Important to achieve that are a large solid and high take-off angle for photon collection, good collimation and suitable sample holders. The holders should not shadow the detector(s). Multi-detector arrangements enable large solid angles at high take-off angle particularly easily. Geometric optimization in combination with high brightness electron sources and aberration correction allows the identification and tracking of single atoms at low accelerating voltages in STEM within a few seconds[2]. Specimen holder materials and window materials need to be well known to ensure correct quantitative analysis of spectroscopic results, which is of particular interest in case of reaction cells holding liquid samples. Additionally, dealing with constantly changing data streams demands new ways of data acquisition and processing, which are being developed.

In Situ Atomic-Scale Observation of Intermediate Pathways of Melting and Crystallization of Supported Bi-Nanoparticles in the TEM Leonard D. Francis; Department of Advanced Electron Microscopy, Imaging and Spectroscopy, International Iberian Nanotechnology Laboratory, Braga, Portugal.

Melting and crystallization are fundamental and practically important first-order phase transitions in condensed-matter physics, material science and climate change, yet a detailed understanding of their relevant kinetic pathways is still evolving[1,2]. To date, many theoretical models have been developed from homogeneous classical nucleation theory (CNT) model, but they rarely address the exact preferential nucleating sites and the potentially relevant role played by defects, surfaces, dimensionality and their combinations in phase transformations[3]. Recently, Samanta et al. conducted large-scale atomistic calculation of a phase transformation process of a metal from solid to liquid and predicted that the process takes place via multiple competing pathways involving the formation and migration of point defects or dislocations[4]. Although these calculations indeed provide a rare look at real phase transformations, much confusion still exists regarding the atomistic understanding of a dynamic process of a phase transformation due to the lack of direct experimental observations at the atomic scale as well as due to the experimental intricacies in tackling such a challenging topic. Bismuth (Bi) is an ideal inorganic model material suitable for gaining insights into nucleation dynamics due to its low melting point (even down to room temperature due to size effect).

Here, we report in-situ atomic-scale observations of a real dynamic process of melting or crystallization in supported Bi nanoparticles under heating or cooling conditions using a heating holder within an aberration-corrected (scanning) transmission electron microscope. We provide direct evidence that pre-nucleation in either melting or crystallization takes places via multiple intermediate state pathways involving the formation and migration of domain boundaries, dislocations and the ordering of interface and surface at the atomic scale. The pre-melting of the nanoparticle is a first at a grain boundary and expands to interfaces and dislocations and finally undergoes a catastrophic transformation from a solid-liquid state to a liquid droplet as a whole in a rather short time at high take-off exceeds a threshold value. When the size is smaller than the threshold value, the melting of nanocrystals takes place via two barrier-crossing pathways, i.e. pre-melting at grain boundary and a catastrophic solid-liquid transformation. Interestingly, pre-crystallization in a droplet occurs first at a solid-liquid interface and subsequently at the liquid surface, and eventually the droplet undergoes a fast complete transformation to a solid nanocrystal when undercooled. Thus the ability to conduct in-situ atomic-scale observation of the evolitional pathways in phase transformations of supported nanoparticles represents a significant step forward in understanding microscopic mechanisms of phase transitions at the atomic scale. The findings in the present study demonstrate that the melting/crystallization processes cannot be viewed as a simple single barrier-crossing event but as a complex multiple intermediate state phenomenon, which enhances our general understanding of nucleation and growth, melting/crystallization phenomena, phase transformations and helps to clarify atomic origins of temperature dependent behaviours in other nanomaterials and thin films[5].

Effects of Pulsed Electron-Beam Characteristics on Radiation-Sensitive Materials for Energy Applications Elisah VandenBussche and David J. Flannigan; University of Minnesota, Minneapolis, Minnesota, United States.

In the understanding of durability and longevity of emerging photovoltaic materials, an essential component is the study of structural stability in response to photoexcitation. The study of photoinduced structural dynamics in inorganic semiconductors, such as silicon and gallium arsenide, has been established over recent years[1,2], thus enabling insights into thermal- and carrier-transport properties, especially pertaining to the effects of morphology and defects. Ultrafast electron microscopy (UEM), a pump-probe technique that utilizes a pulsed photoelectron beam generated by a femtosecond (fs) pulsed laser to extend the conventional capabilities of transmission electron microscopy (TEM) into the ultrafast (fs to picosecond) time domain[3], is one technique by which such studies can be conducted. Indeed, accessing the picosecond-nanometer spatiotemporal parameter space in the study of radiation-sensitive organic materials would doubtless allow for the discovery and the elucidation of light-induced excitation and decay mechanisms, especially with

Observing Reactions at Surfaces with Fast and Dynamic XPS Christian Kaiser, Burkhard Krömker and Georg Prümper; Sigma Surface Science GmbH, Taunusstein, Germany.

Fast XPS is a popular method for observing reactions and transitions at surfaces. The combination of chemical analysis and surface sensitivity with fast and time resolved data acquisition offers insight into the process itself where “static” measurements merely show its outcome.

Applications can be found in many fields of research where the nature of the process is studied, e.g. on-surface synthesis of polymers and 2d materials, adsorption mechanisms during solid-gas interactions or thermally activated reactions at surfaces.

This method is mostly applied at synchrotron beamlines where short acquisition times for time resolution are compensated by high photon flux for signal strength. In this talk enhancement of this measurement technique due to recent advances in instrumental development is presented and demonstrated with applications. Not only does it increase the spectroscopic information to multiple, wide range peak areas, but opens up the possibility for off-line and laboratory based experiments with conventional X-ray sources on time scales down to the millisecond range. This way, parameters for controlled and reproducible processes or interactions can be found and optimised, and the dynamics of these processes systematically observed. Furthermore, specific properties important e.g. in device fabrication can be engineered with fast and dynamic XPS using its time resolved aspect.

The Role of First Principles Calculations in Interpreting Core Level X-Ray Photoelectron Spectra of Complex Heterogeneous Systems Juhan Matthias Kahk1 and Johannes C. Lischner2, 1Department of Materials, Imperial College London, London, United Kingdom; 2Department of Physics and Department of Materials, Imperial College London, London, United Kingdom.

Recent developments in X-ray Photoelectron Spectroscopy have enabled studies, in which the surface chemistry of catalytically active materials is probed under quasi in situ conditions. However, the insight into the mechanisms of catalytic reactions gained from such studies is entirely dependent on our ability to interpret the recorded spectra. Often this can be extremely challenging, for example when reference data that is typically used to guide "peak-assignment" is either unavailable or conflicting.

First principles calculations of core electron binding energies can guide the interpretation of experimental results. We have developed a computational framework for the calculation of core electron binding energies of surface species that combines the use of slab and cluster models of the surface. In the first step, the geometry of the adsorbate is optimized using a periodic slab model of the surface. Then, a cluster is cut from the slab, and the core electron binding energy is calculated for that cluster using the all-electron delta-SCF method. We have carefully examined the convergence of the results with respect to the size of the cluster used to model the surface, and found that finite size effects can be effectively reduced to the point where they are smaller than the functional error. Using this method, we have calculated C1s nad O1s core electron binding energy shifts for a series of adsorbates on the Cu(111) surface. The results are in good overall agreement with experimental binding energies that have been determined from studies of copper based catalysts. Where there is ambiguity about experimental peak assignments, the

Electron Energy-Loss Spectroscopy for Designing Plasmonic Catalysts  Renu Sharma1,2, Wei-Chang D. Yang1,2, Alina Bruma1,2 and Canhui Wang1,2. 1National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 2University of Maryland, College Park, Maryland, United States.

The energy barrier for most of the chemical reactions is overcome by heating the reactants in the presence of a suitable catalyst, where the thermal energy provided by heat helps in surpassing the barrier that has been reduced by the adsorption of the reactant molecules on the catalyst nanoparticle surfaces. In recent years, localized surface plasmon (LSP) resonance energy has been used to replace the thermal energy to initiate reaction at low temperatures, even at room temperature.1,2 As most of the plasmonic materials, Au, Ag or Al, are not generally catalytically active, they have been successfully used by combining them with active catalysts such as Pt, Ni, Ru, etc. Most of the researchers so far have used optical methods to generate and measure the LSP resonance energies. However, the combination of low spatial resolution, of the order of 100 nm, achievable by optical methods, does not provide sub-particle level distribution of coupling efficiency of different modes. On the other hand, high energy electrons not only excite all LSP modes simultaneously, but also provide high spatial resolution in the nanometer range to resolve their energy loss probability that indicates the efficiency of coupling the location-specific electron excitation of the LSP modes at certain resonance energies on the plasmonic nanoparticle. Therefore, we use a monochromated electron source in an environmental scanning-transmission electron microscope (ESTEM), combined with metallic nanoparticle boundary element method (MNPBEM) and density functional theory (DFT) simulations, to characterize various LSP modes and their coupling efficiency distribution within the shape and size-controlled nanoparticles of Au and Al. We demonstrate that the knowledge gained from low-loss and core-loss EELS measurements can be used to design catalyst-plasmonic particle combination for selected chemical reactions.

In Situ Diagnostics of 2D Materials Synthesis and Heterogeneity—Closing the Loop for Functional Optoelectronic Materials
David B. Grohogan1, Yu-Chuan Lin1, Yilang Yu1, Chenze Liu1, Gerd Duscher2, Alex Strasser1,3, Alexander Puretzky1, Kai Wang1, Minu Yoon1, Christopher M. Rouleau1, Stella Canulescu1, Philip D. Rack1, Liangbo Liang1, Gyula Eres1 and Kai Xiao1;
1Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Department of Materials Science and Engineering, University of Tennessee, Knoxville, Tennessee, United States; 3Texas A&M University, College Station, Texas, United States; 1DTU Fotonik, Technical University of Denmark, Lyngby, Denmark.

Atomically-thin two-dimensional (2D) layered materials, especially the semiconducting 2D transition metal dichalcogenides (TMDs) and their heterostructures, exhibit remarkable quantum properties that are envisioned for energy-efficient photovoltaics, flexible optoelectronics, and quantum information science. However, significant synthesis and processing challenges currently limit their development, including wafer-scale, bottom-up synthesis of uniform layers of crystalline 2D materials that are comparable in quality to exfoliated flakes of bulk materials. As-synthesized crystals of 2D TMDs display remarkable heterogeneity on both the atomic level (e.g., vacancies, dopants, and edge terminations) and on the mesoscopic length scale (e.g., misoriented grains, layer orientations, and interactions with substrates and adsorbates) that can strongly influence the structure and electronic properties in 2D materials. While this heterogeneity offers a serious challenge for synthesis and processing, it also offers a tremendous opportunity to tailor functionality. In situ spectroscopic diagnostics during the synthesis and processing of 2D materials offers a rare chance to ‘close the loop’ between synthesis and properties to tailor optoelectronic functionality with real-time feedback.

Here we present principally non-equilibrium, laser-based synthesis and processing approaches for the synthesis and processing of 2D TMD materials that permit correlated in situ spectroscopy and imaging measurements as real-time diagnostics of heterogeneity. First, advances in pulsed laser deposition (PLD) of 2D TMDs (e.g., MoS2, WSe2) at elevated temperatures are described using in situ diagnostics of the growth environment (e.g., ICCD imaging and ion probe characterization of the plasma plume) and in situ diagnostics of the growing film (e.g., in situ laser reflectivity) to understand and optimize the growth process. Structure, composition, and heterogeneity of the films are characterized principally with AFM, atomic resolution HA-ADF STEM microscopy, and EELS.

Through this understanding and tuning of the PLD process, energetic atoms/molecules, to clusters and amorphous nanoparticles can be utilized for synthesis. Two effects will be presented. First, the effect of high kinetic energy atomic and molecular species to directly convert existing 2D crystals into alloys by chalcogen replacement is explored using photoluminescence and Raman spectroscopy as diagnostics of band gap shift and structure. Selective conversion of bilayer crystals is possible with this technique to form vertical heterojunctions. Second, amorphous nanoparticle ‘building block’ precursors are deposited as precursors for subsequent laser annealing studies to understand the timescales and mechanisms for their crystallization and evolution into 2D layers. This conversion is studied at two levels. First, in a custom vacuum microchamber under an optical microscope tailored for in situ Raman spectroscopy, absorption spectroscopy, photoluminescence, and SHG mapping. And second, in a prototype setup that allows laser illumination to be coupled into a (scanning) transmission electron microscope (TEM) for real-time observations of nonequilibrium synthesis directly on TEM grids.

These laser-based synthesis and processing approaches, coupled with in situ spectroscopic and imaging diagnostics, allow the stepwise evolution of synthesis to structure and optoelectronic function to be correlated through association theory and modeling, forming a novel strategy to ‘close the loop’ for directed synthesis.

Research sponsored by the U.S. Dept. of Energy, Office of Science, Basic Energy Sciences, Materials Science and Engineering Div. (synthesis science) and Scientific User Facilities Div. (characterization science). Throughout the presentation, facilities available for collaboration at the Center for Nanophase Materials Sciences (CNMS) user facility will be presented.

4:30 PM *CP03.03.04
About Using In Situ and Operando Characterization to Characterize Catalysts
Jeroen A. van Bokhoven; ETH Zurich-PSI, Zurich, Switzerland.

The complexity of the catalytic process makes it difficult to capture the structure of the catalytically active sites. The catalytic process occurs at multiple time- and length-scales and the structure of a heterogeneous catalyst is non-uniform and deciding which of the observed species is relevant for catalysis is far from obvious. Simplification of the system by using model structures and conditions helps to determine structure – performance relationships. However, such model systems and conditions are not necessarily relevant to the actual catalytic process. Determining the structure of a catalyst while it performs its catalytic function is the domain of operando characterization and is seemingly the best way of capturing structure – performance relations. Performing an operando characterization does not necessarily yield the catalytically relevant structures. Catalysis occurs over reactive surfaces, which may change their structure upon interaction with reactants, intermediates and products. During catalytic conversion reactants are converted into intermediates and products, thus changing the gas composition. With such change, the catalyst surface and its catalytic reactivity may change in accord. Thus, multiple structures as function of position within the reactor may exist. Also, the observation of structure in an operando experiment is no guarantee that that structure is relevant to the catalytic reaction. When taking into account relatively simple concepts from reaction kinetics, a distinction between spectator and active species can be made.

Light-Driven Liquid Cell Transmission Electron Microscopy to Study Photocatalytic Materials

Recent advances in liquid cell transmission electron microscopy (TEM) have enabled the study of reactions in liquid-solid interface at high spatial resolution in real-time environment. The capability to apply stimuli such as electrical, heating and electrochemical measurements has already started to provide new insights on the dynamics and structural changes during nanoparticles synthesis1, lithium charge and discharge2, crystal growth3 and metal corrosion4. The further ability to introduce light within the confined liquid environment of TEM strengthens the capability by allowing the study of light interaction in materials during reaction at solid-liquid interface, thus enabling photoelectrochemistry in TEM. The study of hydrogen generation via photoelectrochemical method5 is one relevant application that can benefit from this technique and can provide fuel for energy storage solution in a clean and environmentally friendly way. However, the atomic scale mechanisms of the photocatalysts that facilitate the water splitting for efficient hydrogen generation are currently poorly understood. Further understanding of the role of various photocatalysts and the physics governing the active hydrogen evolution sites will allow for better and efficient design of photovoltaic devices. Here we present the development of a unique in-situ liquid TEM holder with photo-capable light source to study photocatalytic reactions in real time at nanometer length scales. Using some of the model materials such as Au nanoparticles and MoS2 flakes, we will present the correlation of I-V characteristics with water splitting and simultaneous structural changes at the catalytically active sites. For accurate quantitative information and reliability of materials interface in liquid, we will also present strategies to deposit materials of interest in the desired electrodes of liquid cell chips by using an inkjet materials printer. The availability and utilization of photo stimuli in liquid cell TEM can provide important fundamental insights into the understanding of several other photoelectrochemical systems.

References:
Two-dimensional (2D) materials have been extensively studied in recent years due to their unique properties and great potential in energy-related applications, such as hydrogen evolution reaction (HER) and CO₂ reduction reaction (CO₂RR). To gain in-depth atomic-level understanding on the correlation between the catalytic surface and reaction mechanism, we employed ambient pressure X-ray photoelectron spectroscopy (APXPS) to investigate the electronic and chemical properties of Mo₅S₃ interfaces at various environments. Our APXPS data showed a pristine Mo₅S₃ ultrathin film surface exposed to CO₂/H₂O ambient formed several intermediates, including physisorbed (linear form, f-CO₂) or chemisorbed (bent form, b-CO₂) CO₂ states and oxygenate species, such as hydroxyl, formate or carbonate groups. The adsorption configuration of CO₂ (f-CO₂ vs. b-CO₂) depends on the experimental conditions. If we introduced CO₂ then H₂O, more physisorbed CO₂ were detected; in contrast, if H₂O were introduced first then CO₂, more chemisorbed CO₂ were obtained. Identifying the first CO₂ adsorption step is to promote initiation of reaction steps. Furthermore, the valence band offset was also observed due to surface band bending during CO₂ reduction reaction. While CO₂ can induce upward surface band bending due to an acceptor molecule CO₂ has accepted electron from Mo₅S₃ semiconductor surface, co-dosing H₂O into system facilitates the adsorbing molecules to take holes from Mo₅S₃ semiconductor surface, consequently, induces downward band bending on semiconductor surface.

Our APXPS results suggest a strong correlation between the electronic and chemical properties of the material surface during catalytic reaction. The results in this study have added our understanding of the underlying mechanism involved in catalytic reaction, and helped us gain insights in designing and improving CO₂ reduction catalysts.

In Situ Analysis and Simulation of Heat Generation During Charging and Discharging of Ni-Rich Layered Oxide Cathode Gaheee Kim, SAI, Suwon, Korea (the Republic of).

Thermal management and design are very important for lithium-ion batteries (LIBs) to prevent thermal runaway under normal and abnormal conditions such as overcharge and short circuit. In this study, in-situ thermal analysis was performed on LiNiO₂-rich cathode materials. We have investigated the layer structure of a powder sample to determine the phase composition of the material. The thermal behavior of the sample was recorded during the charging and discharging cycles. The results show that the charging and discharging processes are accompanied by changes in the temperature profile of the material. The thermal performance of the battery was also analyzed and compared with the theoretical predictions. The simulation results were in good agreement with the experimental data, indicating the reliability of the simulation approach.

Rapid High Shear Viscosity Measurements Using a Microfluidic Rheometer Matt Vandcn Eynden 1, Thanina Amiar 1, Hubert Ranchon 2 and Gerard Meunier 2; 1Formulation, Inc., Worthington, Ohio, United States; 2Formulaclon, Toulouse, France.

Viscosity is an essential physical property when studying the rheological behavior. However, rheological studies remain a challenging task for many laboratories, as traditional techniques are time-consuming and face to volatility and drying issues. In a new approach to confined, high shear viscosity measurements, a novel microfluidic rheometer is equipped with an enclosed system suitable for volatile and fast drying products, providing viscosity measurements as a function of shear rate and temperature in a single experiment set-up with an excellent precision and accuracy even at very low viscosity values. Visual analysis of a laminar flow interface generated from a reference and an unknown sample allows for viscosity to be measured by taking a picture of the main channel inside the microfluidic chip, using dedicated algorithms to automatically extract viscosity data over a controlled range of shear rates and temperatures. The technology allows flow viscosity measurements of liquid products from water-like to thick formulations using a small amount of product under a wide range of shear rates from 10³ to 10⁶ s⁻¹. In the work, we have analyzed a model blend of two solvents aimed for Li-ion electrolyte batteries at 35 °C consisting of dimethyl carbonate, ethyl methyl carbonate and dissolved lithium salts.

Dopant Profiling Using Low-Voltage SEM for GaN Power Electronics Shantan Reddy Alagubeli 1, Houqiang Fu 2, Kai Fu 2, Hansxiao Liu 1, Yujie Zhao 2 and Fernando A. Ponce 2; 1Department of Physics, Arizona State University, Tempe, Arizona, United States; 2School of Electrical, Computer and Energy Engineering, Arizona State University,
GaN is a material of interest for power electronics due to its high critical breakdown electric field of 3.3-3.75 MV/cm, compared to 0.3 MV/cm for silicon. A typical GaN-on-GaN power device has regions that are doped differently. For example, vertical- junction field-effect transistors (VJFTs) have p-GaN regions as the gate, intrinsic regions as the drift layer, and the n-GaN region as the source and drain. Identifying these regions with a good spatial resolution is critical for the understanding of the device characteristics and failure analysis after malfunction. Dopant sensitive techniques like SIMS, electron holography are destructive and time consuming. Also, SIMS does not have the capability to resolve lateral variations in the layer design.

Low-voltage scanning electron microscopy has been used to study dopant contrast in GaN p-i-n epitaxial structures for power electronics applications. Secondary electron emission intensity is highest from p-layer and lowest from the unintentionally-doped (UID)-layer. Quantification of dopant contrast requires identification of all the parameters effecting the secondary electron emission intensity. In this work, we discuss about the factors effecting the secondary electron emission intensities from p-, i-, and n-type GaN layers. Also, we examine the effect of surface preparation on the dopant contrast. This technique is reliable for dopant profiling in GaN power electronics.

Non-Uniform Mg Doping in GaN Epilayers on Mesa Structures
Hanxiao Liu, Houqiang Fu, Kai Fu, Shanthan Reddy Alugubelli, Yuji Zhao and Fernando A. Ponce
Department of Physics, Arizona State University, Tempe, Arizona, United States; School of Electrical, Computer and Energy Engineering, Arizona State University, Tempe, Arizona, United States.

Gallium nitride (GaN) based power electronics has attracted much attention in recent years due to its advantages over traditional Si-based power devices in terms of energy conversion efficiency, switching speed, operation temperature, and system size. In the fabrication of advanced vertical power devices, such as junction barrier Schottky diodes, superjunction diodes, and normally-off vertical junction field effect transistors (VJFTs), it is important to produce laterally patterned p-n junctions, i.e., alternating n-type and p-type regions arranged in lateral directions. However, the mechanism of selective area doing of GaN is poorly understood. The characterization of the lateral dopant distribution in selectively doped GaN regions is difficult, due to the spatial resolution limitation of secondary ion mass spectroscopy. In this work, selective area p-type doping of GaN on GaN bulk substrates was achieved by etching and epitaxial regrowth. The optical properties of p-GaN epilayers grown on an unintentionally-doped GaN mesa structure have been studied using spot mode cathodoluminescence (CL) and monochromatic CL mapping. A strong variation in the luminescence characteristics has been observed, with the sidewall of the mesa structure being different to the flat upper and lower mesa regions. A comparison with luminescence characteristics of p-GaN films grown with different Mg concentrations indicate that the Mg concentration at the sidewall is significantly lower. The lower Mg concentration at sidewall is attributed to inefficient Mg incorporation of semi-polar growth. This work demonstrates that CL spectroscopy can be used as a nondestructive, contact-free method to probe local p-GaN doping distribution with submicron resolution. The determination of Mg distribution in p-GaN on a mesa structure is important for GaN-based power devices.

Identification of Point Defects in BAIN Using High-Resolution Electron Energy Loss Spectroscopy
Shuo Wang, Katia Mareh, Peter Rez and Fernando A. Ponce; Arizona State University, Tempe, Arizona, United States.

Although there are many techniques that can detect bandgap GaN regions associated with point defects in the lattice, it is not routinely possible to determine the type of defect at submicron spatial resolution. Here we show that high-resolution electron energy loss spectroscopy (EELS) in a scanning transmission electron microscope can locate and identify point defects with a sub-nanometer probe in a wide-bandgap BAIN semiconductor.

Two BAIN thin films of 50 nm thickness were grown by metalorganic chemical vapor deposition on top of AlN templates, with B/(B+Al) gas-flow ratios of 0.12 and 0.18, respectively. In the atomic-resolved high-angle annular dark-field images, the two films exhibit considerable variation in the B concentration. The high-resolution monochromated spectra from the high B concentration BAIN film taken at 60kV show energy losses in the bandgap region. The film with low B concentration has similar energy thresholds, but with lower intensities. These energy-loss thresholds are still detectable in the AlN substrate, although with diminishing intensity as the beam is moved further from the interface, due to the long-range nature of the electromagnetic interaction. Since there is an analytical theory for the spatial variation of the signal as a function of distance between the probe and the dipole, it would be in principle possible to fit this functional form to the observed signal to localize the dipole with nanometer resolution.

To identify the origin of these features, calculations of densities of states with the VASP Density Functional Theory (DFT) code were used to explore whether postulated point defects give rise to states in the band gap, and whether transitions involving these states match experimental observations. VASP DFT calculations were performed using projection augmented wave, local-density approximation potentials for single Al, B and N interstitial atoms, single Al and N vacancies in a supercell constructed from 3x3x2 AlN unit cells. Although the bandgap energy is underestimated as 4.6 eV, it could be argued that the DFT energies for the point defect states are reliable. In our calculations, there are no bandgap states when B is substituted for Al, and the density of states is very similar to that of AlN. In all the other cases the calculations showed states in the band gap, consistent with previous reports on point defects in AlN. The EELS thresholds at 0.39 eV and 0.79 eV respectively, are attributed to B interstitials. It is expected that they would be present in both the high and low concentration B films, albeit with lower intensity in the lower concentration film, given that the solubility limit of B in AlN is reportedly 2.8%. It would seem that other thresholds at 0.53 eV and 0.66 eV, arise from N or Al vacancies, and possibly Al interstitials. Not surprisingly these thresholds attributed to displaced Al and N atoms are more likely in the film with higher B concentration.

In Situ Electron Beam Induced Current STEM Measurements of the Minority Carrier Diffusion Length in n-GaN
Zhao Wareck, Andrew Armstrong, Alec Talin and John Cunning; University of Maryland, College Park, Maryland, United States; Sandia National Laboratories, Livermore, California, United States.

Gallium nitride (GaN) offers several advantages over current silicon based devices, such as temperature applications, high-power electronics, and space-based or other high radiation exposure applications [1]. Measurements of the minority carrier diffusion length in GaN can be studied using cathodoluminescence (CL) or electron beam induced current (EBIC) in a scanning electron microscope (SEM). However, as recently reported in Yakimov et al., the EBIC planar geometry in SEM often leads to an over estimation of the minority carrier diffusion length in n-GaN [2]. This over estimation is attributed to the interaction volume in SEM, which is on the order of hundreds of nanometers to a few microns and within the same order of magnitude as reported minority carrier diffusion lengths of n-GaAs, which are reported to be between a few tens of nanometers to a few microns. Instead of SEM EBIC, we use bulk scanning transmission electron microscopy (STEM) EBIC to measure the minority carrier diffusion length in n-GaN. Our sample consists of a high purity single crystal n-type GaN substrate (275 µm thick) grown by hydride vapor phase epitaxy (HVPE) with a threading dislocation density of ~10^6/cm² and patterned with a nickle Schottky contact as well as an indium ohmic contact. Using a 100 kV or 200 kV accelerating voltage causes the interaction volume in our bulk specimen to be large enough to separate from the minority carrier diffusion length. We then fit the STEM EBIC line profiles in order to determine the minority carrier diffusion length of n-GaN as well as the interaction volume. In addition, we have imaged the growth of the depletion edge during an applied reverse bias, and indirectly measure the depletion width at zero applied bias.

This research was performed at the University of Maryland NanoCenter Advanced Imaging and Microscopy Laboratory. The data was taken on a JEOL 2100F TEM operating at 100kV and 200 kV in STEM mode using a NanoFactory STM-TEM holder.

In Situ TEM Biasing Experiments with Easy-to-Move Mobile Probes
Transmission electron microscopy (TEM) sample holders with biasing capabilities in which a mechanical mobile probe acts like one of the electrodes allow to investigate, simultaneously, the electrical properties of materials and their structural and chemical states, by using the full battery of characterization techniques available in a TEM (high-resolution imaging, electron-based spectroscopy, electron diffraction, etc.). This in-situ biasing microscopy technique has been used to investigate the conductance through rows of metal and carbon atoms [1,2], the switching of resistive memories [3], anode materials for batteries [4,5], etc. Here, we present several examples in where a recently developed in-situ TEM sample holder with a mobile probe was used to bias samples locally and discuss the practical considerations of the technique, with the objective of facilitating the experiments—which can be challenging during the mobile probe mechanical approach to the sample.

Specifically, we discuss how to approach the sample with coarse and piezoelectrically-driven fine movements and how to prepare the mobile probe, inside the TEM column, to obtain a good electrical contact between the sample and the probe prior to the experiment; by “good” we understand contacts without contamination or oxide layers that can disrupt the contact’s intrinsic electronic properties. The sample holder used during these experiments allows to approach the sample with the mobile probe in manual coarse mode with smooth and uncoupled steps of μm (or fractions of μm) among the three spatial axes. Likewise, it allows to do the final contact approach with a piezoelectric controlled mechanism that allows uncoupled nanometer-sized (or less) steps among the three spatial axes. We will present three examples: 1) observation of the Li-alloying process in yolk-shell p-Si nanorods/voids/nitrogen-doped carbon nanostructures relevant for anode materials in Li-ion batteries [4]; 2) the investigation of the high capacity retention of Sr2Te3/C composites relevant for sodium-ion batteries [5]; and 3) the reaction of a solid-sate electrolyte particles under load. These examples illustrate the convenience of this in-situ biasing technique when creating a contact prior to the experiment is difficult.

Exploring the Interfacial Structure in Aqueous Colloidal Tin Dioxide Dispersions
Viktor Mackert, Thomas Winter and Markus Winterer; Nanoparticle Process Technology, Universität Duisburg-Essen, Duisburg, Germany.

Nanoparticles immersed in liquids (i.e. water or electrolyte solutions) change their solid-gas interface into a solid-liquid interface which substantially modifies the surface chemistry of the particles. Consequently, existing surface charges lead to an electrochemical double layer formation around the dispersed nanoparticles. Furthermore, the structure of the electrochemical double layer has a profound influence on reaction kinetics [1]. Many properties and applications of nanoparticles such as ion exchange, adsorption or catalytic reactions rely on the structure of the solid-liquid interface. The solid-liquid interface plays a major role in photocatalytic water splitting, electrocatalysis, solid-electrolyte batteries and fuel cells. SnO2 is a material that finds application as photocatalyst or in lithium ion batteries as anode material. Here, chemical vapor synthesized (CVS) SnO2 nanocrystals are studied with X-ray absorption spectroscopy (XAS) in liquid colloids. The local structural environment of tin dioxide – water interface is analyzed over a range pH values (using HBr and RbOH) and the ionic strength (RbBr) to reveal changes in the interfacial region due to the modified particle-ion interaction at the particle surface. XAS spectra at the Sn K-edge, Br K-edge and Rb K-edge are measured and compared to dry SnO2 nanocrystals.

Designing Perovskite Nanoparticles to Probe Structural Changes During Catalytic Activity by In Situ X-Ray Absorption Spectroscopy
Jeremias Geiss and Markus Winterer; Faculty of Engineering, University of Duisburg-Essen, Duisburg, Germany.

Heterogeneous catalysis of photocatalytically active perovskite nanoparticles like LaFeO3 occurs by the interaction of molecules with active sites of the particle surface. While the crystalline core is resolved using conventional X-ray diffraction (XRD), structural changes of the boundary layer during catalytic activity are accessible by In situ X-ray spectroscopy (XAS) [1]. Since nanoparticles have a high ratio of surface to volume atoms, a large fraction of the measured signal originates from the surface. By Reverse Monte Carlo (RMC) analysis, pair distribution functions can be retrieved from XAS measurements which contain the structural evolution and information of the local structure of the particle and its surface.

To constrain the RMC model, it is important that the initial single particle model closely represents measured particles. Since in situ XAS is an ensemble measurement over thousands of individual nanoparticles, the measured nanoparticles must be phase pure, monodisperse, very small, highly crystalline and dispersible. The requirements of colloidal perovskite photocatalytic nanoparticles for in situ probing of the structure-activity-relationships are discussed and first ex situ measurements using RMC analysis will be presented.

Coupling Operando Electrochemical Mass Spectrometry with Post-Mortem Analysis of Electrodes for Revealing the Degradation Mechanisms of Electrochemical Capacitors During High Voltage Operation
Patryk Przygocki, Paula Ratajczak and Francois Beaugnon; Poznan University of Technology, Poznan, Poland.

Recently, the research on carbon/carbon electrochemical capacitors (ECs) is essentially dedicated to increase their extractable energy which is directly related to the maximum operating voltage of the electrode/electrolyte system [1,2]. Long-time operation at maximum voltage (so-called potentiostatic floating) accelerates ECs ageing, revealed by loss of capacitance, increase of resistance and internal pressure. The worsening of these three parameters is related to carbon surface oxidation and/or pore blockage by electrolyte decomposition products, together with ionic starvation in the electrode due to decrease of electrolyte concentration and gas evolution which entails weakening of the adhesion between the active mass and the current collectors [3,4]. Besides, the surface of the aged positive carbon electrode is modified by new oxygenated groups, while the aged negative electrode is also functionalized, although one could expect that it should not occur at this electrode under reductive conditions. Indeed, H2O2 which is first produced at the positive electrode as by-product of water electrolysis, migrates through the separator towards the negative compartment being then further involved in oxidation of the carbon surface [5].

In this context, it will be shown that it is possible to obtain information about all the realistic mechanisms of ECs ageing as well as to determine the relative impact of each process on the system degradation by using a combination of operando analyses consisting of electrochemical measurements, mass spectrometry and cell pressure records, together with post-mortem surface functionality analysis of individual carbon electrodes by temperature programmed desorption (TPD). On the example of an electrochemical carbon/carbon capacitor in aqueous Li2SO4, the approach is based on assigning the charge passing through the cell under potentiostatic floating (known as leakage current) to the charge: i) spent at each electrode for production of gases (taking into account operando EMS analysis and pressure records); ii) utilized to oxidize the electrodes surface (from post-mortem surface functionality analyses realized by TPD); iii) being redistributed throughout the electrochemical cell (taking into account the steady-state leakage current measurements).
Colossal Transformations in Metal-Organic Frameworks with Ultrahigh Porosity

Stefan Kaskel1,2, Fraunhofer IWS, Dresden, Germany; Chemistry, TU Dresden, Dresden, Germany.

Metal-Organic Frameworks (MOFs) have become promising alternatives for gas storage and sensing applications. However, the ultrahigh porosity of MOFs often results in low structural stability due to the presence of defects and vacancies. In this work, we introduce a novel strategy to fabricate ultrahigh porous MOFs with improved stability by employing a combination of high-temperature synthesis and post-treatment techniques.

Abstract: The synthesis of ultrahigh porous MOFs involves a balance between structural stability and accessibility for gas adsorption. By optimizing the synthesis conditions and applying post-treatment methods, we have achieved the highest reported porosity in MOFs, exceeding 23.4 mA/cm² for CO₂ capture via In Situ DRIFTS Techniques. The characterization of these materials using advanced techniques such as Time-Resolved Thermoreflectance and X-ray Powder Diffraction has revealed unique structural and mechanistic insights into the CO₂ capture process.

Keywords: Metal-Organic Frameworks, Ultrahigh Porosity, CO₂ Capture, In Situ DRIFTS, Time-Resolved Thermoreflectance.

In Situ Measurements of Plasma-Surface Interactions via Time Domain Thermoreflectance—Electron Heating, Surface Cooling and Chemical Reactions in Materials

Patrick Hopkins1, John A. Tomko1 and Scott Walton1; 1University of Virginia, Charlottesville, Virginia, United States; 2U.S. Naval Research Laboratory, Washington, DC, District of Columbia, United States.

The energy flux to a surface during plasma exposure and the associated surface heating are of long standing interest as they contribute to the physico-chemical changes that occur during plasma-based materials synthesis and processing. Indeed, the energy delivered to the surface, via a flux of particles and photons, in concert with a flux of reactive species serves to chemically modify, etch, and/or deposit materials, with an efficacy that depends on the plasma processing environment. A unique feature of plasma synthesis and processing is that most of the delivered energy is absorbed at or very near the surface over short (picosecond) time scales. The dissipation of thermal energy proceeds through electron-electron and/or electron-phonon interactions as they propagate through the material, with relaxation time scales that can be orders of magnitude slower. Typically then, the surface is not in thermal equilibrium with the bulk material. Fast, surface-sensitive techniques are thus required to fully appreciate the dynamics of the plasma-surface interaction.

In this work, we employ pump-probe Time-Domain Thermoreflectance, a surface sensitive technique typically used to measure thermal properties of thin films, to determine electron heating of thin metal films during exposure to an atmospheric pressure plasma jet. The results, in conjunction with current measurements, are used to develop a first order understanding of plasma jet-surface interactions. The results show that the energy delivered by the plasma jet causes a localized increase in electron energy within the thin film over an area commensurate with the plasma jet radius. We also describe measurements in which we monitor the temperature evolution of the surface during plasma exposure and plasma excitation, demonstrating both heating and cooling due to chemical changes to the surface.

Jonathan Holmér1,2,3,4, Lubjana Zeng1,2,3,4, Thomas Nordkvist2, Peter Kroegstrup2, Jesper Nygård2, Ludvig de Knop1 and Eva Olsson1; 1Chalmers University of Technology, Gothenburg, Sweden; 2Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark.

Semiconductor nanowires are promising building-blocks for the next generation of solar cells. With diameters of a few hundred nanometers, vertical nanowires can act as waveguides for the incoming sunlight and thereby enhance the light absorption. The nanowire geometries further enable the growth of defect-free heterostructure interfaces including also defect-free growth on lattice mismatched substrates, not possible for bulk structures due to the magnitude of interfacial strain. Because of these and other unique properties, nanowire-based solar cells have the potential to provide higher efficiencies and lower material costs than their thin-film counterparts. One of the main challenges for realizing these high-performance nanowire solar cells lies in the optimization of the electrical and photocatalytic properties at the individual nanowire level. Here characterization techniques play a vital role. Standard solar cell characterization methods do not reveal the contribution of individual nanowires. Techniques involving single nanowire lift-off after the working conditions, do not include the effect of the nanowire/substrate interface and generally demand a great deal of sample preparation. Hence, techniques where single nanowires can be probed directly on the growth substrate are advantageous.
In this work, we have developed a technique where a scanning tunneling microscope (STM)-probe is operated inside a scanning electron microscope (SEM) for characterization of the photovoltaic and electrical properties of single as-grown semiconductor nanowires. The SEM provides live imaging with nanoscale resolution while the piezo-controlled STM-probe contacts individual nanowires forming a closed electrical circuit. Reproducible ohmic contacts between the STM-probe and the nanowires were established through electron beam induced Pt deposition and Joule heating. Photocurrent measurements were enabled by mounting a light emitting diode (LED) in the SEM chamber. Current – voltage (I-V) measurements in both dark and illuminated conditions were performed on single GaAs nanowires with built-in radial p-n junctions. The best performing nanowire had an apparent power conversion efficiency of around 11 % under white LED illumination. Electron beam induced current (EBIC) maps were recorded to show the local charge separation ability within a nanowire with a spatial resolution of around 250 nm. Furthermore, the STM-probe was used to bend single nanowires, which affected the I-V characteristics. In conclusion, in situ STEM-SEM technique offers the possibility to investigate and compare the functional properties of individual as-grown nanowires that are part of a nanowire solar cell. The properties can be directly linked to the structure of the individual nanowires. This may play a key role in the further improvement of nanowire solar cells.

In Situ Transient Absorption Spectroscopy During Materials Formation Cathy Y. Wong; University of Oregon, Eugene, Oregon, United States.

In situ diagnostics can yield fundamental insights into the materials formation process and aid in the design and optimization of materials for energy technologies, but in situ measurement has not been widely adopted for many time-resolved spectroscopic measurements. In particular, transient absorption (TA) spectroscopy can reveal the kinetic pathways of photoexcited species that dictate materials function, but TA is rarely performed in situ during materials formation. In TA a pump pulse photogenerates electronic excitations in the material, and the differential absorption caused by these excited species is measured by a probe pulse after a controlled delay time. The measurements at each delay time are typically collected in series, resulting in data acquisition times from many minutes to multiple hours. Many materials undergo formation processes on a shorter timescale than the data acquisition time for TA, precluding the accurate measurement of excited state dynamics in these systems. In this work, we introduce a novel implementation of transient absorption spectroscopy that can measure transients with up to a 60 ps pump-probe time delay in one shot. Data with an excellent signal-to-noise ratio can be acquired in just a few seconds. The measurement is validated by comparison to typical implementations of TA in static systems, and we report the results of in situ measurements during the formation of materials with applications in photovoltaics and light emitting devices. The information gained using this technique will be used to modify environmental parameters during the materials formation process to steer the material towards kinetically trapped states with excited state dynamics tailored for particular types of devices.

In Situ Studies of Ion Transport in Electrolyte and Electrolyte/Lithium Interfacial Reactions Yuan Yang; Columbia University, New York, New York, United States.

The interface of lithium/ electrolyte is critical to the performance of lithium metal anode and next-generation batteries. The interfacial reaction is affected by the metallic lithium, SEI together with ion transport in the electrolyte. While numerous studies have been carried out to study SEI and lithium metal, little attention has been paid to ion transport in the electrolyte, since it is extremely difficult to visualize. In this talk I will first discuss how to use an ultrafast Stimulated Raman Scattering microscope to visualize ion transport in the electrolyte, which illustrates positive feedback between ion concentration in the electrolyte and the growth of lithium dendrite. Besides visualizing ion transport in electrolyte, interfacial reaction between LATP ceramic electrolyte and lithium metal is also studied in-situ by TEM. We show that a BNA nanoscale coating layer is highly effective to prevent the side reaction between lithium and lithium metal. The impedance of Li/BN/LATP/Li cell only increases by 70% after 400 hours. In contrast, Li/LATP/Li cell impedance increase by three orders of magnitude after 400 hours. Consequently long term cycling is achieved in LiFePO4/LATP/Li metal battery with trace amount of PEO to wet the interface. The capacity retention reaches 95% over 100 cycles.

Tracking the Underlying Redox Mechanism in Na2FePO4 Pyrophosphate Cathode for Sodium-Ion Batteries Ritambhara Gond and Prabeer Barpanda; Indian Institute of Science, Bangalore, India.

Rechargeable batteries presently govern the energy sector for potable electronics, hybrid vehicle and large scale grid storage devices. There are plethora of electrode materials have been reported to intercalate charge carrier species (Li, Na, K, etc.). 3d transition metal oxides, including layered LiCoO2, Li4Ti5O12, and olivine LiFePO4 exhibit good rechargeability and considered among the best cathodes for Li-ion batteries (LIBs). LiFePO4 has driven interest towards polyaminic materials for battery application due to its robust and safe cathode chemistry towards LIBs. There is no doubt that LIBs exhibit high energy density but due to its scarcity and non-uniform geographical distribution it needs to be complemented with similar chemistry. This has led researchers to find cheap and abundant material which is Na for large scale energy storage devices. Thus electrodes for Na-ion batteries (SIBs) need to be developed for sustainable energy storage. Which demands for more efficient, less hazardous and safer electrodes. In the race of developing novel and safer cathode material for LIBs and SIBs “pyrophosphate-based” polyaminic compounds has rekindled scientific attention.[1,2] Based on earth-abundant elements, Na2FePO4 and LiFePO4 can form an economic cathode for grid storage and other applications respectively. Among pyrophosphates, Na2FePO4 and LiFePO4 has been reported as a low cost cathode with promising electrochemical performance and thermal stability.[3,4] Na2FePO4 has triclinic (space group: P-1) and LiFePO4 has monoclinic (space group: P21/c) structure, where each corner of FeO6 octahedra is bridged to PO4 tetrahedra. In particular, in Na2FePO4 during the galvanostatic charge-discharge, reversible desodiation reaction occur between pristine Na2FePO4 and desodiated NaFe2+PO4 end-members involving an Fe3+/Fe2+ redox reaction. During this redox process, it goes through various mixed-valence intermediate compositions [Na2+xFe2-x+xPO4 , x = 0-1] followed by steady structural ordering/reorientation. These intermediate stages can be traced with a combination of electrochemical techniques and in-situ X-ray diffraction technology.[5] Here, in this present work the underlying redox mechanism has been studied by preparing a custom-made in-situ cell, able to perform both in reflection and transmission mode. Combustion made pristine Na2FePO4 was taken for the electrochemical testing which was prepared using Ferric nitrate (III) precursor. Carbothermal reduction was done using Ascorbic acid (for reduction of Fe3+ into Fe2+) and Urea fuel. Further, electrodes were prepared and Na half-cell was prepared using 1 M NaClO4 in PC as an electrolyte. In-situ X-ray diffraction patterns were recorded at C/25 rate during electrochemical testing. XRD pattern were recorded for 3624 seconds at an interval of 2 seconds in the angular domain of 9-60°. First peak coming at 10.78° 20 value corresponds to [010], and peak at 45.89° 20 value of [301] plane do not show any change during the sodium intercalation/ de-intercalation from Na2FePO4. Which reveals that these planes do not take part into charge carrier migration. Whereas, [011], [10-1], [01-1], [120] and [122] are the planes which reveals the extraction and insertion of Na-ion. Such observations simply tell the composition variation of Na into Na2FePO4 host during the galvanostatic charge-discharge process. Thus in the present paper we tried to study and track the changes made into the structure during the migration of charge species.

Synchrotron-based soft x-ray spectroscopies, namely soft x-ray absorption (XAS) and emission (XES) spectroscopy, as well as their combination resonant inelastic soft x-ray scattering (RIXS) are powerful techniques to investigate the electronic structure of a variety of systems. We have intensively used these tools for the investigation of applied materials including thin-film solar cells, photoelectrochemical devices, batteries, ... (e.g., [1,2,3]). For these systems, in situ and operando studies are often required to answer the pertinent materials questions necessary for a further optimization of the respective device. Due to the photon-in-photon-out nature of XAS, XES, and RIXS with soft x-rays, it is, in fact, possible to investigate gaseous and liquid samples as well, making such in situ and operando investigations possible. However, since these spectroscopies and the corresponding synchrotron beamline environment usually require ultra-high vacuum (UHV) conditions, this requires the development of sophisticated experimental setups. In this presentation, we will discuss our recent progress in developing suitable environmental cells for in situ and operando soft x-ray studies. Showing selected examples, it will be presented how these techniques give insight into the electronic and chemical properties in the gas and liquid phase, as well as at liquid/solid interfaces. In many cases, the investigated materials are very sensitive to x-ray radiation, which requires careful experimenting with optimized approaches that will be discussed as well.

Systematic Design of High Performance Lithium-Sulfur Battery Using Efficient Polysulfide Adsorbent Porous Host Materials
Tilahun A. Zegeye; Chemical Engineering, National Taiwan University of Science and Technology, Taipei, Taiwan.

Abstract

The need for large-scale energy storage, improved safety, and sustainable transport are driving research into alternative battery technologies with higher specific energies. Rechargeable Li-S batteries have high capacities (1675 mAh g\(^{-1}\)) and theoretical energy densities as high as 2600 Wh kg\(^{-1}\) making them promising candidates for the next-generation of energy storage systems. However, due to its insulating nature, polysulfide dissolution and poor cycle life, it has been challenging to achieve the existing technology requirement.

Herein we choose porous carbon as conducting agent and TiO\(_2\) nanotube as polysulfide adsorbent and forming hybrid nanostructured materials to overcome active material utilization and polysulfide dissolution problems. The porous host materials for sulfur was produced by a low cost, hydrothermal and annealing process with one step green synthesis approach. The process is facile, cheap, scalable and environmentally friendly. The material was characterized and examined by XRD, BET, XPS, SEM, TEM, Raman, TGA, CV, EIS and galvanostatic charge-discharge tests. It is found that the materials are highly porous and show both the characteristics of microporous and mesoporous behavior and contain large pore volume to impregnate large amount of sulfur. Moreover, the microporous carbon can effectively adsorb smaller sulfur (S\(_{2}\)) molecules in their narrow pores with increasing the electrical conductivity of the cathode by decreasing the resistance of sulfur and enhance active material utilization. Meanwhile, mesoporous carbon doped TiO\(_2\) nanotube were placed on the surface to prevent the overflow of sulfur as well as the dissolution of polysulfides in the electrolyte effectively and improve the strength of the entire electrode thereby enhancing the electrochemical performance. As a result, using the porous host-sulfur nanocomposite as a cathode material, we demonstrate excellent cycle stability with initial discharge capacity of 916 mA h g\(^{-1}\) with coulombic efficiency of over 98.6% at a current density of 0.2 C after 140 cycles.

In Situ Synchrotron X-Rays Studies on the Synthesis of Energy Materials for Li-Ion Battery
Jianning Bai; Brookhaven National Laboratory, Upton, New York, United States.

Synthesizing new electrode materials with the desired phases and properties has often found difficult and mostly relies on trial and error since there are a variety of parameters that can have a strong influence on the structural properties (crystal structure, morphology, particle size), and eventually on electrochemical performance (e.g., capacity, rate capability, and durability) of the synthesized materials. Materials synthesis is such a complex process and often undertaken under non-equilibrium conditions, therefore posing a great challenge to theoretical predictions. In-situ, real-time tracking of the structural chemistry evolution during the synthesis reactions can provide details on reaction process, elucidating intermediate phases and how temperature, pressure, time and the precursor concentrations affect the kinetic reaction pathways. Synchrotron X-ray powder diffraction (SXPD), with its high beam intensity and angular resolution, allows in situ structural characterization in short time scales capable of catching subtle structural changes in the materials under synthesis. The presentation will introduce the in situ SXRD techniques developed at NSLS-II, as applied in the study of synthesis processes of cathode materials for Li-ion batteries. Specific examples on different materials and synthesizing methods will be given to show how the insights gained from in-situ studies may provide guidance to rational design and synthesis of new battery materials.

Large Area and Multimodal Study of Li-Ion Batteries with New In Situ Technologies
Stefanie Freitag; Zeiss, Munich, Germany.

In this study it was demonstrated that large area and multimodal in-situ lithium distribution studies and the comparison with the overall performance parameter enable an understanding of the context of batteries. It was shown in a first step that light microscopes allow a fast large area scan and in-situ dendrite grows observation in batteries. By means of an electron microscope with 61 electron beams (MultiSEM) it was then possible to image 1mm by 1mm large area with nanometer resolution, uncovering various material properties within the inspected region. New in-situ technologies like Raman, SIMS and TOF-SIMS laid out correlations between different material conditions and the respective local lithium distribution. In addition, electron beam absorption current (EBAC) experiments allowed a surface resistance and absorption current measurement. These results give direct evidence for material ageing and/or process errors.

In Situ Probing of Anionic Redox in Li-Rich Layered Cathodes
Chong Yin\(^{1,2}\), Bao Qiu\(^{2}\), Jianning Bai\(^{2}\), Zhaoping Liu\(^{1}\) and Feng Wang\(^{1}\); \(^{1}\)Sustainable Energy Technologies, Brookhaven National Laboratory, New York, New York, United States; \(^{2}\)Brookhaven Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China; \(^{3}\)National Synchrotron Light Source II, Brookhaven National Laboratory, New York, New York, United States.

Lithium-rich layered oxides (Li\(_{2}\)M\(_{O}\), Li\(_{1+x}\)M\(_{2+x}\)O\(_{4}\), M=Ni, Co, Mn) are among the most promising high energy cathode candidates for next-generation Li-ion batteries, with excess capacity enabled by both cationic and anionic redox. However, activating anionic redox (AR) may cause voltage hysteresis and voltage decay and so rational design of Li\(_{2}\)M\(_{O}\) of controlled AR activity becomes crucial to practical application. In this presentation, we will present recent results from combined in situ Synchrotron X-ray scattering and absorption studies on the AR activity in Li\(_{1+x}\)M\(_{2+x}\)O\(_{4}\) under operating conditions. Findings from this study, particularly about correlation between AR activity and local structural ordering, along with its implication to rational design of LR layered oxide cathodes will be discussed.
Materials storing energy via alloying reaction are promising anode candidate in rechargeable lithium ion batteries due to their much higher energy density than current graphite anode. Among these materials, bismuth provides a high theoretical volumetric capacity of 3800 mAh/cm$^3$ when it alloys with Li$^+$ to form Li$_x$Bi. Yet, its further development has been hindered by the unclear alloying mechanisms with Li$. In this work, we carry out real-time study of the de-alloying kinetics of Bi nanomaterials working as a Li$^+$ anode combining both in situ synchrotron XRD and in situ TEM. In situ synchrotron XRD reflects the phase transition information of the ensemble of many Bi nanoparticles, while in situ TEM demonstrates the structural evolution of single Bi nanoparticle at both high spatial resolution and high temporal resolution. Both two methods reveal that the Li-Bi alloying is a two-step process featuring two two-phase reactions with formation of Li$_x$Bi as the intermediate phase. More importantly, our work reveals an energetically favorable lithiation pathway along Bi-(012) planes during the Bi-Li phase transition process, which is further theoretically understood by DFT calculations. The fundamentals discovered in this work are expected to further guide the design of Bi-based electrode materials for battery performance enhancement in the future.

High-Ni transition metal layered oxides are among the most promising cathodes for Li$^+$-ion batteries. Their electrochemical activity is largely determined by the cationic ordering in octahedra (i.e., the basic building units, BBUs, of the systems). Therefore, mechanistic understanding of how the BBUs are inherited from precursors and subsequently evolve into the desired ordering during synthesis, may provide guidance to preparation of high-performance high-Ni layered oxides. Herein, a multimodal in situ x-ray characterization approach is employed to investigate structural/chemical evolution at scales ranging from very long range to the local individual octahedral units during solid-state synthesis of LiNi$_{0.5}$Mn$_{0.5}$O$_{2}$/Co$_{0.5}$O$_{2}$. Real-time observation corroborated by first-principles calculations reveals a topotactic transformation throughout the entire process, during which the breaking and reconstruction of NiO$_6$ octahedra occurs, leading to Li/Ni mixing and ordering. Findings from this study shed light on designing high-performance layered oxide cathodes and, broadly, various functional materials through synthetic control of the constituent BBUs.

Neutron and synchrotron x-ray facilities are indispensable scientific resources and provide powerful instruments and experimental techniques for both fundamental and applied researches. Neutrons and X-rays interact with matter in different ways, thus are often used as complementary tools for studying materials at the electronic, atomic and molecular levels. We have been utilizing neutron and synchrotron techniques to investigate a variety of materials for energy storage applications. In this talk, we will discuss the difference and similarity of neutrons and synchrotron x-rays, and their complementary use in battery materials research. We will present our recent results on in-situ/operando characterization of advanced materials for rechargeable batteries, from material synthesis to characterization. We will also discuss some challenging issues in battery materials characterization.

Neutron and synchrotron X-ray studies provide a unique insight into the materials' properties that are not easily accessible by other conventional techniques. They can provide information on the atomic scale, the structure and dynamics of materials, and their changes under various conditions. In this talk, we will present examples from our recent work on battery materials. We will discuss the strengths and limitations of neutron and synchrotron techniques, as well as the challenges and opportunities in the field.

References
chemical-vapor-deposition process. The 3D Graphene gives not only conductivity to electrode but also the effect of controlling electric potential for inhibition of solid-electrolyte interphase formation. With these properties, a solid-electrolyte interphase forms on the outer surface of the graphene, while solid-electrolyte interphase-free nanowires enable fast electronic and ionic transport, as well as strain relaxation over 2000 cycles, with 84% capacity retention even at ultrafast cycling (>20C). Moreover, these anodes exhibit high rate capabilities with capacity retention higher than 88% at 80C (vs. the capacity at 1C).

Proving Structural Evolutions of Silicon Anode in an Advanced Li-Ion Batteries Using In Situ Synchrotron X-Ray Studies Sungwon Lee1, Sung Sik Lee1, Jaewook Lee2 and Randall E. Winters1; 1Argonne National Laboratory, Lemont, Illinois, United States; 2LG Chem Ltd, Daejeon, Korea (the Republic of).

A major limitation to the advanced lithium ion batteries with silicon based anode is the huge volume expansion during lithiation, which leads the breakdown of the electrode structure, a low initial columbic efficiency and capacity fading upon cycling. A number of approaches, such as downsizing the silicon structures, modifying the structures with nanowires or porous matrix or making SiC composites have been performed to reduce the volume expansion phenomena. However, several critical issues such as un-satisfactory cyclability and the capacity decay still could not be avoided despite the prolonged cyclic life of Si anode. In present work, a synchrotron radiation based x-ray spectroscopic techniques with in-situ/operando capabilities were conducted to elucidate the structural evolutions of silicon anode upon electrochemical reactions in real time. Mg-doped SiO/C anodes were employed as a target material since they have revealed the excellent capacity retention. The results demonstrate that in-situ/operando x-ray characterization techniques provide the unique information for understanding the real reaction mechanism.

The Visualization of Single Grain Evolution in Operando Cathode Materials with the Coherent Hard X-Ray Diffraction Lixu Li1, Ross Harder1, Yingying Xie2 and Evan Maxey1; 1Argonne National Laboratory, Lemont, Illinois, United States; 2Shanghai Jiao Tong University, Shanghai, China.

As the in-situ X-ray powder Diffraction has become a routine method to characterize the crystal structure of battery particles under operando condition, it reflects the assemble average of all fundamental particles in the X-ray illumination volume. However, the local behavior remains a mystery until Ulvestad et al. [1] first applied Coherent X-ray Diffractive Imaging on a single LiNi0.5Mn1.5O4 nanocrystal under operando condition. The application of the Coherent Hard X-ray Diffraction in Bragg geometry enable us to visualize the structural, morphological and strain field evolution of crystals in operando battery materials. Coherent multi-crystal diffraction provides collective information of tens of crystals that bridges the statistical and individual behaviors of battery particles. In this presentation, Coherent Hard X-ray Diffraction experiment is demonstrated with a layered cathode material under operando condition [2]. I will show in details the fundamentals of Coherent X-ray Diffraction, the sample screening, instrumentation, data acquisition and interpretation.

X-Ray Spectroscopic Studies of Energy Storage Systems Mahalingam Balasubramanian and Jason Croy; Argonne National Laboratory, Lemont, Illinois, United States.

There is significant interest worldwide to develop new battery systems for transportation and grid-storage applications. Development of new transformational technologies will require tailoring advanced materials and incorporating additional chemical or electrochemical processes. Using X-ray absorption, X-ray emission, and X-ray Raman spectroscopy, we seek to capture the fine details of the redox behavior (electronic structure) and the complex local structure of battery materials under device operating conditions. Such studies provide unique insight to develop structure-property correlations that are important to predict long-term battery performance and also help tailor new novel materials with high energy and power densities and stable crystal structures. In this talk, we will discuss operando studies of battery systems performed at the Advanced Photon Source.

2:00 PM CP03.07.02
In Situ XAS Studies of Layered Double Hydroxide Catalysts for Electrochemical Oxygen Evolution Reaction Maoyu Wang and Zhenxing Feng; Oregon State University, Corvallis, Oregon, United States.

In the past decades, renewable energy storage and conversion systems, such as fuel cells, water electrolysis, and metal-air batteries, have attracted great attention. Oxygen evolution reaction (OER) is a key half reaction of water splitting to produce clean fuels. However, the sluggish kinetics of OER has significantly limited the performance and commercialization of such energy conversion devices. Up to now, the most efficient OER catalysts are still noble metal and metal oxides of Ruthenium (Ru) and Iridium (Ir), which are not cost-effective catalysts and unstable under high potentials. Recently, single atom catalysts have been used to improve the surface-to-volume ratio to increase OER catalytic activity. In our work, we used layered double hydroxides (LDH) known as anionic or hydroxolate-like clays, which are inexpensive but are good catalysts or support for single atom catalyst to exhibit much improved OER activity. In particular, we utilized in situ XAS to identify the catalytic active centers. In our in situ works also provide insights into the mechanism of these catalysts during OER.

2:15 PM CP03.07.03
Laboratory-Based Hard X-Ray Photoelectron Spectrometer for the Study of Advanced and Complex Materials Anna Regoutz1, Manfred Mascheck2, Tomas Wiel1, Susanna Eriksson1, Cristopher Liljenberg1, Kornelius Tetzner1, Benjamin A. Williamson3, David O. Scanlon4 and Paul Palmgren1; 1Imperial College London, London, United Kingdom; 2Scienta Omicron, Uppsala, Sweden; 3University College London, London, United Kingdom.

The success of material discovery and engineering is partly based upon the development and application of highly advanced characterisation methods. Hard X-ray photoelectron spectroscopy (HAXPES) has traditionally found its application in the core topics of condensed matter physics, but the slowly growing number of beamlines worldwide has widened its appeal to other interest groups. HAXPES uses x-rays in the 2-10 keV range to excite photoelectrons, which are used to non-destructively study the chemical environment and electronic structure of materials. As its soft X-ray counterpart (SXPS or simply XPS) it delivers qualitative and quantitative information on elemental distributions, chemical states, and electronic structure.

In contrast to the very surface-sensitive XPS, HAXPES is much more bulk sensitive. This makes it applicable to bulk materials and structured samples, e.g. layered samples and heterostructures. In addition, its bulk sensitivity means that realistic experiments can be investigated without the need of prior surface preparation. Furthermore, results can easily be correlated to a whole range of other bulk-sensitive characterization results, and therefore to structural information and material properties. However, the number of existing HAXPES systems is very small and they are predominantly located at synchrotrons (approx. 20 beamlines worldwide) due to low photonization across sections necessitating high X-ray intensities, limiting their availability to users and applications.

This work presents a new laboratory-based instrument capable of delivering monochromated hard x-rays with an energy of 9.25 keV and a focused 30x45 μm² X-ray spot, giving excellent energy resolution of <0.5 eV. Systematic reference measurements are presented outlining the systems capability, including energy resolution, X-ray and signal intensity, and stability. Results from a rutile TiO₂ bulk sample show the wide range of possible signals that can be collected, such as shallow and deep core levels, Auger lines, and valence bands. The valence band measurements are benchmarked against theoretical results from density functional theory. Furthermore, pure bulk measurements a range of metal oxide
ultimately, this spectrometer presents an alternative to synchrotron-based endstations and will help to expand the number and range of HAXPES experiments performed in the future. HAXPES is a cutting edge characterisation method and the advancement of this technique will tremendously increase the potential to study an ever increasing range of inorganic materials and beyond.

In Situ Determination of Active Species and Active Sites in Water Gas Shift Reaction Over Pt/\text{CeO}_2 Catalysts

Yuyuan Li\textsuperscript{1}, Matthew Kottwitz\textsuperscript{2}, Ralph Nuzzo\textsuperscript{3} and Anatoly Frenkel\textsuperscript{1,3}; \textsuperscript{1}Materials Science and Chemical Engineering, Stony Brook University, The State University of New York, Stony Brook, New York, United States; \textsuperscript{2}Chemistry, Brookhaven National Laboratory, Upton, New York, United States.

Determining the structure of active species and active sites, and their evolution in reaction conditions is a required step towards understanding catalytic mechanisms. In heterogeneous catalysts, multiple species of the same element: single atoms, larger clusters and nanoparticles may appear, disappear and coexist during the reaction. There is therefore a strong need to monitor the charge and geometry of metal centers, as well as their dynamic changes, in reaction conditions. Even with that capability achieved, the reaction mechanism may not be understood until it is known which species are catalytically active, and which ones – spectators. One possible way to address that is to combine multiple in situ probes that can resolve between the heterogeneously distributed species with the online product analysis. This combination will correlate the changes in the spectra (and thus – in the structure) with the changes in activity and thus help identify the active species during the reaction.

To illustrate these ideas, and highlight an exemplary application of this multimodal approach I will show how we treated the complexity of a newly synthesized and highly active selective oxidation catalyst, a model single atom catalyst formed by the dilute substitutional doping of Ceria by isolated Pt atoms, (Pt)\text{CeO}_2. Among the techniques chosen for its characterization, STEM probes the distribution of single atoms and nanoparticles in the sample, in situ XANES and EXAFS probe the local structure around metal atoms/ions, XPS and RIXS – their charge states, DRIFTS – surface composition, and online MS – product formation. We used this multimodal approach to reveal the correlation of the number of Pt\textsuperscript{4+} ions in Pt/\text{CeO}_2 catalysts with the observed change in the water-gas shift reaction activity—data definitively establishing that Pt nanoparticles formed during the reaction, and not the Pt single atoms, are the active species. The Pt atoms on the nanoparticle perimeter with proximate Ceria bonding interactions comprise the catalytically active sites.

Unveiling Site-Selective CO Disproportionation Mediated by Electron Beam Excited Localized Surface Plasmon Resonance

Wei-Chung D. Yang\textsuperscript{1,2}, Canhui Wang\textsuperscript{1,2}, Henri J. Lezec\textsuperscript{1} and Renu Sharma\textsuperscript{1}; \textsuperscript{1}Physical Measurement Laboratory, National Institute of Standards and Technology, Gaithersburg, Maryland, United States; \textsuperscript{2}Maryland NanoCenter, University of Maryland, College Park, Maryland, United States.

Optically-excited localized surface plasmon (LSP) resonances have been used to induce chemical reactions, such as hydrogen dissociation, water splitting, and ethylene epoxidation\textsuperscript{1}. Energy harnessed by plasmonic nanostructures and transferred to adsorbed reactants on nanostructure surfaces initiates chemical processes that compensates for the thermal energy required otherwise. However, sub-particle level information, regarding the relevant LSP resonance modes and their response to reactants, has not been identified by variants of optical spectroscopy.

Herein, we use a focused electron beam in an environmental scanning transmission electron microscope (ESTEM) to excite LSP resonances on triangular Au nanoparticles on TiO\textsubscript{2} support to drive CO disproportionation at room temperature (commonly driven by thermal energy at 400 °C to 600 °C), and the carbon product labels the catalytically active site at the sub-particle level. ESTEM, operated at 80 kV and equipped with a monochromated electron source with an energy resolution of 0.08 eV, was used to acquire in situ low- and core-loss electron energy loss spectroscopy (EELS) maps to spatially resolve both LSP mode distribution (low-loss EELS) and gas adsorption sites (core-loss EELS) on a Au nanoparticle by comparing the data collected in vacuum and CO environment. The optimal electron beam position to excite specific LSP resonance modes on the Au nanoparticle can be identified by applying the non-negative matrix factorization (NMF) to a low-loss scanning transmission electron microscopy (STEM) EELS map\textsuperscript{2}. We found a dipole mode that resulted in the maximum LSP electric field can be excited by placing electron beam at an aloof position outside the cantilevered nanoparticle corner (near-field excitation). This dipole mode displayed a spectral blue-shift in the presence of CO (P\textsubscript{CO} = 110 Pa) and returned to the original resonance energy when CO is evacuated. More importantly, STEM cathodoluminescence (CL) measured simultaneously with EELS allowed us to probe the scattering from the Au nanoparticle in either vacuum or CO environment, which can be used to apprehend the absorbed energies by the Au nanoparticle during the LSP induced chemical process.

A core-loss STEM-EELS map acquired at P\textsubscript{CO} = 110 Pa, showed increased carbon K-edge signal at the selective locations on the nanoparticle edges, which can be related to CO adsorption. By either raster-scanning an electron beam over the Au nanoparticle or deliberately placing it statically at an optimal near-field excitation position in CO environment, the electric field of excited LSP mode can drive disproportionation of the adsorbed CO molecules in the vicinity and deposit amorphous carbon at the cantilevered corner. The location of carbon deposit suggests that the catalytically active sites on Au nanoparticles are those where preferred CO adsorption sites and locations of maximum LSP electric field magnitude (resonance antennas) superimpose. Our findings provide, for the first time, detail experimental information on sub-particle localization of plasmonic catalysis with nanometer scale precision and possible guidelines to develop antenna based plasmonic catalysts.

X-Ray Absorption Study on Iron(III)Acetylacetone Vapor and Nanoparticles Produced from It

Oleksandr Levish and Markus Winterer; Nanoparticle Process Technology, Universität Duisburg-Essen, Duisburg, Germany.

Iron containing nanoparticles exhibit a broad spectrum of applications due to a large variety of chemical (e.g. redox potential) and physical properties. Those are highly depending on the oxidation state and crystal structure. Different phases and morphologies can be achieved by changing the nanoparticle synthesis parameters [1]. Chemical vapor synthesis (CVS) is a technique which enables reproducible synthesis of nanoparticles with reliable control of synthesis parameters. Organometallic compounds are used to introduce metals into CVS reactor. Solid precursors offer easier handling, mostly lower toxicity and are advantageous for adjusting gas redox potential through a higher carbon content. Iron(III)acetylacetone (Fe(acac)\textsubscript{3}, Fe(C\textsubscript{5}H\textsubscript{7}O\textsubscript{3})\textsubscript{3}) is such solid precursor used for CVD (chemical vapor deposition) and CVS to generate iron containing nanoparticles. However, due to a higher molecular mass and intermolecular interaction, the volatility of Fe(acac)\textsubscript{3} is relatively low, still it needs to be sublimated to deliver it as vapor to CVD and CVS processes. In fact, only little is known about the local and electronic structure of Fe(acac)\textsubscript{3} vapor.

In this study we designed a novel vapor cell for measuring vapor species in the gas phase. With this vapor cell Fe(acac)$_3$ vapor is successfully provided for XAS (X-ray Absorption Spectroscopy) measurements under fluorescence detection. We investigate Fe(acac)$_3$ vapor in-situ at the Fe-K edge using the vapor cell at conditions close to those in the reactor. We compare these data to solid Fe(acac)$_3$ and Fe(acac)$_3$ in solution (water, isopropanol and acetone). Additionally, we investigate nanoparticles made from Fe(acac)$_3$ under different synthesis conditions by XAS. This enables a better understanding of processes occurring in the CVS systems using iron as a probe.

In Situ X-Ray Absorption Spectroscopy Studies of Catalysts in Electrochemical Reactions Zhenxing Feng; Oregon State University, Corvallis, Oregon, United States.

Electrocatalysis plays a key role in producing/converting molecular energy carriers and metal to either store electricity from solar or wind energy in chemical forms or produces electrical energy through fuel cells and metal-air batteries. In the search of highly efficient electrocatalysts, it is important to understand how catalysts work, then subsequently a rational design rule can be provided. We use several in-situ synchrotron X-ray techniques, particularly X-ray absorption spectroscopy (XAS), to probe the element-specific changes from heavy metal (e.g., Mn, Co, Fe, etc) to light element (e.g., O, N) during various electrochemical reactions including CO$_2$ reduction and oxygen evolution/reduction reactions. We not only directly observe how catalysts adjust their local structures and valence state to promote reactions, but also identify different reaction centers that weren’t considered before and couldn’t be found from ex situ experiments. In my talk I will show couple of cases to highlight the importance of our in situ studies as well as new thoughts for catalyst designs.

SESSION CP03.09: Small Angle Scattering, Ion Scattering and Related Methods

8:30 AM *CP03.09.01
Exploring Pore Formation of Atomic Layer-Deposited Overlayers by In Situ Small Angle X-Ray Scattering Tao Li1,2,1; Argonne National Laboratory, Downers Grove, Illinois, United States; 2Chemistry & Biochemistry, Northern Illinois University, DeKalb, Illinois, United States.

In this presentation, we explore the pore structure of overcoated materials by in situ synchrotron small-angle (SAXS) and wide-angle X-ray scattering (WAXS). Thin films of aluminum oxide (Al$_2$O$_3$) and titanium dioxide (TiO$_2$) with thicknesses of 4.9 and 2.5 nm, respectively, are prepared by atomic layer deposition (ALD) on nonporous nanoparticles. In situ X-ray measurements reveal that porosity is induced in the ALD films by annealing the samples at high temperatures. Moreover, this pore formation can be attributed to densification resulting from an amorphous to crystalline phase transition of the ALD films as confirmed by high-resolution X-ray diffraction and the pair distribution function. Simultaneous SAXS and WAXS results show not only that the porosity is formed by the phase transition but also that the pore size increases with temperature.

9:00 AM CP03.09.02
In Situ Small-Angle X-Ray Scattering Observation of Electrophoretic Deposition at the Nanoscale Viktor Mackert and Markus Winterer; Nanoparticle Process Technology, Universität Duisburg-Essen, Duisburg, Germany.

Electrophoretic deposition (EPD) is a colloidal forming process which may be described by two steps: (1) migration of charged particles in an electric field due to electrophoresis and (2) deposition on a substrate working as electrode. Nevertheless, due to a lack of in-depth mechanistic understanding of the film deposition and formation process control of the film microstructure remains still a challenge. Generally accepted is that particle agglomeration plays an important role during deposition. Recent studies investigated ligand-stabilized nanoparticles in organic solvents during EPD with small-angle X-ray scattering [1, 2]. We investigate the EPD process of chemical vapor synthesized (CVS) SnO$_2$ nanocrystals. Purely electrostatic stabilized colloidal SnO$_2$ nanocrystals in aqueous media are deposited on silicon anode due to their high negative charge in an X-ray transparent liquid EPD cell. We use synchrotron radiation based small-angle X-ray scattering (SAXS) in situ in the near electrode region. This approach allows to study structural changes like radius of gyration, fractal dimension at the nanoscale during EPD by probing locally with high spatial resolution (nanobeam) time dependent at the local electrode environment (200 – 3200 nm).

Advanced Setups for In Situ Growth and Characterization of Materials by Ion Beams Tuan T. Tran1, Barbara Bruckner1, Karim Kantre2, Marcos Moro2, Mauricio Sortica2, Silma Correa1, Svendja Lohmann1, Valentina Paneta1 and Daniel Primetzhofer1,2; 1Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden; 2Tandem Laboratory, Uppsala, Sweden.

The Ion Physics group and the Tandem laboratory at Uppsala University have recently developed substantial infrastructure for in-situ film deposition, modification and high-resolution characterisation using ion beam-based methods, by set-ups located at three separate accelerators: a 5 MV Pelletron Accelerator, a 350 kV ion implanter/medium-energy-ion-scattering (MEIS) system and a 10 kV Time-of-Flight low-energy-ion-scattering (ToF-LEIS) system. For example, the 6th beam line of the Pelletron Accelerator features an analytical chamber equipped with a triple-electron-beam evaporator, an ion source used for sputtering, a solid state detector, an X-ray detector and a pure germanium detector used for a series of ion beam characterisation techniques: Rutherford backscattering spectrometry (RBS) providing depth profiles of targets constituents with down to 20 nm depth resolution, nuclear resonance analysis (NRA) and particle-induced X-ray emission (PIXE). Additionally, different gases, such as hydrogen and oxygen, can be introduced into the chamber during thin-film growth or beam exposure [1]. The sample temperature can be controlled from cryogenic levels up to typical values 600 °C during or after the growths. A fully independent load-lock chamber can be detached and transferred to the MEIS system for further analysis without exposing the film to air. For the MEIS system, the operational energies range from 20 kV to 350 kV, enabling high-resolution near surface analysis [2]. Scattering data can be acquired by two independent ToF-position-sensitive detectors. One system features a large solid angle (0.25 sr), suitable for acquisition of blocking pattern permitting to study depth-resolved crystallographic properties in real space. The other detector features smallersolid angle (0.02 sr), but is situated at larger distance from the sample in order to achieve superior depth resolution (typically ~5 Å). The sample holder can be heated up to 600 °C for in-situ annealing experiments. Finally, for the LEIS system, the main analytical potential is to grow and investigate ultra-thin films in a regime very close to the sample surface (few monolayers). An ultra-high vacuum sample preparation chamber connected to the LEIS system features a triple-electron-beam evaporator, an annealing stage, a sputter gun mainly used for surface cleaning prior the measurements, low-energy-electron-diffraction and Auger electron spectroscopy.

Cluster Tool for In Situ Processing and Comprehensive Characterization of Energy Materials at High Temperatures Matthias Kräuse1, Robert Wenisch1, Frank Lungwitz1, Irene Hera2, Daniel Janke1, Ibon Azkon1, Ramon Escobar Galindo3 and Sibylle Gemming1, 3. 1 Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany; 2 Department of Applied Physics, University of Salamanca, Salamanca, Spain; 3 IMEMYAT, Universidad de Cádiz, Puerto Real, Spain; 3 Technische Universität Chemnitz, Chemnitz, Germany.

In situ processing and comprehensive characterization is essential for design and development of materials used and processed at high-temperatures. Here, a new cluster tool for processing and depth-resolved compositional, structural and optical characterization of layered materials with thicknesses ranging from sub-nanometer up to 1000 °C is described [1]. The implemented techniques comprise magnetron sputtering, ion irradiation, Rutherford backscattering spectrometry, Raman spectroscopy and spectroscopic ellipsometry. The combination of techniques enables sample processing by cold, clean, waste-free, and industry-relevant technologies, quantitative depth-profiling for elements with z ≥ 6, structural and chemical characterization, sensitivity and nm-precise thickness and optical information for single layers, multilayers and composites. In this study, the cluster tool was used for i) metal-induced crystallization with layer-exchange of a-Si/Ag layer stacks, and ii) for high-temperature characterization of two types of solar-selective coatings for concentrated solar power (CSP), namely Al,Ti,(O,N)x-y (O,Ru)z single and multilayer [2, 3] and an n-type doped solar-selective transparent conductive oxide [4]. Starting with an a-Si/Ag bilayer stack, metal-induced silicon crystallization with partial layer exchange occurs at about 540 °C. The final stack is approximately described by the sequence crystalline Si (c-Si)/Ag/c-Si. All the layers contain minor fractions of the other elements. Moreover, the Si volume fraction comprises approximately 10 % of amorphous Si. For the CSP coatings, no compositional and structural changes were found up to a maximum temperature of 840 °C in vacuum. Both types of solar-selective coatings thus represent promising materials for the next generation of CSP technology.

With theoretical specific capacity of 1672 mAh/g and specific energy of 2600 Wh/kg and practical specific energy of 500 Wh/kg demonstrated recently, values that are highest among all solid elemental redox couples, rechargeable Li-S batteries are regarded as the next step in emerging “green” electrical energy storage technology revolution to replace Li-ion batteries [2020-2025] for applications in transportation (EVs), national security (UAV, UGV), communications, potable electronics, etc. Produced using abundant, environmentally friendly nontoxic materials, light-weight high-energy density Li-S batteries also offer the possibility of significantly reduced cost. The continuous quest for better, high-performance batteries is currently targeting novel Li-S chemistries, shifting R&D efforts towards battery architectures with optimally engineered functional interphases which offer longer cycle life and high rate capabilities. Despite recent advances, more efforts should be applied to achieve the requisite performance, lifetime and reduced cost needed for new battery technologies to enter the market.

For a long time, practical implementation of Li-S technology has been hindered by poor rate capability and short cycle life due to deleterious effects caused by Li polysulfide redox processes. In the past, new battery technologies to enter the market. highly-localized Angstrom-scale source to locally excite molecular vibrational resonances. Plasmonic nanoparticles amplify the process and enable molecular-scale Raman mapping. Finite difference time domain simulations of molecule-decorated gold nanorods show that laser pump intensities less than 3mW/µm² can locally enhance the Raman peak, with sub-2nm resolution of molecular fingerprints. Experimentally, we synthesize colloidal gold NRs functionalized with 4-Nitrophenol (4NTP) as a Raman reporter. Upon electron beam excitation of the nanorod plasmon modes, we observe a ten-fold increase in the Raman intensity of the 1335cm⁻¹ and 1579cm⁻¹ lines of the 4NTP molecule. Monochromated electron energy loss spectroscopy (EELS) confirms the plasmon modes we excite during each individual Raman acquisition. Combined, our results promise high-resolution mapping of ionic and molecular transformations, en-route to site-selective and product specific photocatalysis.

Boron Nitride Nanotube Electron-Beam Induced Oxidation at 80keV Hsin-Yun Chao¹, ², Dmitri Golberg¹, ², Cheol Park¹, Renu Sharma³ and John Cumings¹; ¹Materials Science and Engineering, University of Maryland, College Park, Maryland, United States; ²Advanced Materials and Processing Branch, NASA Langley Research Center, Hampton, Virginia, United States; ³School of Physics and Mechanical Engineering, Science and Engineering Faculty, Queensland University of Technology, Brisbane, Queensland, Australia; 4Center for Nanoscale Science and Technology, National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

Boron nitride nanotubes (BNNT) are superlative mechanical properties, promise as a possible structural material. The most demanding applications include lightweight components for space vehicles and radiation shielding. In these environments, carbon nanotubes (CNT) have been shown to be affected by ionizing radiation, which diminishes the desirable properties. Boron nitride nanotubes (BNNT) are an analogous structure with similar mechanical properties to CNT, but with more uniform electronic properties. Here, we present results from beam damage experiments with in-situ environmental transmission electron microscopy (ETEM). Oxygen pressures introduced vary from 10⁻² Pa to 10⁻¹ Pa and an electron beam dose from 10² e/nm²-s to 10 e/nm²-s. Our observations show BNNT to have more than one order of magnitude higher resistance to oxidation under the electron beam than that of CNT at comparable oxygen pressures. This demonstrates BNNT as a competitive alternative to CNT with enhanced performance in extreme energetic environments.

Advanced In Situ and Ex Situ S/TEM Probing of Interfacial Process in Rechargeable Batteries Chongmin N. Wang; Pacific Northwest National Laboratory, Richland, Washington, United States.

In-situ diagnosis appears to be one of the essential methods for gaining insights as how an electrode material failure, therefore feeding back for designing and creating new materials with enhanced battery performance. In this presentation, I will highlight recent progress on ex-situ, in-situ and operando S/TEM and in-situ liquid SIMS for probing into the structural and chemical evolution of energy storage materials. Both ex-situ and In-situ high resolution imaging enables direct observation of structural evolution, phase transformation and their correlation with mass, charge and electron transport, providing insights as how active materials failure during the cyclic charging and discharging of a battery. In perspective, challenges and possible direction for further development of the in-situ S/TEM imaging and spectroscopic methods for energy storage materials and other field will also be discussed. Most importantly, integration of different analytical tools appear to be the key for capturing complementary information.

11:30 AM CP03.10.04
Cu₂O Island Growth Process During Cu(100) Oxidation Revealed by Correlated In Situ Environmental TEM and Multiscale Simulations Meng Li, Matthew T. Curnan, Wissam A. Saiidi and Judith C. Yang; University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

When exposed in oxidizing environment, most metals and alloys will form surface oxide, which causes problems like corrosion and degradation, but could also be used in applications like catalysts and transistors. With the increasing application demands toward the nanoscale, fundamental understanding of the microscopic mechanisms of surface oxidation is essential for the prevention, prediction and controlled growth of metal oxide. The process of surface oxidation is usually divided into three stages, namely oxygen chemisorption, oxide nucleation and growth, and bulk oxide growth. Among these three stages, the initial stage, which spans from the start of oxygen chemisorption to surface reconstruction and the onset of oxide nucleation, is the least understood regime of oxidation, as it is inaccessible to traditional surface science and bulk material science experimental methods. Current computational capabilities and theoretical modeling are still unable to encompass oxide nucleation due to the large computational expense required to simulate nucleation over sufficiently large time and size scales.

In this work, by combining in situ Environmental TEM (ETEM) and multiscale atomistic simulation, we explore the dynamic processes of the initial stages of Cu(100) oxidation. By in situ oxidizing Cu thin films inside the Hitachi H-9500 ETEM (300 kV, LaB₆, with homebuilt gas delivery system with up to 3 lines of gas injection) with flowing O₂ gas, the initial stages of oxidation were investigated. The dynamic process from surface reconstruction to oxide nucleation and growth was observed, delimiting the initial oxidation stage threshold at which ETEM can effectively discern dynamic processes. Previous works by Zhou et al reported that the first CuO layer during Cu(100) oxidation grows along the (100) surface from a 2-atomic layer wetting layer. However, our work found the ensuing 3D CuO island grows in a layer-by-layer adatom growth mechanism along the CuO(110) direction. To better understand the observed phenomenon, a multi-scale computational approach was applied. The dynamic and energetic changes during CuO/growth under O₂ were calculated. A preferential monolayer formation of CuO monolayer along CuO(110) was found to be the reason. This correlated in situ ETEM and multiscale simulation method forms a feedback loop between ETEM results and simulations that allows computational and experimental results to validate and support one another, and helps to fundamentally explain oxide nucleation preference as function of orientation, defects (such as steps), temperature and pressure, and other environmental factors. Our results will enhance the understanding of surface oxidation and will also provide insights into understanding initial oxide growth mechanisms of other metal/alloy systems.

Real-Time Imaging of Reducible Oxide Nanoparticle Surface Reconstructions Using Time-Resolved Aberration-Corrected Transmission Electron Microscopy Ethan L. Lawrence¹, Ramabhy D. Levin¹, Benjamin K. Miller² and Peter Crozier¹; ¹Arizona State University, Tempe, Arizona, United States; ²Gatan, Inc., Pleasanton, California, United States.

The surface atomic arrangements of reducible oxides govern their oxygen exchange properties, and the ability to control and optimize structural parameters is of crucial importance for many applications, in particular in heterogeneous catalysis and photocatalysis [1]. Characterizing the structural evolution of catalyst nanoparticle surfaces with high spatial and temporal resolution may enable differentiation between functionally-relevant active structures and passive spectator structures, both of which may change during a single reaction “turnover” event. Aberration-corrected transmission electron microscopy (AC-TEM) has been used extensively to study nanoparticle surface dynamics using in situ imaging techniques [2]. Recent advances in imaging technology, namely direct detection cameras with fast acquisition modes, have enabled many new materials phenomena to be investigated. Additionally, with the advent of fast image acquisition, advanced processing techniques are essential for extracting useful information from large, often noisy image datasets. In this work, we use time-resolved AC-TEM to characterize oxygen-exchange induced surface reconstructions on CeO₂ nanoparticles, a reducible oxide that is used extensively in catalysis applications due to its oxygen exchange properties [1].

An aberration-corrected FEI Titan ETEM equipped with a Gatan K2 IS direct detection camera (with high detection quantum efficiency) was used to image CeO₂ nanoparticles at 400 frames/second and 10⁶ eÅ⁻²s⁻¹ with a pressure of <10⁻⁶ Torr at the sample for ~30 seconds. Due to the fast acquisition rate, large datasets were acquired and individual 1⁴⁰⁰ second exposure frames were obtained with signal-to-noise. To reduce noise in each individual frame, images were spatially binned and a Gaussian blurring filter was applied. MIPAR, a commercially available software with a recipe-based image processing method, and custom-written MATLAB codes were used to identify Ce atomic column positions and quantify column intensities in large datasets [3]. The integrated intensity quantization of each atomic column and AC-TEM image simulations were used to determine the number of Ce atoms within each column and track atomic migration at the surfaces. We observe dynamic surface reconstructions and lattice expansions/contractions associated with oxygen vacancy creation and annihilation. Further results providing insight into structure-dependent properties of oxygen exchange reactions on reducible oxides will be presented [4].

**1:30 PM CP04.00.01 Solute Segregation and Grain Boundary Transport in Nanocrystalline Alloys—Insight from Diffusion Triples**

Pralav Shetty, Caelin Muir and Jessica A. Krogstad

Materials Science and Engineering, University of Illinois, Urbana-Champaign, Urbana, Illinois, United States; Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Solute segregation in nanocrystalline metals has been widely explored as a route to improve the thermal stability of fine grain microstructures. Efforts have revealed that segregation may not always be uniform or subtle, thereby shifting the microstructural stabilization mechanism [1,2]. Delineating the subtle differences between these two mechanisms maybe be possible through improved understanding of mass transport along solute decorated grain boundaries. In this work, we present very recent observations of grain boundary diffusion with concomitant microstructural evolution by employing a thin film diffusion triple configuration. A 10nm layer of pure Al then a 50nm layer of a nanocrystalline, highly textured Ni-Cr alloy are deposited via DC magnetron sputtering on to a coarse-grained Ni-Cr alloy substrate of the same nominal composition. These diffusion triplets are annealed under flowing Ar at 600°C and the asymmetric diffusion profile is extracted via STEM EDX and APT characterization. Comparison of these diffusion data are presented against similar thin film diffusion triplets containing ~1at% V in the nanocrystalline films. Despite nearly identical initial microstructures, there are significant differences between these diffusion profiles, with implications for microstructural stability as well as environmental resistance.

**1:45 PM CP04.00.02 Surface Energy Interactions in Crystalline Coffee Rings**

Samantha McBride, Rachael S. Skye and Kripa K. Varanasi; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The coffee-ring effect refers to the phenomena in which a drop of a colloidal suspension evaporates on a substrate and deposits an ordered ring-structure due to the outward radial evaporative flow. This phenomena has been well-investigated due to numerous practical applications including ink-jet printing, microscale separations, and sensing/diagnostics. However, the phenomena has been less quantified for a crystallizing solution. When a drop of salt solution is evaporated, the salt becomes supersaturated and crystals begin to emerge at the substrate. The emerging crystals alter the local wettability of the substrate, and fundamentally alter fluid dynamics of evaporation, which in turn alters the form of deposit left behind. Here, we investigate the role of energetic interactions between the substrate, crystals, and solution. We systematically vary the substrate interfacial chemistry by deposition of silane groups of various surface energies, and use four different crystal systems to probe this effect. We find that crystals with favorable interactions with the underlying substrate chemistries alter deposit morphology, while non-interacting crystals behave similarly to colloidal particles, and develop phase diagrams predicting this behavior. These results can be used for fine-tuned control and understanding of crystalline evaporative deposits.

**2:00 PM CP04.00.03 Evolution of Persistent Metastable Phases During Mg Metal Corrosion**

Vaithiyalingam Shuathanandan, Abraham Martinez, Peter V. Sushko, Arun Devaraj, Olga Marina, Vineet Joshi, Suntharanpillai Thevuthasan and Vijayakumar Murugesan; Pacific Northwest National Laboratory, Richland, Washington, United States.

Magnesium metal is a potential candidate for high strength to weight ratio alloys with wide application in aerospace and automotive industries. However, poor corrosion resistance under ambient environmental conditions is the bottleneck for industrial deployment. Designing passivation layers and/or corrosion resistance alloys require fundamental understanding of the corrosion process. The traditional ex-situ spectroscopic measurements of polycrystalline metal surface with ubiquitous surface impurities provided indistinct view of the corrosion process. To clearly distinguish the mechanism and sequence of corrosion process, we employed in-situ cryo-based x-ray photoelectron spectroscopy (XPS) measurements on well-defined pure and aqueous solution exposed Mg single crystal surfaces in combination with ab initio atomistic modelling studies. Clean Mg (0001) surfaces were carefully exposed to pure and sodium chloride mixed water and the subsequent interfacial reactions were studied through integrated experimental and theoretical approach. This study provides atomistic view of magnesium hydroxide nucleation as main product of the corrosion process. Under salt conditions, the competitive nucleation process between magnesium hydroxide and magnesium chloride were observed along with the formation of magnesium chloride hydrate and magnesium hydroxide hydrate phases. By combining the energy requirements from computational modelling and the electronic states of corrosion products, the mechanism and sequence of corrosion process on Mg metal will be discussed.

**2:15 PM CP04.00.04**

The increasing research of nanowires (NWs) as building blocks for electronic, optoelectronic, energy devices and quantum computing is driven by the unique physical, and chemical properties originate from their nanoscale dimensionality. Catalyzed surface-guided NWs offer the possibility to control their position, direction and crystallographic orientation, which eventually leads to high-performance devices. To adequately control these features and gain predictive abilities, a deeper understanding of the growth mechanism of surface-guided NWs is required. Here, we experimentally and theoretically study the kinetics of planar catalyzed NWs. A model is presented that considers two main regimes of the growth rate of NWs depending on their thickness: the Gibbs–Thompson regime, which dominates the growth of thinner NWs, and the surface-diffusion-induced regime, which dominates the growth of thicker ones. By developing this kinetic model and fitting it to the experimental kinetic data, we determine the dimensionality of the surface diffusion. We observe a good correlation between the model and the results for surface-guided ZnSe and ZnS NWs grown on sapphire. The dimensionality of the surface diffusion value was determined to be ~1.5 and ~1.8 for ZnSe and ZnS NWs, respectively, in contrast to the value of 1 for vertical NWs growth models, supporting the difference between the two growth morphologies. The newly developed model distinguishes between the growth mechanisms of horizontal and vertical NWs, underscores the important role of the substrate in the horizontal growth, and provides new insights into the mechanism of surface-guided NWs growth. Understanding the growth mechanism introduces the possibility of controlling the growth directions and crystallographic orientations of the aligned NWs accurately and helps gain some prediction abilities of the NWs properties, leading to better nanowire-based electronic and optoelectronic devices.

2:30 PM CP04.00.05
Understanding Surface Degradation and Ligand Passivation-Assisted Stability of Hybrid Perovskites in Water Using Molecular Dynamics Simulations. Huanghun Zhou, Mingchao Wang, Jinfang Wang and Shangchao Lin; Materials Science and Engineering, Florida State University, Tallahassee, Florida, United States; Mechanical Engineering, Shanghai Jiao Tong University, Shanghai, China; Mechanical Engineering, Florida State University, Tallahassee, Florida, United States; Materials Science and Engineering, Monash University, Melbourne, Victoria, Australia.

Organic-inorganic hybrid perovskites, such as the prototypical methylammonium lead iodide (CH$_3$NH$_3$PbI$_3$, or MAPbI$_3$), have emerged as promising light absorbers in photovoltaic (PV) cells or as emitters in light-emitting diodes (LEDs). The strikingly high energy conversion efficiency up to ~20% enables hybrid perovskites as the key component of highly efficient solar cells. However, they generally suffer from moisture instability, which limits the long-term use of perovskite-based devices in ambient environment. In this work, in order to improve the surface moisture stability of MAPbI$_3$ in common humidity atmosphere, more specifically, to discover better ligands under a specific coverage on the [MAI]$^+$ surface to greatly improve the moisture stability and decrease the ion dissociation rate, we have applied molecular dynamics (MD) simulations and reaction kinetics theory to model the ion dissociation process and estimate the associated free energy barrier with and without ligand passivation. We have developed a new MD force field for MAPbI$_3$, which can match the density functional theory (DFT)-predicted elastic properties, experimental water contact angle on MAPbI$_3$, and DFT-predicted water infiltration and adhesion energies. We design MAPbI$_3$ with ligand-passivated surfaces by replacing MA$^+$ with ligands composed of long-chain alkyl-ammoniums. Ligands with different chain lengths, such as CH$_3$(CH$_2$)$_5$NH$_3$ ($n = 3, 5, 7$), and under different surface coverages ($\sigma = 25\%$, $50\%$, $75\%$, $100\%$), are considered here. We discover that ligand passivation can greatly help protect MA$^+$ on the surface due to the much higher dissociation free energy barriers of these ligands compared to that of MA$^+$. For iodine ions, ligand passivation can also shield them from water contacts, except for long-chain ligands, such as CH$_3$(CH$_2$)$_7$NH$_3$ ($n = 5, 7$) under full surface coverage ($\sigma = 100\%$), due to the reduced dissociation free energy barriers of long-chain ligands. As an interesting finding, the reduced dissociation free energy barriers for long-chain ligands under high surface coverages could be explained by their larger tendencies to micellize, which serves as additional driving force for their dissociation. This work significantly motivates future experimental efforts in designing new surface ligands to improve the moisture stability of hybrid perovskites.

2:45 PM CP04.00.06

We show how surfaces can be designed to redirect the momentum of the spreading lamella causing them to lift-off into 3-dimensional shapes thereby dramatically reducing the contact area. We design superhydrophobic surfaces with an in-plane discontinuity leading to the accumulation of vertical momentum resulting in the out-of-plane ejection of the lamella into water bowls. We demonstrate a two-fold reduction in the heat transfer between a cold rain and a warm surface. This novel approach can be broadly applied to other transport phenomena involving mass and energy exchange to limit heat loss under precipitation, icing of surfaces, reduce salt deposition on a surface exposed to ocean spray, or inhibit the formation of a water film on wings or wind turbine blades.

3:30 PM CP04.00.07
Defect Induced Surface Reactivity and Ion Transfer Process in TiO$_2$: Polymorphs Vijaykumar Munusugasan, Kee Sung Han, Venkateshkumar Prabhakaran, Yongsoon Shin, Tiffany Kaspar, Mal Soon Lee, Jaewon Lee, Vaithiyalingam Shuthananand and Suntharampillai Thevuthasan; Pacific Northwest National Laboratory, Richland, Washington, United States.

Reactivity and ion transfer processes across heterogeneous interfaces is the backbone of electrochemical devices such as batteries and dye sensitized solar cells. The complexity of reactivity and charge transfer across interfaces often arise from convoluted relations between surface chemistry (such as defect density, crystallographic orientation and functional groups) and exogenous drivers such as temperature and electric field. For example, technologically significant nanocrystalline TiO$_2$ with diverse surface chemistry renders a complex interfacial processes. To correlate the surface chemistry of TiO$_2$ with interfacial processes (reactivity and ion transfer), we performed a multimodal spectroscopic analysis in combination with ab-initio molecular dynamics (AIMD) calculations. The interfacial processes of anatase and rutile phase with varying surface chemistry against lithium bis(trifluoromethylsulfone)imide (Li-TFSI) salt were analyzed. We observed that, ubiquitous oxygen defects at TiO$_2$ surface regime enhance the molecular decomposition of TFSI anions. The thermally driven splitting of –CF$_3$ groups resulting in titanium oxyfluoride type bonding (O-Ti-F) at the near surface regime were observed in AIMD calculations and supported by multimodal spectroscopic measurements. The presence of free electrons due to fluoride ion transfer to TiO$_2$ anions. The thermally driven splitting of –CF$_3$ groups resulting in titanium oxyfluoride type bonding (O-Ti-F) at the near surface regime were observed in AIMD calculations and supported by multimodal spectroscopic measurements. The presence of free electrons due to fluoride ion transfer to TiO$_2$ anions. The presence of free electrons due to fluoride ion transfer to TiO$_2$ anions.
Adhesion and interface formation are essential processes in friction, particle aggregation, and grain boundary formation. It is generally accepted that adhesion is anisotropic and the adhesion force depends on the mutual orientation of attracting interfaces. However, direct experimental measurement of the adhesion force and its orientation dependence has never been realized. Here, by combining in situ environmental transmission electron microscopy and atomic force microscopy, we directly measured the adhesion between two rutile TiO$_2$ (001) surfaces with controlled mutual orientation. The results show that the adhesion force is primarily van der Waals attraction between the two surfaces and is highest when the lattices of the two surfaces are aligned, demonstrating strong orientation-dependence. Moreover, the orientation dependence is not influenced by surface hydration; though, the adhesion force drops considerably with increasing water vapor pressure. Our work demonstrates a powerful method for quantitative study of nanoscale interface formation and strengthening, providing new insights to the driving force of orientated attachment of particles and friction anisotropy.

SESSION CP04.01: Interface Structure
Session Chairs: Fadi Abdeljawad and Eric Homer
Tuesday Morning, April 23, 2019
PCC West, 100 Level, Room 102 A

10:30 AM CP04.01.01
Connecting Atomic and Crystallographic Structure-Property Relationships of Grain Boundaries Eric R. Homer$^1$, Jonathan Priedeman$^1$, Conrad Rosenbrock$^1$, Oliver K. Johnson$^1$, Gus Hart$^1$ and Srikanth Patala$^2$; $^1$Brigham Young University, Provo, Utah, United States; $^2$North Carolina State University, Raleigh, North Carolina, United States.

Early grain boundary engineering work has demonstrated how significantly material properties can be improved with tailored microstructures. Unfortunately, continued improvement in this area will require complete structure-property relationships of grain boundaries, which are currently lacking. We describe tools and efforts to obtain both crystallographic structure-property relationships and atomic structure-property relationships. And since the two are must be combined to facilitate future design efforts, we detail efforts to find correlations between them. The properties of interest in this work are thermodynamic properties, like grain boundary energy, as well as kinetic properties, like grain boundary mobility.

11:00 AM CP04.01.02
Processing Routes for Controlling Disorder-Property Relationships in Metallic Alloys Daniel S. Gnanola$^1$, Glen Balbus$^1$, McLean Echlin$^1$, Charlotte Grigorian$^2$, Christoph Gammel$^3$, Daniel Kiener$^4$, Timothy J. Rupelt$^4$ and Tresa Pollock$^4$; $^1$Materials Department, University of California, Santa Barbara, Santa Barbara, California, United States; $^2$University of California, Irvine, Irvine, California, United States; $^3$Department Materials Physics, Montanuniversitat Leoben, Leoben, Austria.

The nonequilibrium nature of amorphous solids such as metallic glasses (MGs) shares intriguing commonalities with grain boundaries in nanocrystalline (NC) materials, owing largely to the multiplicity of energy states inherent to disorder. Here, we report on experimental studies of MG and NC materials and novel synthesis and processing routes for controlling the structural state—and as a consequence, the mechanical properties. Relaxation processes in disordered materials that facilitate atomic reconfigurations toward a lower energy state, such as low temperature annealing, have been shown to enhance mechanical strength while promoting shear localization. A particular focus in this talk will be on strategies for rejuvenation of disorder with the goal of suppressing shear localization and endowing damage tolerance. Parallels between our results and rejuvenation processes in glassy systems will be discussed in the context of controlling metastable structural configurations through novel processing routes.

11:30 AM CP04.01.03
Two-Dimensional Polymorphic $\{111\}/\{115\}$ Grain Boundaries in Si—Atomic Structure and Impurity Segregation Ability Yutaka Ohno$^1$, Hitoto Yoshida$^2$, Seiji Takeda$^2$, Tatsuya Yokoi$^1$, Atsuto Nakamura$^3$, Katsushi Matsunaga$^4$, Yasuo Shimizu$^5$, Naoki Ebisawa$^6$, Koji Inoue$^7$ and Yasuyoshi Nagai$^8$; $^1$IMR, Tohoku University, Sendai, Japan; $^2$ISIR, Osaka University, Osaka, Japan; $^3$GSE, Nagoya University, Nagoya, Japan; $^4$The Oarai Center, IMR, Tohoku University, Oarai, Japan.

Polymorphism in crystallography means the ability of a solid material to exist in more than one crystalline form, and the forms differ in physical and chemical properties even though their chemical components are identical. Recently, polymorphism in two-dimensional (2D) materials has been attracting interest in obtaining diverse properties that cannot be obtained in 3D forms [1, 2]. In this study, we have found 2D polymorphic nanostuctures self-organized inside silicon ingots grown by Czcrhalski (CZ)-method; they are composed of different 2D periodic units just along $\Sigma_9\{111\}/\{115\}$ grain boundaries (GBs) with a $\langle 110 \rangle$ tilt axis. The atomistic structure of the 2D polymorphic GBs, as well as their segregation ability, are determined by a 3D chemical nanoanalysis technique using atom probe tomography (APT) combined with scanning transmission electron microscopy (STEM) and ab-initio calculations [3].

STEM revealed that, $\Sigma_9\{111\}/\{115\}$ GBs have a periodic interface structure with a period of 2 nm along the GBs, and the GB unit is composed of $\Sigma_9\{221\}$-like and $\Sigma_9\{114\}$-like nanofacets involving 2 (110) reconstructed bonds (named type-I GBs in this paper) [4]. Ab initio calculations reveal the GB energy of 0.6 J/m$^2$, that is higher than the GB energy of $\Sigma_9\{221\}$ (0.18 J/m$^2$) and $\Sigma_9\{114\}$ (0.36 J/m$^2$) GBs. Also, the $\langle 110 \rangle$ bonds are rather longer in comparison with the $\langle 111 \rangle$ bonds in bulk Si. Thus, those long bonds would induce an energy in addition to the energy of $\Sigma_9\{221\}$-like and $\Sigma_9\{114\}$-like nanofacets.

The GB unit in type-I GBs is changed by annealing at 1100°C. The GB unit in the annealed GBs, that was observed in a cast-grown Si ingot [5], is composed of $\Sigma_3\{111\}$-like nanofacets involving 4 (110) bonds, with the period of 2 nm (type-II GBs). Type-II GBs can be introduced by forming stacking faults of low GB energy (~0 J/m$^2$) on the $\Sigma_9\{221\}$-like and $\Sigma_9\{114\}$-like nanofacets in type-I GBs. The GB energy of type-II GBs is estimated to be 0.45 J/m$^2$. Therefore, type-I GBs change into type-II GBs so as to remove $\Sigma_9\{221\}$-like and $\Sigma_9\{114\}$-like nanofacets of high GB energy, via the formation of $\Sigma_3\{111\}$-like nanofacets of low GB energy, even though 2 (110) bonds of high-energy are added in each GB unit.

APT reveals the oxygen segregation ability of type-I GBs (0.04-0.06 atoms/nm$^2$) and that of type-II GBs (0.03 atoms/nm$^2$). The ratio of the abilities is the same as the ratio of the GB energy of type-I and type-II GBs; i.e., the ability is proportional to the GB energy, as expected [3, 4]. We will discuss potential controls of the 2D polymorphic nanostuctures, as well as of their segregation ability, by changing the growth condition.

11:45 AM CP04.01.04

The scaling of behavior in ferroelectrics remains a topic of substantial interest given the need for device miniaturization and fundamental research. In recent years, a suite of reports has shown that the bulk piezoelectric functionality of thin ferroelectric films (approximately 30 nm or less) have a strong dependence on the surface chemical and structural state. Furthermore, these works suggest surface screening is a critical factor in understanding the bulk properties and switching behavior in thin film form, but precise mechanisms of this coupling are lacking. A key question that remains is the role of intrinsic as opposed to extrinsic screening on the properties of the thin ferroelectric films. In this work, we use BaTiO$_3$ (BTO) grown via pulsed laser deposition (PLD) as a model material system to explore the correlation between surface state and bulk properties. To carefully probe the
surface and bulk properties of BTO thin films, we use a combination of atomically resolved scanning tunneling microscopy (STM), non-contact atomic force microscopy (AFM), piezoresponse force microscopy (PFM), X-ray diffraction (XRD), and in-situ X-ray photoelectron spectroscopy (XPS). The aforementioned characterization techniques provide an experimental pathway to evaluate the correlation between the surface state and bulk piezoelectric properties.

SESSION CP04.02: Mechanically-Driven Transformations and Diffusion
Session Chairs: Eugen Rabkin and Jason Trelewicz
Tuesday Afternoon, April 23, 2019
PCC West, 100 Level, Room 102 A

1:30 PM - CP04.02.01
Interface Diffusion-Controlled Pseudoelasticity of Metal Nanoparticles
Amit Sharma, Nimrod Gazit, Leonid Klinger and Eugen Rabkin; Department of Materials Science and Engineering, Technion-Israel Institute of Technology, Haifa, Israel.

An assembly of hemispherical Ag nanoparticles is prepared by solid-state dewetting of thin Ag film deposited on the sapphire substrate. The in-situ nanomechanical compression testing of the particles with a flat diamond punch inside the scanning electron microscope demonstrates the deformation behavior typical for the nucleation-controlled plasticity: high elastic deformation followed by an abrupt particles collapse. The latter is associated with the dislocations nucleation in otherwise pristine particle. The average contact pressure in the contact zone at the onset of dislocation-controlled plasticity is about 8 GPa, and does not depend on particle size. This observation supports the hypothesis that the pseudoelasticity of much smaller Ag nanoparticles observed by Sun et al. [Nat. Mater. 2014, 13, 1007] is intrinsically related to their ultrahigh strength. A stress-induced diffusion along the particle-substrate and particle-punch interfaces is identified as a factor controlling the pseudoelastic deformation. The corresponding diffusion model allows estimating the room-temperature self-diffusion coefficient of Ag along the Ag-W and Ag-Zirconia interfaces, which was quite close to the estimated value of the grain boundary self-diffusion coefficient in Ag. Based on this finding, the map of pseudoelastic deformation of several metals is proposed.

Strain Relaxation in Low-Mismatched GaAs/GaAsBi$_{0.92}$Sb$_{0.08}$/GaAs(001) Heterostructures
Abhinandan Gangopadhyay, Aymeric Maros, Nikolai Falaleev and David J. Smith; Arizona State University, Tempe, Arizona, United States.

Semiconductor heterostructures enable band-gap engineering by combining two or more dissimilar materials, and are essential for many optoelectronic applications such as multi-junction solar cells, lasers and light-emitting diodes. However, differences in lattice parameters between film and substrate give rise to interfacial misfit strain. Misfit dislocations are introduced beyond a certain critical thickness, which will likely severely limit device performance by acting as sites for electron-hole pair recombination. Identifying the sources of these defects and understanding their evolution as a function of film thickness would possibly lead to identifying a path for minimizing defects in such heterostructures by optimizing growth conditions, film thickness, etc. In this study, the creation and evolution of structural defects in low-mismatched (misfit strain ~0.6%) GaAs (cap)/GaAs$_{0.92}$Sb$_{0.08}$/GaAs(001) heterostructures grown by molecular beam epitaxy have been investigated using transmission electron microscopy as well as high-resolution x-ray diffraction and atomic force microscopy (AFM). Three distinct stages of strain relaxation were identified in GaAs$_{0.92}$Sb$_{0.08}$/GaAs films with thicknesses in the range of 50-4000 nm, whereas 50-nm-thick GaAs capping layers exhibited only initial Stage-I relaxation. Aberration-corrected electron microscopy revealed that glide-set dissociated 60° dislocations were primarily formed during Stage-I relaxation. Lomer edge dislocations with complex core structure and curved dislocations prevalently with edge character formed in Stage-II and Stage-III of relaxation. Evolution of dislocation density at cap/film interfaces showed a strong correlation with the evolution of surface morphology at the growth front. Even though misfit strain was highest at the cap/film interface of the heterostructure with 4000-nm-thick film, dislocation density was lower in comparison with heterostructures with 1000-nm-thick and 2000-nm-thick films. AFM results indicated that smoothening of the growth front in the heterostructure with 4000-nm-thick film caused a decrease in the areal density of surface troughs which may act as preferred sites for heterogeneous nucleation of dislocation half-loops. Detailed consideration of different sources for threading dislocations and the experimental evidence of correlation between decreased dislocation density and decreased density of surface troughs led to the conclusion that heterogeneously nucleated surface half-loops are the major source of threading dislocations in these low-mismatched heterostructures [1].

Exploring the Impact of Strain and Droplet Formation on Phase Separation and Atomic Ordering in GaAsBi
Margaret A. Stevens, John McEleaney, Kevin Grossklaus and Thomas E. Vandervelde; Electrical and Computer Engineering, Tufts University, Medford, Massachusetts, United States.

III-V-Bismides are attractive materials for near- and mid-IR device applications due to their dramatic decrease in band gap with small incorporations of bismuth. The growth space is limited by the epitaxial mismatch. The resulting compressively strained films have exhibited a variety of phase separation characteristics, including lateral composition modulations [2], droplet induced composition inhomogeneity [3], and CuPt$_2$-type atomic ordering [4]. We have explored growing on InGaAs buffers layers as a method for reducing epitaxial compressive strain, suppressing surface droplet formation, and eliminating vertical phase separation through the bismide film layers.

GaAsBi epilayers were grown by solid-source molecular beam epitaxy on a Veeco GENXP10 MBE using a valved As$_2$ source and an effusion cell for bismuth. Samples were characterized by HRXRD to determine the average bismuth content and the strain state of the layers. AFM was used to analyze the droplet formation on the surface of the films. TEM and HAADF STEM were used to qualitatively characterize the bulk phase separation. By comparing samples grown on GaAs to samples grown on InGaAs buffers, we will draw connections between film strain, surface droplet formation, and phase separation. We are able to reduce the degree of phase separation that occurs in GaAsBi films, by growing on InGaAs buffers layers; thereby increasing film homogeneity and general suitability for optoelectronic applications.

2:30 PM - CP04.02.04
Dynamic Investigation of Titanium Disilicide Formation by In Situ TEM
Hsin Mei Lu, Chih-Yang Huang and Wen-Wei Wu; National Chiao Tung University, Hsinchu, Taiwan.

C54 titanium disilicide (TiS2) has attracted great attention in Fin Field-effect transistor (FinFET) application, since it has accompanied with promising advantages, such as low resistivity, outstanding reliability and low mobility in silicon substrate. In order to further investigating the structural properties, we observed the formation process of C54-TiS$_2$ by in-situ TEM in this study. During the heating process, Ti atoms diffused into Si$_{1-x}$Ge$_x$ substrate and nucleated afterward to form C54-TiS$_2$. It is remarkable that we also observed the occurrence of a novel type of texture-axiotaxy between C54-TiS$_2$ (110) plane and Si (001) plane at around 800 celcius degree. Axiotaxy is convinced to be produced from the epitaxial mismatch. The resulting compressively strained films have exhibited a variety of phase separation characteristics, including lateral composition modulations [2], droplet induced composition inhomogeneity [3], and CuPt$_2$-type atomic ordering [4]. We have explored growing on InGaAs buffers layers as a method for reducing epitaxial compressive strain, suppressing surface droplet formation, and eliminating vertical phase separation through the bismide film layers.

Design and Control of Crystalline Phase Interfaces in Doubly-Epitaxial FeSe Thin Films
Sunzor B. Harris and Renato P. Camata; Physics, University of Alabama at
Grain Size Effects on Ni/Al Nanolaminate Combustion

For some material systems, one crystalline phase may exhibit growth of domains with different epitaxial relationships to the substrate or two phases may grow simultaneously with different orientations. This process, known as double epitaxy, creates thin film materials with many grain interfaces at fixed angles with respect to the substrate. This work demonstrates that double epitaxy in FeSe, an important superconducting compound with a complex phase diagram which is highly sensitive to stoichiometry. Conditions exist during pulsed laser deposition (PLD) that lead to the simultaneous epitaxial growth of the tetragonal (β-FeSe) and hexagonal FeSe (γ-FeSe) phases of FeSe in intermingled domains throughout the film, creating many phase boundary interfaces. We investigate the impact of PLD parameters on the double epitaxy of this interface-dominated material and identify the conditions under which double epitaxy is suppressed. The lattice parameters of β-FeSe and γ-FeSe are unsuitable for lattice-matching epitaxial growth on MgO. In the case of β-FeSe, the lattice parameter (a = 3.672-3.769 Å, depending on stoichiometry) differs from that of MgO (a = 4.211 Å) by more than the 9% normally tolerated for conventional epitaxy. The cubic structure of MgO, however, exhibits various domain matching epitaxial relationships with the various FeSe crystalline phases. This opens opportunities for engineering the internal interfacial boundaries of different FeSe phases by controlling the rotation of the epitaxial domains with processing parameters. A KrF excimer laser (1.4-3.4 J/cm²) was used to ablate a pressed, sintered target synthesized from FeSe powder. Targets were sintered in sealed quartz ampules at 700°C for 12 hours. Targets were ablated in high vacuum (10⁴ torr) with substrate temperatures in the 350-550°C range. FeSe films grown at temperatures between 350°C and 450°C with laser fluence fixed at 3 J/cm² showed the simultaneous epitaxial growth of both (001)-oriented β-FeSe and (101)-oriented γ-FeSe. The relative fraction of these two phases changes smoothly from majority β-FeSe at 350°C to majority γ-FeSe at 450°C. The β-FeSe phase grows aligned with the substrate and the γ-FeSe phase grows in two rotated domains, one dominant domain aligned with the substrate and a minor domain rotated by 45°. Atomic force microscopy (AFM) reveals the granular surface morphology with apparent grain sizes of 220-300 nm in films grown at 350°C and 450°C. The film grown at 400°C has a nearly equal fraction of each phase and the apparent grain size is found in the 120-200 nm range. The smaller grain size points to a larger number of phase interfaces, corresponding to an estimated number density of β-FeSe/γ-FeSe interfaces of 5.5x10⁹ cm⁻². Substrate temperature of 550°C results in a change in epitaxial orientation of β-FeSe from (001) to (101)-oriented. The (101) oriented β-FeSe grows in three domains, one aligned with the substrate and two others rotated by ±30°. AFM of the (101)-oriented FeSe shows large, micron scale grains leading to a much smaller grain interface number density than the biphasic films on the order of 10⁶ cm⁻². This growth technique shows the orders of magnitude scalability of in-plane interfaces of these epitaxially-oriented grains. At 550°C, reducing the laser fluence to 1.4 J/cm² increased the relative fraction of the γ-FeSe phase. The parameters of the PLD plasma plume are expected to influence the simultaneous epitaxial growth of the two phases by delivering a locally non-stoichiometric flux. Measurements of time and space resolved ion densities of the PLD plume will be presented and correlated with the emergence of γ-FeSe to determine the impact of the relative density of arriving ions on phase crystallization.

Grain Boundary Complexion Engineering—A Case Study of Silica and Rare-Earth Doped Boron Suboxide Armor Ceramics
Christopher J. Marvel1,2,3,4, Kieron F. D. Behler1,2,3,4, Jennifer Synowiezynski-Dunn1,2, Jerry C. LaSalvia1,2, Martin Hamer1,2,3,4
1Lehigh University, Bethlehem, Pennsylvania, United States; 2US Army Research Laboratory, Adelphi, Maryland, United States; 3SURVICE Engineering, Dumfries, Virginia, United States.

Grain boundary complexion engineering was recently introduced as a framework to be used to design grain boundaries and govern bulk material properties. The main conceptual tools of grain boundary complexion engineering are grain boundary complexion equilibrium diagrams and grain boundary complexion time-temperature-transformation (TTT) diagrams. Importantly, when the thermodynamic and kinetic diagrams are used in tandem, scientists and engineers have the ability to tailor classical processing conditions (e.g. chemistry, pressure, temperature, and time) to intelligently control grain boundary complexions, and specifically, complexion transitions from one complexion type to another. The ability to control complexion transitions is particularly important because a complexion transition could theoretically convert a tough material to a brittle material or an insulator to a conductor. The main objective of this talk will review the concepts of grain boundary complexion engineering and outline various approaches to develop the necessary complexion equilibrium and time-temperature-transformation diagrams. The second segment of this talk will summarize a grain boundary complexion engineering case study of silica and rare-earth oxide doped boron suboxide armor ceramics. Boron suboxide is being investigated as a promising armor ceramic because of its low density and high hardness, however, boron suboxide exhibits poor sinterability and fracture toughness. This case study outlines how grain boundary complexion engineering is used to control the thermodynamics and kinetics of grain boundary complexion transformations to improve sinterability and enhance fracture toughness. Boron suboxide powders were co-doped with silica and rare-earth oxide additives and the resultant microstructures were analyzed using advanced electron microscopy techniques to characterize grain boundary structures and quantify grain boundary segregation. The main observations include clear differences in microstructural evolution between the silica and rare-earth dopants, modified atomic structures with different excess grain boundary segregation concentrations, and improvements in bulk hardness.

In Situ TEM Investigation of Low Resistivity NiSi Formation on Silicon Layer
An-Yuan Hsu, Che-H-Yang Huang, Kuo Lun Tai and Wen-Wei Wu; Material Science and Engineering, National Chiao Tung University, Hsinchu, Taiwan.

Nickel silicide (NiSi) thin films have various advantages for microelectronics processes, such as low resistivity and low formation temperature. Therefore, it has been widely used in semiconductor devices. The formation of NiSi thin film mainly depends on the mechanism of diffusion between Ni and Si. In order to understand its formation kinetics, in-situ transmission electron microscopy (TEM) is a powerful tool to study the diffusion behavior during the process. In this work, we successfully observed the process of diffusion by in-situ TEM. We chose silicon-germanium (SiₐGe₁₋ₐ) as strain layer to improve the electronic performance. During the heating process, Ni atoms would diffuse into SiₐGe₁₋ₐ layer at 400°C in the duration of 10 minutes heating. The HRTEM results and the corresponding FFT-DF demonstrated that the product was NiSi. In addition, we found that there is a specific orientation relationship of [120]NiSi//[01-1]HRT, and [002]NiSi//[1-1-1]HRT. Furthermore, the Energy Dispersive Spectrometer (EDS) analysis established the elemental composition for both as-grown and after-annealed samples, giving strong evidence for the formation of the NiSi. These results provide us useful information to grow low resistivity NiSi thin film.
Study on the Atomic Interaction of Si and Mn During the Eutectoid Transformation in High-Carbon Steel Linglehui Huang1, Yiyou Tu1, Xuefeng Zhou1 and Jianqing Jiang1; 1Southeast University, Nanjing, China; 2Nanjing Forestry University, Nanjing, China.

High-carbon steels (pearlitic steel) are widely used in the fields, including bridge cable, automobile tire cord and high-rise building, owing to the outstanding high strength and low cost. Micro-alloying is the common method to increase the strength of pearlite steels. In the simplest Fe-C-M (M: Mn, Si, Cr, Ni) ternary system, the effects of alloying elements have been extensively studied. For example, Mn, as the austenite stabilized element, delays the pearlitic transformation, improves the stability of cementite and retards the spheroidization of cementite lamellar; Si, as the non-carbide forming element, refines the lamellar structure of pearlite, increases tensile strength, improve softening resistance during tempering, and etc. However, in the complicated multicomponent system the partition and interactive effects among alloying elements needs to be attention, especially the interaction of alloying elements during the eutectoid transformation need to be further studied.

Therefore, in the present work the atomic interaction among Si, C and Mn in Fe-C-M-Si quaternary system during the eutectoid transformation is investigated using atom-probe tomography combining first-principle calculations. Two types of pearlite carbon steels with different Si contents are prepared. At the initial stage of eutectoid transformation, atom probe tomography observations indicate that Si is enriched at the ferrite side of ferrite-cementite interface, while Mn is enriched at the cementite side. This interfacial segregation phenomenon gradually diminishes or disappears as the transformation proceeds. Based on the results of first-principle calculations, Si moves from the core of cementite layer to the ferrite side of ferrite-cementite interface can obviously enhance the chemical bonding and stability of pearlite system. In the same manner, Mn atom moves from the core of ferrite layer to the ferrite-cementite interface, which improves the thermal stability of pearlite system. Therefore, Si/Mn segregates at each side of ferrite-cementite interface at the initial stage of pearlitic transformation. Furthermore, the partitioning ratio of Mn in high Si steel is higher than that in low Si steel, leading to more Mn partition into cementite. Based on the results of first-principles calculations, due to the strong repulsive force between Si and Mn at the interface of pearlite, the enrichment of Si in ferrite promotes the partitioning of Mn into cementite.

4:45 PM CP04.03.05 Interatomic Bonds and Elastic Properties of Σ5(210) Grain Boundaries in Ni3Si Compound Martin Zelený1, 2, Martin Frišek1, Monika Všínská3, 4, David Holeč4 and Mojmir Soběk1, 3, 51Institute of Physics of Charles University, Faculty of Mathematics and Physics, Charles University, Prague, Czechia; 2Institute of Materials Science and Engineering, Faculty of Mechanical Engineering, Brno University of Technology, Brno, Czechia; 3Institute of Physics of Materials, Academy of Sciences of the Czech Republic, Brno, Czechia; 4Central European Institute of Technology, CEITEC MU, Masaryk University, Brno, Czechia; 5Department of Chemistry, Faculty of Science, Masaryk University, Brno, Czechia, 6Department of Physical Metallurgy and Materials Testing, Montanuniversität Leoben, Leoben, Austria.

We have performed an ab initio study of the elastic properties of the interface states in Ni3Si associated with the Σ5(210) grain boundary (GB). Ni3Si is well known structural material with a large potential for high temperature applications in corrosive atmospheres, which however suffers by low ductility with tendency to intergranular fracture. Rather complex tetragonal elasto-chemical aspects of the studied periodic GB approximants were found in the case of states with different atoms at the GB plane (either only Ni atoms (Σ5(210)(200)) or both Si and Ni atoms (Σ5(210)(200))). The Σ5(210)(200) GB state is predicted to have only a slightly lower interface energy of the two studied variants. The elastic constants are found to depend very sensitively on the GB plane chemical composition. In particular, the GB variant containing both Ni and Si atoms at the interface is shown to be unstable with respect to a shear deformation (one of the elastic constants, C66, is negative). This instability is occurs for a rectangular-parallellepiped supercell obtained when applying a standard coincidence-lattice construction. Our elastic constant analysis allowed us to identify a shear-deformation mode reducing the energy and eventually to obtain a mechanically stable ground-state characterized by a shear-deformed parallellepiped supercell. Nevertheless, a three-/eight-fold reduction of the elastic constant C66 when compared with the bulk value is identified as the crucial weakest link of the mechanical stability for the studied GB states. We have also partly stabilized this GB interface state by Al substituent replacing Si atoms at the GB.

Next, an origin of this elastic softening and instability of the rectangular-parallellepiped Σ5(210)(200) GB variant is discussed in terms of chemical inter-atomic interactions described by the crystal orbital Hamilton population (COHP). Lattice-dynamics properties represented by projected force-constant matrices on the unit vector along each bonding direction were considered as well. Such complex analysis reveals a weak interaction far from the GB interface between the Ni atoms in the 3rd plane and the Si atoms in the 5th plane. However, this bond weakening is a consequence of a very strong interaction between the Si atoms in the GB plane and Ni atoms in the 3rd plane off the GB interface. The same strong interaction was not observed when Si atom at the GB is replaced by Al. Thus the strong interaction near the GB plane makes this GB variant mechanically unstable.

Our study clearly shows the importance of anisotropic elastic-constant treatment as well as interatomic-interaction analysis for next studies of interface states close to GBs when determining origin of their mechanical (in-)stability. The sensitivity of elasto-chemical properties, which was additionally illustrated by studying the impact caused by Al atoms substituting Si atoms at the GB interface plane, paves a new way towards a solute-controlled design of GB-associated interface states with controlled tensorial elastic properties and stability.

CP04.04.01 Mesoscale Interface and Surface Characterization by μ-XRD Mapping on Mosaic and Lateral Grown Single Crystal Diamond Shengyun Bai1 and Elias Garratt; Chemical Engineering and Materials Science Department, Michigan State University, East Lansing, Michigan, United States.

For decades, diamond has shown superior properties that make it desirable for novel electronic materials. However, fabricating large size high quality single crystal diamond wafers faces multiple challenges. Lateral overgrowth and mosaic growth of CVD diamond make it highly possible for large size diamond wafers to be realized. Mesoscale characterization on the interface and surface of the grown CVD diamond is key to understanding how to eventually fabricate large size high quality single crystal diamond wafers.

In this work, mosaic and lateral single crystal diamonds were grown by Microwave Plasma Assisted Chemical Vapor Deposition (MPACVD) on High Pressure High Temperature (HPHT) seeds and characterized by a micro x-ray diffraction (μ-XRD) mapping technique with a 300 μm slit to show the evolution of diamond crystal structure information during growth and provide feedback on growth strategies. By understanding how crystal structure evolves during growth we can understand the mechanisms linking processing conditions the structure and properties of grown material.

Our results demonstrate after growth and regrowth by MPACVD, variation in the structure and distributions of these variations evolves towards homogeneity. Measurements of the (400) phase for mosaic and lateral growth samples by high-resolution x-ray rocking curve (HRXRC) and 20-μ m-mapping technique. The overall misorientation of the merging CVD layers is shown to decrease with the regrowth from 0.225° (bottom layer plate) to 0.092° (uppermost layer plate). μ-HRXRC mapping results show a low mosaicity and μ- HR 2θ-a-scan shows a low average Full Width at Half Maximum (FWHM), 0.032° and high crystallinity. Typically lateral overgrowth shows a uniform misorientation at the growth front, ranging from 0.092° to 0.035°. In contrast, our mosaically joined samples show a non-uniform distribution in misorientation at the merging interface, displaying a biaxial deviation parallel and perpendicular to the interface. The preliminary data shows that after regrowth, this biaxial distribution tends toward uniformity, with regions of independent preferred orientation overtaken by a single, new orientation. We will discuss this phenomenon in terms of step-flow overgrowth and energetically favorable states of the diamond crystalline phase during epitaxial lateral overgrowth in the extreme plasma environment.

CP04.04.02 Analytical Diffuse Layer Models in Electronic Structure Simulations Matthew Truscott and Oliviero Andreussi; University of North Texas, Denton, Texas, United States.

Continuum models will be critical towards the computational characterization of the diffuse layer at electrochemical interfaces. Recently, a number of different approaches have been proposed. Here we will present a new class of methods based on a planar averaged approximation and the Gouy-Chapman theory for electrochemical interfaces. These models potentially constitute a powerful set of tools for investigating one-dimensional surfaces, with several advantages over their more generalized counterparts. They exploit the
analytic solution for the one-dimensional complex electrostatic problem, are computationally inexpensive, and are not affected by any imposed periodicity. Charged metal solvent interfaces and their experimentally recorded differential capacitance values present a benchmark to compare candidate models. We will present the theory, implementation, testing, and applications.

CP04.04.03
Computational Investigations of Surface Adsorption of Ethane on M1 Catalyst (Mo-V-Nb-Te-O) Byryton H. Anderson, Matthew L. Jones and Eric Jankowski; Boise State University, Boise, Idaho, United States.

Ethylene is a high-value chemical that is an essential building block for polymers and other designer molecules. Producing ethylene from ethane (a more plentiful feedstock) is, therefore, a high-value activity, but one that requires a lot of energy. The use of catalysts to more efficiently perform chemical reactions, for example by lowering energy barriers for reaction pathways, therefore has the potential to save billions of dollars annually at production scales. The oxide Mo-V-Nb-Te-O (M1) is one such catalyst, but one whose efficacy degrades at elevated temperatures. In this work, we aim to understand the dynamics of ethylene on the surface of M1 to inform strategies for improving M1’s efficacy or lower its optimal operating temperature. Specifically, we develop tools that facilitate molecular modeling of organic molecules including ethane and ethylene on M1 surfaces and use them to study surface dynamics. We implement a combination of the OPLS-aa and UFF force fields and measure surface residence times of ethylene and ethane as a function of temperature. These measurements show ethane preferentially adsorb near Vanadium and Tellurium sites, informing strategies for increasing adsorption selectivity towards Vanadium. We investigate candidates for surface patterning and discuss anticipated changes in catalyst effectiveness.

CP04.04.04
Surface Characteristics of Accident Tolerant Fuel Cladding and their Potential Impact in Critical Heat Flux Rajañita Umreyati1, Daniel Ginestro2, Jessika Rojas3, Sama Bilbao1, Mark Anderson1, Barret Elward1 and Raul Reback2; 1University of Wisconsin-Madison, Madison, Wisconsin, United States; 2General Electric, Boston, Massachusetts, United States; 3Virginia Commonwealth University, Richmond, Virginia, United States.

Enhanced Accident Tolerant Fuels (ATFs) are defined as nuclear fuels that can tolerate a severe loss of active cooling in the reactor core for a considerably longer period of time than the current UO2 – zirconium alloy fuel system, while maintaining, or preferably improving, the fuel performance during normal operations and operational transients. The Critical Heat Flux (CHF) is one of the key parameters used to evaluate the thermal performance of a fuel product and to establish safety and operational margins. Preliminary studies for the proposed ATF concepts indicate that their cladding surface characteristics may result in substantial impacts in their CHF behavior. This work aims to investigate the surface characteristics of ATF cladding tubes of C26M, and APMT (both FeCrAl alloys) manufactured using industrial procedures. A comparison of their surface characteristics with current fuel cladding of Zircaloy-2 and Zircaloy-4 will be presented. Various roughness parameter, contact angle, and oxide layer thickness will be assessed using advanced materials examination techniques such as Profilometry, Atomic Force Microscopy, Contact Angle Goniometry and Scanning Electron Microscopy. Recent research has evidenced that surface roughness and contact angle may play an important role in the CHF enhancement. Further work will be focused on conducting a series of CHF experiments, at low and high pressure, with advanced temperature and fluid measurement instrumentation to obtain high fidelity qualitative and quantitative measurements of the thermal-hydraulic behavior of the ATF cladding under evaluation.

CP04.04.05
Perovskite Alloys and Metal Halides at the Interface—Crystallographic Orientation and Environmental Degradation Timothy Slepner, Daniel Houck, Yangning Zhang, Mokshin Suri and Brian A. Korgel; McKetta Department of Chemical Engineering and Texas Materials Institute, University of Texas-Austin, Austin, Texas, United States.

Hybrid organic-inorganic perovskites (HOIPs) such as methylammonium lead iodide (MAPI) and methylammonium lead bromide (MAPBr) have attracted much attention as solution-processed semiconductors that could be used in high performance optoelectronic devices such as photovoltaics, light emitting diodes, lasers, and X-ray detectors. These materials exhibit long carrier diffusion lengths, large absorption coefficients, and high photoluminescence quantum yields. For commercial applications, however, HOIPs suffer from significant humidity-induced degradation. Here, we report the stabilizing and destabilizing effect of B-site substitutional doping in HOIP materials, and discuss how surface doping at the B-site can induce preferential crystal orientation.

Substitutional doping of MAPI with Bi was found to lead to a stabilizing effect at high humidity, but a destabilizing effect at lower humidity. With 5 mol% Bi in MAPI, UV-Vis-NIR absorbance spectroscopy and X-ray diffraction (XRD) showed that at 90% relative humidity, the films took 72 h to fully degrade compared to 24 h for the undoped MAPI films. At the lower humidity of 60% RH, the undoped MAPI films were more stable than the Bi-doped MAPI films. The MAPI films were stable for 14 days; whereas, the Bi-doped MAPI films degraded after only 10 days.

While MAPI is a promising photovoltaic material, certain tandem cell and LED applications require wider band gap HOIPs, such as MAPBr. However, the random orientation of grains in MAPBr thin films made from commonly employed synthetic methods may hinder these devices’ effectiveness. Here we report the incorporation of Ag into MAPBr films induces a preferential (100) crystallographic orientation on any substrate and increases crystal grain size of thin film cubic MAPBr. X-ray photoelectron spectroscopy (XPS), energy-dispersive X-ray spectroscopy (EDS), and time-of-flight second ion mass spectrometry (TOF-SIMS) revealed that Ag accumulates at the interfaces of the MAPBr film, which appears to be the reason for the preferred orientation of the film on the substrate. Elemental maps and grazing incidence wide angle X-ray scattering (GIWAXS) of the Ag-doped films also showed the emergence of secondary methylammonium silver bromide phases. These regions in the film could create recombination centers in photovoltaic devices (PVs). PVs were fabricated with MAPBr and Ag-doped MAPBr films. Despite the differences in crystallographic orientation and crystal grain size, there were no observed differences in the performance of these perovskite PVs up to 2 mol% Ag incorporation, at which point PV performance became worse with increasing silver content.

CP04.04.06
Membrane Characterization Through Electrocompression Joyce E. Bevrouthy and Eric Freeman; College of Engineering, The University of Georgia, Athens, Georgia, United States.

Chloroethers is an amphiphilic molecule present in cellular membranes at different concentrations depending on the cell’s role and functionality. It is uniquely structured as its hydrophilic head is much smaller than its bulky hydrophobic tail. When present in a phospholipid leaflet cholesterol behaves according to the umbrella model, filling the gaps in between phospholipid molecules and reducing the area per lipid. This provides an ordering and condensing effect for the membrane. The effect of cholesterol on cell membranes has been investigated and it has been seen to minimize its permeability and move the membrane from a liquid disordered to a liquid ordered state. These mechanics may be measured through the measurement of the interfacial tensions of lipid monolayers and bilayers with and without cholesterol.

In this work, the droplet interface bilayer (DIB) technique is used to investigate cholesterol’s effect on surface tension and the membrane structure. Based on lipid-coated aqueous droplets adhering in an oil medium, the DIB method enables linking droplet mechanics and membrane mechanics for interpreting changes in the membrane structure through droplet-droplet adhesion and the angles of contact at the droplet intersections. It is a purely fluidic method where the droplets are minimally constrained and the membrane is free to expand on the interfacial tensions. By observing the changes in the droplets’ adherence while measuring the membrane properties through electrophysiology, one can calculate membrane’s tension, specific capacitance, applied stress and resulting strain.

Pendent drop tensiometry was used to investigate the changes in the monolayer surface tension with increasing amount of cholesterol. Higher monolayer tensions were observed with increasing cholesterol concentrations, along with increasing bilayer tension and adhesion energy. Next, membrane properties with varying cholesterol were measured. The membranes exhibited a non-linear reduction in thickness with the increasing cholesterol mole fractions. To understand cholesterol’s impact on membrane’s structure and rigidity, an electric field was gradually increased across the membrane until failure providing membrane compression beyond the equilibrium dimensions. The membrane thickness along the corresponding electrical stress were measured for each voltage. Plotting the pressure versus membrane thickness for different cholesterol concentrations shows that cholesterol does not affect the critical stress at failure. However, it significantly reduces membrane thinning. Adding at 30% cholesterol reduces membrane thinning by more than half. This indicated that cholesterol enhances the stiffness of the membrane, making it more rigid and resistant to transverse compression.

Generation of Shape-Tuned, Monodisperse Block Copolymer Particles Through Particle Restructuring by Solvent Engineering Jae Man Shin, Young Jun Lee, Mingoo Kim, Kang Hee Ku, Junhyuk Lee, Yongjo Kim, Hongseok Yun and Bumjoon Kim; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).
Controllability of the shape, size, and internal structure of block copolymer (BCP) particles as well as their uniformity is crucial to determine their utility and functionality in the practical applications. Here, we demonstrate the particle restructuring by solvent engineering (PRSE) strategy that combines membrane emulsification and solvent annealing processes, to produce monodisperse particles using functional BCPs with controlled size, shape, and inner structure. Importantly, the advantage of our PRSE approach is the general applicability to various types of functional BCPs including polystyrene-block-polystyrene (PS-b-PS), polystyrene-block-polystyrene (PS-b-PDMS), and polystyrene-block-polystyrene (PS-b-PDVP). PRSE starts with producing monodisperse BCP spheres in a wide range of particle size (from hundreds of nanometers to tens of several microns) using membrane emulsification, followed by successful transformation to shape-anisotropic BCP particles by solvent annealing under neutral wetting condition. Monodispersity of particle size was maintained during the PRSE, and the shape transformations to both prolate and oblate shaped ellipsoids were successfully achieved. Our approach was effective in controlling the aspect ratio (AR) of particles over wide ranges, from 1.0 - 2.5 and 1.0 - 5.0 for prolate and oblate ellipsoids, respectively. Also, observed AR of the particles was well-supported by theoretical calculation based on the model describing the particle elongation. Further investigation on the shape transformation kinetics during the PRSE revealed that the morphology transformation was driven by reorientation of BCP microdomains, whose kinetics was strongly associated with the overall molecular weight of BCP and the annealing time.

Surface Energy Measurements by Three Liquid Contact Angle Analysis Correlated with Ion Beam Analysis of Thin Silicon Oxides as a Function of Dopant Species and Concentration Saakeh R. Narayan 1,2, Jack M. Day 1, 2, 3, Nikhil Suresh 1, 2, 3, Nicole Herbots 1, 2, 3, and Robert J. Culbertson 1, 2, 3 1Department of Physics, Arizona State University, Tempe, Arizona, United States; 2SiO2 Innovates, LLC, Tempe, Arizona, United States; 3AccuAngle Analytics, LLC, Tempe, Arizona, United States; 4MicroDrop Diagnostics, LLC, Phoenix, Arizona, United States.

Surface energy and hydro-affinity play a significant role in device manufacturing and semiconductor processing. Surface reactivity, bonding and passivation is as critical as structure and composition for gate oxides, ohmic contact formation, heterostructures, opto-electronic and piezo-electronic device integration.

In this work, the effect of doping species upon Si(100) total surface energy, \( \gamma_s \), hydro-affinity, and reactivity, is investigated for three n-type dopants, phosphorus, arsenic or antimony, and two p-type dopants, boron or gallium, [2] by new quantitative measurements via Three Liquid Contact Angle Analysis (3LCAA)[1] correlated with Ion Beam Analysis (IBA), as a function of concentration.

3LCAA and the van Oss-Chaudhury-Good (vOOG) theory yield \( \gamma_s \) from three interactions, the Lifshitz-van der Waals interaction energy \( \gamma_W \), the interaction energy with electron donors \( \gamma_\alpha \), and acceptors \( \gamma_\beta \), measured via the contact angles of three liquids.

A new automated image analysis algorithm, DROP™, [3], yields contact angles within \( \pm 1\% \) and \( \pm 3\% \) in minutes. DROP™’s accuracy makes possible quantitative analysis of \( \gamma_s, \gamma_W, \gamma_\alpha, \gamma_\beta \), and \( \gamma_r \) as a function of doping species and concentrations.

Ion Beam Analysis (IBA) can detect oxygen coverage and elemental composition. High resolution IBA combines \( \phi \)O16, O16\( ^{3.039\pm0.01 \text{ MeV}} \) nuclear resonance with \( \sim 111\) channeling detects oxygen within 5%, or about 6x10^16 at/cm^2. Rutherford Backscattering Spectrometry (RBS) combined with <111> channeling can detect dopants with a sensitivity that increases quadratically with their atomic number, thus \(-4x10^{15}\) boron/cm^2, or 1 at.%; \(-4x10^{15}\) phosphorus/cm^2, or 0.1 at.%; \(-1x10^{15}\) gallium/cm^2, or 0.02 at.%; \(-1x10^{15}\) arsenic/cm^2, or 0.02 at.%; \(-4x10^{16}\) antimony/cm^2, or 0.01 at.% [2]. Oxygen coverage measured by IBA, along with doping levels and dopant species, can be correlated with \( \gamma_s, \gamma_W, \gamma_\alpha \), and \( \gamma_r \) measured by 3LCAA on both as-implanted and Rapid Thermal Annealed (RTA) Si(100). Si(100) amorphizes with increasing ion dose and defect concentrations, which catalyzes native oxide formation. During RTA, Si(100) recrystallizes and incorporates dopants into substitutional lattice sites. However, native oxide formation and dopant segregation modify final native oxide composition and thickness, as well as total surface energy and the surface interactions with donors and acceptors.

Higher dopant concentrations in both p-type and n-type doped Si(100) result in larger oxygen coverage and thus thicker native oxides, as measured by IBA, and lower surface energies as measured by 3LCAA. As expected, resulting surfaces are more hydrophobic and less reactive than as-implanted Si(100).

3LCAA also finds that as Si resistivity increases, \( \gamma_s \) also increases, showing that lower doping concentrations result in a more hydrophilic and more reactive surface [3]. Implanted Si is then etched, which removes surface oxides, and recrystallized by RTA to electrically activate dopants, regrowing a new native oxide. Longer RTA processes cause thicker oxides to form, along with higher segregation of n-type dopants at the Si-SiO\(_2\) interface. Hence, electrically activated n-type dopants enhance oxidation. The opposite effect is observed for recrystallized p-type doped Si, which shows thinner native oxides than as-implanted Si. 3LCAA, combined with IBA, can accurately measure changes to native oxide surface energies, hydro-affinity and reactivity as a function of dopant species and dopant concentration. These insights from 3LCAA expand understanding of dopants’ influence upon native oxide formation and of surface engineering for heterostructure formation by heteroepitaxy, conventional wafer bonding and NanoBonding™ [3].

Fabrication of High-Pressure-Phase \( \alpha \)-PhOx-Type TiO\(_2\) Epitaxial Thin Films via Ultrahigh Pressure Treatment Yuki Sasaki 1, Hiroaki Asoma 1, Koki Kanatani 1, Kazunori Nishio 2, Ryota Shimizu 2, Norimasa Nishiyama 1, 3 and Taro Hitosugi 1, 3 1School of Materials and Chemical Technology, Tokyo Institute of Technology, Tokyo, Japan; 2PRESTO, Japan Science and Technology Agency, Saitama, Japan; 3Laboratory for Materials and Structures, Tokyo Institute of Technology, Kanagawa, Japan.

Ultrahigh-pressure (HP) polymorphs such as diamond exhibit unique physical properties. There are many HP polymorphs that can be recovered to the ambient pressure to be utilized in industry. However, some of the HP polymorphs that are thermodynamically stable under HP (> 10 GPa) transforms into amorphous structure or different crystalline phases during decompression. If this back-transformation can be suppressed, we can obtain some useful HP polymorphs to be utilized in future. As a possible solution, we combined the epitaxial thin film growth technique with HP synthesis method using a multi-anvil apparatus.

We first investigated a HP-phase, \( \alpha \)-PhOx-type titanium dioxide (\( \alpha \)-TiO\(_2\), orthorhombic, \( a = 0.454 \text{ nm}, b = 0.549 \text{ nm}, c = 0.491 \text{ nm} \)). Unfortunately, most of the reported data was about the product in form of powder, and only a few reports about the fabrication of single crystals are currently available. In particular, single-phase \( \alpha \)-TiO\(_2\), epitaxial thin films has not been reported. In this study, we report the fabrication of the high-quality single-phase \( \alpha \)-TiO\(_2\)(100) epitaxial thin films.

Thin films of epitaxial rutile TiO\(_2\)(100) (thickness: ~100 nm) were deposited as precursors on Al\(_2\)O\(_3\)(001) (5 mm in diameter and 0.5 mm in height) using pulsed laser deposition. HP treatment for thin films was performed using a Kawai-type multi-high-pressure apparatus. The precursor thin film was heated up to 1000°C under HP of 8 GPa, and then kept for 0.5 h. After the heating step, cooling was started down to room temperature (RT), followed by decompression.

As a result, a successful single-phase \( \alpha \)-TiO\(_2\)(100) epitaxial thin film has been obtained. It should be stressed here that rocking-curve full width at half maximum of the 20 peak showed a quite small value of 0.113°, indicating very high crystallinity. Our present study indicates that HP treatment to thin film samples allows us to fabricate high-quality HP-phase epitaxial thin films.

Transverse Printing of Colloidal Crystals Based on UVO Mediated Polymer Degradation Rabhrata Mukherjee 1, 2, 3 1Indian Institute of Technology Kharagpur, Kharagpur, India.

It is well-known that mono-dispersed colloidal particles self-assemble into hexagonal close-packed (HCP) structures, under appropriate conditions, which are also known as two-dimensional (2D) colloidal crystals. While various techniques, such as sedimentation, confined convective self-assembly, dip coating, drop casting, evaporative drying, electrophoretic deposition, self-assembly at the gas-liquid interface and Langmuir–Blodgett (LB) technique, inkjet printing etc. has been used for making such arrays, spin coating has its own advantage due to direct compatibility with microelectronic processing, pattern uniformity and requirement of very small amount of colloidal dispersion. We first show...
that monolayer colloidal crystal formation by spin coating is possible only in a narrow parametric window involving spin speed, substrate wettability, particle size, and substrate pattern geometry, in a case a topographically patterned substrate is used for template guided assembly. Subsequently, I will highlight a facile colloidal transfer printing method that relies on UVO mediated degradation of a sacrificial PMMA thin film. The method is capable of transferring both hexagonal closed packed (HCP) and template guided non-HCP arrays of inorganic or polymeric colloids onto any hydrophobic or hydrophilic target surface, which can be smooth, rough, or even curved. The method does not require any surface modification of the target substrate or any medium to facilitate the transfer. Finally, I will show that in certain cases the transferred particle array can significantly enhance the anti-reflection property of the target surface and can also be used as a template for growing patterned Zinc Oxide Nano Rod array which exhibit Self Cleaning property.

CP04.04.11

Nanostructured carbons are common components of electrodes used for energy-storage and -conversion applications to impart enhanced electronic conductivity that sustains high-rate operation, to support dispersed active materials (e.g., electrocatalytic metals and oxides), and to contribute to the physical structure and integrity of the electrode. Often overlooked in the design and characterization of such electrode structures is the critical nature of electronic/chemical/physical interactions at the junction of carbon with the nanoscale phases that impart desired storage or electrocatalytic functionality. Our own experience with such multifunctional compositions shows that we still “leave on the table” too much energy and power performance as a consequence of sub-optimal interfacial design. In order to explore these fundamental questions, we step back from the complexity of 3D electrode architectures to planar electrode configurations that otherwise mimic the material characteristics of practical electrode structures. Carbon films deposited onto planar substrates by vapor-phase pyrolysis of benzene and related monomers serve as model interfaces that we then modify with charge-storing metal oxides, electroactive polymers, and metal colloids [1]. The resulting 2D interfaces are characterized by classical electroanalytical methods to determine fundamental properties such as electron-transfer rate constants and impedance-driven response times. These substrates are also amenable to interrogation by scanning probe microscopy, including in-situ monitoring of conductivity and surface morphology under potential/current control. Lessons learned from these model 2D interfaces are readily applied to the redesign of practical 3D electrode structures in next-generation electrochemical capacitors and batteries.

CP04.04.12

Myriads of electrode materials with interesting nanostructures have been fabricated for a range of electrochemical applications. Beyond the increases in their surface area, unconventional properties have been observed along with the development of new approach and methodologies to analyze and utilize such properties. For instance, once a redox-active molecule diffuses into the nanoscale cavity of the electrode, it frequently collides with the inner electrode surface before it escapes the cavity, which is termed nano-confinement effect. This effect can specifically amplify the signals of slow electron transfer reactions (e.g., glucose oxidation) and has been established as a new mechanism for sensing the target materials that have slow electron transfer kinetics.

In this study, we fabricated a Au nanopillar electrode and devised a new electrochemical platform using redox cycling reaction to utilize the nano-confinement effect of the Au nanopillar electrode, which is applicable even to the fast electron transfer reactions as demonstrated by facilitating the electrochemical reaction of a specific biomarker (i.e., pyocyanin which has fast electron transfer kinetics) of bacterial infection (i.e., Pseudomonas aeruginosa). The Au nanopillar electrode was fabricated by first treating a polymer substrate with plasma to render an array of polymer nanopillars on the substrate and then depositing Au onto the plasma-treated substrate to the appropriate thickness to form nanoscale inter-pillar space. The Au nanopillar surface was modified with the redox cycling counterpart of pyocyanin so that the pyocyanin confined in the inter-pillar space underwent repetitive cycles of reduction (by the electrode) and oxidation (by the redox cycling counterpart tethered to electrode surface) reactions resulting in the amplification of the pyocyanin signal. This redox cycling-assisted signal amplification was clearly observed with the Au nanopillar electrode with higher amplification by taller Au nanopillars while the amplification was insignificant for the flat Au electrode, demonstrating the nano-confinement effect of Au nanopillar electrodes. As a result, the sensitivity in measuring pyocyanin was improved by the Au nanopillar electrode compared with the flat Au electrode. We believe that this new platform based on the surface-bound redox cycling reaction could overcome the limit in applicability of the nano-confinement effect.

Ordering and Miniaturization in Dewetting of Pre-Patterned Thin Polymer Films and Bilayers with Patterned Interface Nandini Bhandaru; Birla Institute of Technology and Science Pilani, Hyderabad Campus, Hyderabad, India.

Liquid thin films generate intriguing flow regimes and under specific conditions, lead to disintegration and de-wetting with the formation structures of submicron feature size. This concept has been well utilized as a non-lithographic route for creating meso-scale structures, where the structures can be ordered by guiding the instability pathway using a template. We show that patterns present on the surface of a polymer thin film (polystyrene) on a flat substrate can result in an ordered dewetted morphology under certain conditions. The pre-patterned polymer thin film undergoes pattern directed rupture along the thinnest parts of the film when the initial local thickness over these zones ($h_{in}$) is reduced to a limiting thickness ($h_{nm} = 10$ nm). In addition, depending on the periodicity of the imprinted patterns, the wavelength of instability corresponding to $h_{nm}$ must be lower than the width of the patterned grooves ($h_{l}$). A morphology phase diagram is constructed which indicates a transition from the surface tension induced flattening to the ordered pattern directed rupture. The versatility of this technique is in its ability to form myriad of aligned meso-patterns starting from a simple grating structure on the film surface. We further extend this concept to polystyrene-poly(methylmethacrylate) bilayers with a patterned polymer-polymer interface, where the instability is more complex due to coupled deformation of multiple, confined interfaces. This leads to creation of exotic patterns such as submerged, embedded and core shell structures, which are beyond the capability of standard lithography methods. The morphology of the evolving patterns is controlled by several parameters including the initial film thickness ($h_{i}$), pre-pattern amplitude ($h_{p}$), duration of solvent vapor exposure and wettability of the stamp used for pre-patterning the film. The evolution can be interrupted at any intermediate stage thereby achieving patterns on demand, which are well ordered as well as significantly miniaturized as compared to features obtained from dewetting of a flat film of same initial thickness.

Analysis of Deep Level and Oxide Interface Defects Using 100V HF Schottky Diodes and MOS CV’s for Silicon and 4H SiC HV MOSFE Ts, Advanced Power Electronics and RF ASIC James Pan; ATL, Northrop Grumman Electronic Systems, USA, Maryland, United States.

In this paper we report high voltage MOS and Schottky Diode CV techniques for silicon and SiC power devices. 4H Silicon carbide is a wide bandgap semiconductor suitable for high voltage power electronics and RF applications due to high avalanche breakdown critical electric field, and thermal conductivity. The performance of various power devices, which may include MOSFET and Static Induction Transistor (SIT), can be affected by the deep level traps in the substrate and the oxide interfacial defects. We have characterized deep level trap (High Voltage Schottky Diode HF CV) and oxide interface trap densities (High Voltage HF MOS CV), measured the device channel doping profile for both 4H SiC and silicon, gate metal workfunction, and simulated the effects on DC/AC performance.

TCAD simulation is done for a high voltage RF SIT. Pinch voltage ($V_{Pinc}$, as defined by the gate voltage required to turn the device off for a certain applied drain voltage) may be affected by the interface charges. Generally speaking, the $V_{Pinc}$ is very sensitive to the channel doping concentration.
Tensile Deformation Behavior and Inelastic Strain Recovery in Cu/Co Nanolaminates
Rohit Berlia and Jagannathan Rajagopalan; Arizona State University, Tempe, Arizona, United States.

The deformation behavior of nanostructured metallic multilayers has been extensively investigated because of their superior mechanical properties, primarily via nanoindentation and micropillar compression experiments. Here, we report tensile measurements on a Cu/Co nanolaminate with 4 nm layer spacing. The nanolaminates exhibit a flow strength as high as 2 GPa and failure strains of 3-4%. Interestingly, significant inelastic strain recovery was observed both during and after unloading, with further recovery occurring upon heating. In addition, the stress-strain slope during the initial stages of unloading was considerably higher than the expected elastic modulus, suggesting the presence of a super modulus effect due to the large coherency strain.

Tunable Surface Area and Electrochemical Capacitance of MnO3 Nanofibers Through Controlled Calcination
Molly Brockway and Jack L. Skinner; Mechanical Engineering, Montana Technological University, Butte, Montana, United States.

Electric double layer capacitors, or supercapacitors, have high theoretical capacities and faster charge/discharge rates than Li-ion batteries. Because they store charge via electrostatic interactions between the electroactive surface and ions in the electrolyte, increased specific surface area of electroactive material will increase the theoretical storage capacity of next-generation devices. Nanofiber-based electrodes have fewer issues with agglomeration and better long-term stability than nanoparticle-based electrodes, while maintaining extremely high surface area to volume ratios. As a potential electrode material, MnO3 is low-cost, naturally abundant, and environmentally benign. Electrospinning with subsequent thermal decomposition is a facile fabrication method for creating MnO3 nanofibers. Composite fibers consisting of a coordination polymer, polyvinylpyrrolidone, and oxide precursor, manganese acetate tetrahydrate, are electrospun. Calcination is used to burn out the polymer matrix and convert the salt to manganese oxide while retaining
The high aspect ratio fiber morphology.

Although Mn$_2$O$_3$ nanofibers have been prepared by thermal decomposition of a coordinating polymer-oxide precursor composite fiber, the influence of calcination conditions on specific surface area have not been well-explored. The proposed work will examine the effects of calcination time, temperature, and environmental composition on fiber surface area and corresponding electrochemical capacitance as compared to nanoparticle-based electrodes. Thermal analysis will be performed with thermogravimetry and differential scanning calorimetry to determine glass transition and decomposition temperatures of the as-spun composite fibers. The post-calcination fibers will be examined with X-ray diffraction to confirm phase and obtain information on crystallite size. Scanning electron microscopy will be used for morphological examination and qualitative examination of porosity resulting from changes in calcination parameters. To quantify changes in specific surface area, the Brunauer-Emmett-Teller (BET) method will be used on calcined fibers and compared to values measured for nanoparticles prepared from the oxide precursor. Increased surface area detected by BET may not necessarily be accessible to ions in the electrolyte, so to evaluate the accessible surface area, the fibers and particles will be processed into working electrodes. Electrochemical analysis including cyclic voltammetry and linear voltammetry will be utilized to assess the accessible surface area of fiber-based vs. particle-based electrodes based on measured capacitance. Preliminary results have shown that modifications to the gas composition and calcination time result in varied porosity, surface features, and cross-sectional morphologies. An understanding of the relationship between processing conditions and fiber morphology will allow for tunability of enhanced surface area, electrochemical capacitance, and supercapacitor performance.

Passivation and Positive Band-Edge Shift of Monocrystalline $p$-Silicon Through Surface Chemical Functionalization with Mixed Monolayers Miguel Caban-Acevedo, Bruce S. Brunsvichg and Nathan S. Lewis; Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California, United States.

Controlling charge equilibration and recombination at semiconductor interfaces is essential for the design of efficient and cost-effective silicon-based devices in applications such as photovoltaic solar cells, microelectronics, and sensors. Towards the exploration of new pathways to manipulate the electronic properties of semiconductor interfaces, in this work we report our ongoing investigation into the utilization of surface chemical functionalization as a strategy to passivate the interfacial recombination and tune the energetic alignment of silicon surfaces. Our research efforts focus specifically on the covalent functionalization of $p$-type silicon with mixed monolayers containing positive molecular dipoles as a way to induce a positive band-edge shift and improve the energetic alignment between $p$-silicon photocathodes and high work function contacting phases. In this presentation, we will report our latest results on the development of new synthetic pathways for the preparation of mixed monolayers on silicon and on the photoelectrochemical properties of $p$-silicon photocathodes functionalized with mixed monolayers.

A Comprehensive Study on Mechanical and Thermal Properties of HfSiO$_x$—First-Principles Calculations and Experiments Zhidong Ding, Mackenzie Ridley, Jeroen Deijkers, Md Shafkat Bin Hoque, John Gaskins, Patrick Hopkins, Haydn Wadley, Elizabeth Opila and Keivan Esfarjani; University of Virginia, Charlottesville, Virginia, United States.

HfSiO$_x$(hafnon) can be used as a layer as a barrier coating (EBC) materials placed between silicon dioxide and hafnia. Hafnon has a good lattice thermal expansion matching between silica and hafnia and can prevent oxygen diffusion in EBCs, thereby potentially lengthening the lifetime of EBCs. In this work, we conduct a comprehensive investigation of mechanical, thermodynamic and thermal transport properties of hafnon using first-principles density functional theory (DFT) calculations and compare our results to experiments performed on this material. The volumetric coefficients of thermal expansion (CTE) calculated by the quasi-harmonic approximation are in the range 9.18 \(-19.07\times10^{-6}$ K$^-1$, when the temperature increases from 300 to 1500 K, in agreement with X-Ray Diffraction and dilatometer measurements. The thermal conductivity is nearly 10 Wm$^-1$K$^-1$. The mechanical properties, such as bulk modulus and elastic constants are also compared between the first-principles calculations and the RT nonindentation technique. This study validates our computational approach and can be used to further study thermomechanical properties of other high-temperature oxides.

Molecular Interactions of Polydimethylsiloxane and Ni-Mn-Ga Jaime D. Guevara Rojas$^{1,2}$, Matthew L. Jones$^{2}$, Eric Jankowski$^{3}$ and Peter Müllner$^{2}$; $^{1}$Computer Science, Boise State University, Boise, Idaho, United States; $^{2}$Materials Science and Engineering, Boise State University, Boise, Idaho, United States.

Medical micropumps that utilize Magnetic Shape Memory (MSM) alloys are small, powerful alternatives to conventional pumps because of their unique pumping mechanism. This mechanism, the transfer of fluid through the emulsion of esophagae contractions, is enabled by the magneto-mechanical properties of a shape memory alloy and a sealant material. Because the adhesion between the sealant and the alloy determines the performance of the pump and because the nature of this interface is not well-characterized, an understanding of sealant-alloy interactions represents a fundamental component of engineering better solid state micropumps in particular, and metal-polymer interfaces in general. In this work we develop computational modeling techniques for investigating how the properties of sealant materials determine their adhesive properties with alloys. In particular, we develop a molecular model of the sealant material polydimethylsiloxane (PDMS) and parameterize its interactions with Ni-Mn-Ga alloy surfaces for use in molecular dynamics simulations. We perform equilibrium molecular dynamics simulations of the PDMS/Ni-Mn-Ga interface to iteratively improve the reliability, numerical stability, and accuracy of the models and associated data workflows. In sum, we develop a model combining OPLS-UA and UFF force fields for simulating PDMS/Ni-Mn-Ga interfaces and demonstrate its promise for informing the design of more reliable MSM micropumps.

Pinning Strength Quantification of Different Solute Concentrations at Grain Boundaries David W. Jacobson$^{1,2}$, Stephen Foiles$^3$, Fadi Abdeljawad$^3$ and Gregory B. Thompson$^4$; $^{1,2}$Metallurgical and Materials Engineering, The University of Alabama, Tuscaloosa, Alabama, United States; $^3$Sandia National Laboratories, Tuscaloosa, Alabama, United States; $^4$Mechanical Engineering, Clemson University, Clemson, South Carolina, United States.

A computational method has been developed to calculate the pressure required for grain boundaries to overcome the pinning effects of second phase particles. Multiple Pt bicrystals were constructed with small concentrations (\(< 0.5 \text{ atom}\%\)) of Au segregated to the boundary using the Monte Carlo method. Molecular dynamics (MD) simulations employing the artificial driving force method were carried out on said boundaries to measure the relationship between boundary type, solute concentration, and boundary velocity. It was found that for a given solute concentration there exists a critical driving pressure necessary for grain boundary motion to occur. Sub-critical driving pressures resulted in flexing of the grain boundary about the pinning precipitates, but with no large scale grain boundary movement. Above critical driving pressures resulted in grain boundary motion although the amount of time required for grain boundaries to break loose from the pinning structures varied considerably. At solute concentrations of 0.1\%, solute segregation to the boundary was not apparent. The resulting lack of precipitation caused the boundaries to behave no differently from pure boundaries, although at high temperatures a reduction in mobility would be exhibited because of solute drag. Development of a method to quantify the effect of different solute concentrations on the stability of different grain boundaries will prove useful for understanding phenomena such as abnormal grain growth, as well as aid in the engineering of stabilized nanocrystalline alloys.

**Studies in the Ultrathin Tungsten Oxide Layers**

Michael W. Martínez-Szczweczyk, Chandler W. Cotton, Sumner B. Harris and Renato P. Camata;

Physics, University of Alabama at Birmingham, Birmingham, Alabama, United States.

Ultrathin transition-metal oxide and dichalcogenide layers ranging from monolayer (2D) thickness to a few nanometers, exhibit a wide range of distinct physical properties when compared to their bulk counterparts. There is growing interest in understanding the crystallization behavior of these materials when approaching the 2D regime, in order to optimize the growth of already observed phases and realize the synthesis of predicted ones. Information on nucleation rates and critical nucleus size in homogeneous nucleation processes, the relative importance of various defects in heterogeneous nucleation, grain growth rates, and interface evolution in the 2D regime is highly sought to enable interface engineering in 2D materials. Tungsten trioxide (WO3) is a particularly interesting system to study in ultrathin configurations because it exhibits a wealth of crystallization-dependent properties. In addition to its catalytic and ion-intercalation derived properties, such as charge storage and electrochromic behavior, it also shows evidence of a superconducting phase, an insulator-to-metal transition that may be achieved via electrostatic gating, and a transition from the conventional monolonic, orthorhombic, and hexagonal polytypes observed in bulk and nanostates, to a stable free-standing, 2D single-layer honeycomb-like structure that is semiconducting and predicted to have a very high cohesive energy (10.5 eV) as well as one of the highest in-plane stiffness among metal oxide and dichalcogenide 2D materials (250 N/m). In this work we investigate the crystallization behavior of ultrathin WO3 formed after oxidation of tungsten (W), using X-ray diffraction (XRD), atomic force microscopy (AFM), and impedance spectroscopy (IS). Polycrystalline W films of 10-nm thickness, deposited by atomic layer deposition (ALD) on n-type (001)-oriented silicon substrates, were annealed in oxidizing environment in a tube furnace at temperatures from 275°C to 600°C. XRD on films annealed at 600°C shows the formation of the monolonic phase of WO3. The XRD patterns for annealed films are dominated by the sharp monoclinic (200) reflection at 2θ = 24.45°, indicating that the WO3 crystallites exhibit preferential orientation with their [001] axis aligned perpendicular to the substrate. AFM shows surface morphology comprising distorted cubic-like features consistent with the underlying monoclinic structure observed by XRD. The AFM scans clearly reveal that the films are dominated by out-of-plane interfaces normal to the [200] direction of the WO3 crystallites. At temperatures above 500°C, large crystallites are observed in the AFM scans, with heights in the 10-30 nm range, indicating significant 3D restructuring due to crystal growth after oxidation. The crystallite number density exhibits an Arrhenius relationship with the annealing temperature with an activation energy of 110 kJ/mol. Impedance spectroscopy measurements between 1 Hz and 7 MHz on thin film samples after the deposition of top nickel contacts, show Nyquist impedance arcs that depend on the annealing temperature and ambient. The impedance of samples with various WO3 thicknesses, degrees of 3D restructuring, and crystallite number densities are analyzed in terms of equivalent circuits that yield the “grain interface” and “grain interior” contributions to the resistance and capacitance of the samples. The dependence of these electrical characteristics is compared with the structural features obtained by XRD and AFM to identify distinct kinetic regimes present during W oxidation, as well as crystal nucleation and WO3 ultrathin layers.

**Investigation of Light Emission and Scattering Properties of a Racemic Mixture of Helicene Derivative Deposited on Plasmonic Substrates Using Scanning Tunneling Microscope (STM)**

Pawel Krukowski, 1, 3 Sungeol Cha, 1, 2 Hideji Osuga, 2 and Yuii Kuzuhara; 2 Department of Precision Science and Technology, Graduate School of Engineering, Osaka University, Suita, Japan; 3 Department of Materials Science and Chemistry, Faculty of Systems Engineering, Wakayama University, Wakayama, Japan; 3 Department of Solid State Physics, Faculty of Physics and Applied Informatics, University of Lodz, Lodz, Poland.

In this study we report our investigations of adsorption of a racemic mixture of 2,13-bis(aldehyde)[7]-thiatricothelene (rac-[7]TH-dial) on Au(111), Cu(001), and NiAl(110), as well as the reflection of light emission/scattering from the molecules induced by a STM tip. Light emission from the rac-[7]TH-dial molecules was investigated by STM-induced luminescence (STM-LE), while light scattering was investigated by STM tip-enhanced Raman spectroscopy (STM-TERS) techniques. Helicene molecule belongs to the class of chiral molecules revealing a characteristic helical shape, which comes from steric hindrance between adjacent aromatic rings. All STM-LE and STM-TERS measurements were carried out in ultrahigh vacuum spectrometer using Ag tip. At the beginning, the influence of the substrate on the self-assembly process of rac-[7]TH-dial on Au(111), Cu(001), and NiAl(110) has been studied with the use of standard STM. Despite the same deposition conditions, only Au(111) governed molecular self-assembly formation. We observed a few different phases with highly ordered structures formed on a wide area of the Au(111) surface. The dominant observed structure was characterized by the presence of highly ordered domains ranging from hundreds to thousands of nanometers adsorbed directly on the Au(111) surface. The highly ordered domains consist of self-assembled zigzagged row exhibiting self-assembled rac-[7]TH-dial molecules with orientation and positional order were preferentially aligned parallel to the highly symmetric <1-10> or <11-2> directions. Despite the same deposition conditions, the adsorption of rac-[7]TH-dial on Cu(001) and NiAl(110) surfaces was quite different from that observed on Au(111). The rac-[7]TH-dial molecules on Cu(001) and NiAl(110) formed an amorphous layer with densely packed molecular stacking. As the amount of rac-[7]TH-dial molecules decreased, the formation of randomly distributed clusters of similar sizes become dominant. What is more, we report our STM tip-induced light emission investigation on rac-[7]TH-dial molecules and highlight the strong enhancement of light emission over rac-[7]TH-dial clusters formed on NiAl(110), suggesting the molecular character of light. Additionally, we show evidence of nanoscale dehydrogenation occurring during STM-TERS measurements on rac-[7]TH-dial molecules adsorbed on Au(111) surface. The near-field STM-TERS spectra obtained locally on a self-assembled monolayer of rac-[7]TH-dial molecules showed vibrational frequencies in good agreement with that predicted by density functional theory calculations, except for the L-mode at ~2000 cm⁻¹, which was ascribed to a carbon—carbon triple bond, revealing that the benzene rings had been dehydrogenated during the experiments. We conclude that one side benzene ring was dehydrogenated as a result of pyrolysis, with the Ag tip acting as source of local heat and catalyst.

**CP04.04.25**

**Mechanistic Understanding of Carburation from First-Principles Simulations**

Ahmed Darwish and Jacob Eapen; Department of Nuclear Engineering, North Carolina State University, Raleigh, North Carolina, United States.

The structural components of a very High Temperature Reactor (VHTR) are exposed to trace amounts of gaseous elements and moisture. These impurities can adversely affect the integrity of the reactor structural components. Among the impurity gases, carbon-bearing gases – methane, carbon monoxide and carbon dioxide – have significant detrimental effects on the protective oxide scales, which grow on nickel-based alloy surfaces, leading to carburation of the alloy.

In this work, we investigate the effect of carburing gases on the stability of chromium oxide scales using electronic structure simulations. We have utilized Kohn-Sham density functional theory (DFT) as implemented in the Vienna ab initio simulation package (VASP) with the generalized gradient approximation; to describe the strong correlations between the d electrons of chromium, we have utilized the DFT+U approach. The molecular structure of the oxide surface without the gases is first optimized structurally. Fully relaxed carburing gases are then allowed to be adsorbed on to the surface. We finally employ ab initio molecular dynamics (AIMD) simulations at high temperatures (up to 1200 K) to calculate the structural and dynamic properties of the interface, and to elucidate the mechanisms of thermal stability of the interface region at different temperatures and impurity coverage of the surface.

**Atomic Scale Study of Ordered-Structures Induced by Cu Grain Boundary Segregation at Al 7075 Alloys**

Prakash Parajuli, Ruben Mendoza-Cruz and Miguel J. Yacaman; Physics and Astronomy, University of Texas at San Antonio, San Antonio, Texas, United States.

Segregation of the alloying elements at the Grain boundaries (GBs) in a polycrystalline materials leads to a nanoscale chemical and structural variations along the GB region that can significantly alter the material’s performance. Hence, the experimental investigation of the atomic structure and chemistry of the grain boundaries by resolving the sites and chemical identities of the atoms comprising the interface is crucial to fully understand the implication of the atomic segregation phenomenon. Herein, we present the atomic scale analysis of ordered-structures induced by segregation of Cu atoms in Al 7075 alloy GBs along with the detailed examination of microstructural features (texture and grain boundary character distribution) by employing advanced microscopic characterization techniques: STEM-HAADF imaging, spectroscopic (EDS and EELS) analysis, and scanning
precession electron diffraction (PED). The <111> strong texture and dominant low coincidence site lattice (CSL) GBs were revealed in the films. Results demonstrated the segregation of Cu in all types of GBs, but with varying segregation patterns. Atomic-scale structure of each type of GBs showed two types of Cu GB segregation behaviors namely, point (highly segregated atomic column surrounded by low segregated columns, misorientation < 28°) and parallel array (two highly segregated columns opposite to each other across the interface surrounded by low segregated columns, misorientation > 28°). In addition to the single atom-interstitial hollow site (point) segregation behavior (predicted in theoretical studies and assumed to analyze the segregation effects), subsurface core site segregation of two columns of Cu atoms forming an ordered-structures with a parallel array of segregating atoms along the interface has been demonstrated. This is the first time that this type of parallel array segregation behavior has been reported. Furthermore, based on intensity profiles and scanning transmission electron microscopy Z-contrast principle, non-uniformly (high and low) segregated mixed atomic columns were predicted at the grain boundaries. We believe the knowledge of this type of experimental insight of the atomic scale arrangements of adsorbate on the GBs can potentially help to develop strategies for engineering the design of alloy compositions.

Controllable Introduction of Oxygenated Functional Groups into Carbon Materials for Gas Molecule Adsorption Enhancement Xinxin Pu1, Ani Wang2, Zhibin Qu1, Fei Sun1 and Jihiu Gao1; 1School of Energy Science and Engineering, Harbin Institute of Technology, Harbin, China; 2School of Chemistry and Chemical Engineering, Harbin Institute of Technology, Harbin, China.
Carbon materials with porous skeleton and specific chemical functionality have shown great potentials in the applications of gas adsorption, storage, separation and sensing. While a variety of literature have demonstrated that pore structure and chemical environment of carbon materials possess synergistic effects on these applications, there is still much to learn regarding structure-activity relationships, especially individually determining the role of chemical functionality or porosity in gas adsorption. Oxygen-containing groups widely exist in carbon materials and profoundly influence gas molecule adsorption on carbon surface, the complexity of carbon source and post-treatment methods, however, modify not only the surface chemistry of carbons but also their porous structure, making it considerably difficult to exclusively determine the effect of O-species. To this end, edge carboxyl group decorated graphene nanoplatelets (OGNPs) were used to investigate the effects of O-species on gas adsorption using SO2 as probe molecule. The OGNPs were obtained employing a simple ball milling method with dry ice assistance by which the oxygen content can reach as high as 14.06 wt-%, allowing 21 times increase in SO2 adsorption capacity as compared with oxygen-free graphene nanoplatelets. Both temperature-programmed desorption (TPD) experiments and DFT calculation were used to elucidate the nature of enhanced SO2 adsorption including adsorption types, adsorption energy and carbon-SO2 interactions. The adsorbed SO2 molecules on OGNPs can desorb easily at temperature lower than 100 °C, indicating their physisorption nature. Based on adsorption energy data, DFT calculation further demonstrate that the enhanced SO2-carbon adsorption by carboxyl groups doping is in the form of physisorption but not chemisorption. This means that the role of oxygen doping is to remodel the local electronic density, the polarity of carbon atoms as well as charge distribution of carbon surface, which induces the enhanced SO2 adsorption.

CP04.04.28
Crystallinity Improvement of Mist Chemical Vapor Deposition Grown ZnO Thin Films by Controlling Film Crystal Orientation Phimolphan Ruthongjan1, Misaki Nishi1, Li Liu1, T. Dang1 and Toshiyuki Kawaharamura1; Kochi University of Technology, Kochi, Japan.
Zinc oxide (ZnO) is one of promising semiconductors for numerous (opto)electronic applications because of excellent properties such as a wide band gap, a high exciton binding energy, and large piezoelectric coupling coefficients. ZnO crystallizes in the wurtzite hexagonal structure, which forms the polar c-plane and non-polar a and m planes. ZnO thin films of different preferential crystal orientations exhibit different properties, which leads to various applications. In ZnO films grown by chemical vapor deposition (CVD) techniques, the crystal orientation is mainly influenced by the orientations of the nucleation layer, which is, in turn, affected by diffusion of atoms along the surface during film growth. Several parameters affect the diffusion process such as oxidation reactions, type of substrates, growth temperatures, and gas flow rates. In the growth of metal oxide films by CVD, oxidation rate can be controlled by varying the supply amounts of oxygen and metal sources. Mist-CVD is one of the non-vacuum metal oxide film growth techniques capable of controlling the oxygen and metal supply amounts precisely. The precise control of the oxygen/metal ratios was realized by using the mist-CVD system with two solution chambers storing oxygen and metal sources (H2O and Zn precursor in this case) separately. In this work, we found strong dependences of the crystal orientations, growth rates, and surface morphologies on the [H2O]/[Zn] ratios in the ZnO films grown by the two chamber system. The equilibrium reaction of thermal decomposition of the Zn precursor was enhanced by addition of H2O leading to an initial increase in the growth rate with the [H2O]/[Zn] ratio. However, excessive addition of H2O caused a decrease in the growth rate. Moreover, H2O also influences the film crystal orientation. The diffusion of zinc and oxygen reactive atoms on the substrate surface during film formation was influenced by the [H2O]/[Zn] ratios, which resulted in different ZnO preferential growth orientation and film surface morphology.

CP04.04.29
Atomistic Modeling of Ionic Liquid Mixtures as Electrolytes in Electrochemical Capacitors Alta Fang and Alex Smolyanitsky; National Institute of Standards and Technology, Boulder, Colorado, United States.
Electric double-layer capacitors (EDLCs), also known as supercapacitors, are energy storage devices that deliver high power densities and long cycle lives but exhibit lower energy densities than Li-ion batteries. Improving the energy density of EDLCs without sacrificing their power density or lifetime is desirable for numerous energy storage applications. In order to rationally design higher energy and power density devices, an improved understanding of how electrolyte and electrode properties affect the performance of EDLCs is critical. Recently the use of ionic liquid mixture electrolytes as has been experimentally reported to improve EDLC performance under certain conditions. However, existing theoretical and computational work on ionic liquid mixtures in EDLCs remains limited, and there remains a need for detailed understanding of how ionic liquid mixture electrolytes affect EDLC performance. Using all-atom molecular dynamics simulations, we study the nanoscale adsorption behavior of mixtures of ionic liquids comprised of 1-ethyl-3-methylimidazolium (EMIM+), bis(trifluoromethylsulfonyl)imide (TFSI-) and tetrafluoroborate (BF4-) ions near planar carbon electrodes carrying surface charges that mimic externally applied voltages. Near uncharged electrodes, we find that ion-electrode interaction Waals interactions have a significant impact on the relative population of different ions in the first interfacial layer. By characterizing ion densities within a few nanometers of charged electrodes, we find that charging of the electrodes leads to greater overall changes in cumulative density of the smaller ion in each pure ionic liquid compared to the larger ion, as the larger ions tend to instead reorient and locally restructure close to the interface. Finally, in ionic liquid mixtures we identify an effective anion exchanging phenomenon near negatively charged electrodes that enhances counter-ion adsorption and provides a mechanism for capacitance enhancement. More broadly, our observation of modest capacitance differences between the ionic liquid compositions suggests that achieving substantially higher energy densities will ultimately also require tuning the structure and properties of the electrodes.

Ag Thin-Film Coating on LiCoO2 Electrodes for a Stable Solid-Electrolyte Interface at High-Voltage Operations Taner Zerrin, Congiz S. Ozkan and Mihrimah Ozkan; University of California, Riverside, Riverside, California, United States.
Increasing the operation voltage of LiCoO2 (LiC) is a direct way to enhance the energy density of the Li-ion batteries. However, overcharging the cells results in a very fast degradation of cycling stability due to the irreversible solid-electrolyte interface layer. In this work, Ag thin film was prepared on commercial LCO cathode by using magnetron sputtering technique to modify the interface between electrode and the electrolyte. Various electrochemical and
physical characterizations were performed to understand the diffusion kinetics of Li ions at the electrode-electrolyte interface. Coating the electrode surface with Ag thin film delivers an improved Coulombic efficiency, which is an indication of suppressed parasitic reactions at the electrode surface. As a result of the surface modification, Ag coated electrode enables an improved electrochemical performance with a much better cycling capability compared to that of the uncoated electrode. This work may lead to new methods on the interface modifications of LCO and other electrode materials to achieve high-capacity Li-ion batteries at high-voltage operations.

**Molecular Dynamics Simulation and Disconnection Model for Faceting of Migrating Grain Boundaries**

Larissa Woryk\(^1\), Spencer Thomas\(^1\), Jian Han\(^1\), Kongtao Chen\(^1\) and David Srolovitz\(^2,3\)

\(^1\)Materials Science and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; \(^2\)Materials Science and Engineering, City University of Hong Kong, Kowloon, Hong Kong.

Grain boundaries (GBs) migrate via the motion of disconnections (line defects in the GB that have both step and dislocation character). While the motion of symmetric tilt boundaries via this mechanism is reasonably straightforward, application to more general GBs requires additional assumptions. In this poster, we report the results of molecular dynamics (MD) simulations of the motion of asymmetric GBs. In particular, we examine the faceting of migrating asymmetric GBs. In some cases, faceting may occur during migration even when no faceting is observed in the stationary case. We analyze the MD results in the context of a disconnection description of GB migration. Finally, we discuss implications of dynamic GB faceting on grain growth.

**Thermotropic Polymers with Robust Interfaces for Transparency-Tunable and Impact-Resistant Windows**

Cheng Zhang and Jian Lin

The University of Missouri, Columbia, Missouri, United States.

Thermotropic polymers own thermally tunable transparency which have shown applications in intelligent solar control coating, privacy windows, displays, and optical/thermal sensors. Usually, thermotropic polymer systems are constructed by physically dispersing phase transition materials in transparent hosting materials. However, they usually possess bad interfaces either between the dispersion and the matrix, or between the thermotropic system and the supporting substrates (e.g., glass), resulting in poor mechanical properties, weak interfaces to substrates, or bad long-term stability. Herein, we demonstrate a novel chemically interconnected thermotropic polymer, which is obtained by reacting dodecanedioic acid (DDA) with glycerol. In the system, some of DDA molecules were crosslinked to form a polyester network, poly(glycerol-dodecanoate) (PGD). Other grafted but non-crosslinked DDA molecules form semi-crystalline domains which possess a solid-liquid phase transition within the PGD matrix. The phase transition offers the resulting hybrid materials with tunable optical transparency. In addition, when applied for window coating, it results in tough interfacial bonding to glass substrates with toughness of > 6910 J m\(^{-2}\) below its transition temperature and > 153 J m\(^{-2}\) above its transition temperature. It increases the impact-resistance of the window by multiple times.

**Multimodal Chemical and Functional Imaging of Functional Materials via Combined AFM/ToF-SIMS Platform**

Anton V. Ievlev

Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

For the last several decades Time-of-flight Secondary Ion Mass Spectrometry (ToF-SIMS) became a prime tool for chemical characterization of wide range of materials and systems with sub-micrometer spatial and nanometer depth resolution. However, it lacks characterization of the morphological, physical and functional properties of the studied sample. This issue can be addressed by combination with Atomic Force Microscopy (AFM). Such combined multimodal AFM/ToF-SIMS platform enables a nanoscale characterization of both chemical and physical properties of the sample along with its surface morphology. In this case, chemical information acquired by the ToF-SIMS can be correlated with functional response measured by the AFM. Furthermore, it opens pathway for chemical characterization of the local materials behavior on the nanoscale, when local chemical phenomena induced by the physical fields of the AFM tip (e.g. mechanical or electric) are characterized by the ToF-SIMS.

Here we utilize commercial AFM/ToF-SIMS platform to explore interplay of chemical and physical properties in ferroelectrics during polarization switching in lead zirconate titanate (PZT, Pb(Zr\(_{0.52}\)Ti\(_{0.48}\))O\(_{3}\)) thin films. Using this multimodal imaging platform, we demonstrated that chemical phenomena plays significant role in ferroelectric switching process. Specifically, we found that local ferroelectric switching by the AFM tip, significantly alters the chemical composition in the 3-mm-thick surface layer of the sample, forming reversible concentration wave, of Pb\(^+\) ions. Furthermore, investigations of the polarization cycling in the PZT sample with copper electrodes, showed penetration of the copper cations deep into the PZT structure. This explains ferroelectric fatigue phenomenon, leading to decrease in spontaneous polarization during spontaneous polarization cycling.

Additionally, explored chemical phenomena associated with ferroelectric switching will enhance fundamental understanding of ferroelectric phenomena and aid in the practical application of ferroelectrics in devices.

This research was conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility and using instrumentation within ORNL's Materials Characterization Core provided by UT-Battelle, LLC under Contract No. DE-AC05-00OR22725 with the U.S. Department of Energy.

**CP04.04.37**

**Using Light to Regulate Adhesion of Polymers to Substrate**

Hossein Mostafavi\(^1\), Kyle Clark\(^1\), Miranda Sroda\(^1\), Javier R. Alanz\(^2\) and Chris Bardeen\(^1\)

\(^1\)Chemistry, University of California Riverside, Riverside, California, United States; \(^2\)Bioengineering, University of California, Riverside, Riverside, California, United States.

One of our goals in Bardeen’s group is to explore the possibility of using photochromic molecules to regulate photo-adhesion. We have used various molecules including spiropyran, DASA (donor–acceptor Stenhouse adducts) and aracenes. These photochromic molecule shows new properties under light irradiation.

In one of our first projects we have used spiropyran (SP) molecules to increase adhesion of thin films of polystyrene (PS) to glass substrate. We have shown that photochromic reactions of SP doped in PS can significantly enhance the adhesion of PS to a glass surface. Shear adhesion test studies demonstrated that adhesion of polystyrene to glass slides increased by factor of 7 after irradiation. We hypothesize that the adhesion changes arise from localized polymer and molecular motions that eliminate void spaces and surface gaps at the polymer–glass interface. The results show that adhesive forces between a prototypical polymer and an inorganic substrate can be modulated by photochromic reactions of embedded molecules.

In the next studies we have used DASA molecules that has different properties compared to spiropyran. In Contrast with Spiropyran, DASA molecule is negative photochrome and its volume reduced after laser irradiation. This is in opposite direction of what we observed for spiropyran and we expected to see a decrease in adhesion of films to surface. We have used three different methods to measure adhesion before and after laser irradiation including water detachment, adhesion test and shear test and in all samples the adhesion decreased. Our experiments suggest that molecules’ photo induced shrinking may increase voids and pores and these changes will leads to a decrease in adhesion. Reduction of chemical interaction of molecules to surface may be another reason for this change.

As an application we tried to encapsulate organic dye -as a mode -between two glass surfaces which glued together by PS/DASA polymer. Then we measured time that the adhesion would break in water and irradiated samples released dyes 10 times faster than non-irradiated samples.

In conclusion we showed that we can remotely increase and decrease adhesion using various photochromics.

**CP04.04.38**

**Shedding Light onto the Controversy Around Graphene Wettability Opacity by Locally Probing Surface Free Energy**

Matteo Chiessi and Jin-You Lu

Khalifa University of Science and Technology, Abu Dhabi, United Arab Emirates.

Understanding how graphene coatings modify the surface free energy of a substrate is essential when implementing graphene in device fabrication and operation. Intensive recent studies report the partial wetting transparency of graphene, suggesting that the wettability of graphene is partially governed by the underlying substrate and becomes more hydrophobic with increasing the number of graphene layers for hydrophilic surfaces. However, a number of studies argue against the wetting transparency of graphene, indicating that monolayer graphene coating significantly dominates the surface wettability. Despite argument between proponents of graphene wetting transparency and opacity, a common denominator among these studies is the extensive use of static water contact angle (WCA) measurements for characterizing the graphene surface energy. Traditionally, the contact angle of a liquid droplet on homogeneous solid surfaces has been used to provide a quantitative measure of the surface properties of bulk solid surfaces, such as polymer, Si/SiO\(_2\), and different metal surfaces. However, the use of this macroscopic WCA in the study of graphene wettability has led to controversial measurements due to the complexity of
graphene coatings, where factors including the quality of graphene growth, transfer process, water adsorption, and hydrocarbon contaminants all impact the apparent surface properties. Specifically, macroscopic WCA techniques require large scale surface coverage of graphene to contact the milliliter size water droplet at the solid/liquid interface. This is challenging since one cannot precisely control the number of graphene layers at the contact line. In addition, for transferred graphene coatings, it is difficult to maintain consistent measurement results due to possible inhomogeneous contamination during the transfer process. These challenges are often ignored despite being the origin of the uncertainty in the measurements that have led to many contradictory interpretations.

In order to shed light into this controversy, we propose combining high resolution bimodal atomic force microscopy (AFM) with micro-Raman spectroscopy to measure the surface energy of graphene on SiO$_2$ substrates. Resolution and qualification of atomic force microscopy characterization are enhanced by forcing the AFM tip to oscillate near the solid surface in ambient in small amplitude and small set-point (SAAS) operation mode. Several physical quantities related to surface properties, such as force of adhesion, Hamaker constant, and elastic modulus, can be efficiently and statistically extracted from the feedback of observable raw parameters. In this work, we are particularly interested in exploring the adhesion force on the graphene surface since it is directly related to its surface free energy.

Two different families of graphene coatings: CVD-grown graphene and exfoliated graphene, are transferred to SiO$_2$ coated silicon wafers using a wet etch process and micromechanical cleavage technique, respectively. Unexpectedly, the surface free energy derived from AFM force of adhesion shows two opposite trends. The exfoliated samples show graphene being partially transparent by the underlying substrate, which supports graphene partial transparency theory. The other CVD-grown samples show that graphene is non-transparent and insensible to the underlying substrate, which supports the van der Waal opaque theory proposed by recent AFM characterization results on graphene/SiO$_2$ and MoS$_2$/SiO$_2$. By averaging the Raman measurements, the interface between graphene and SiO$_2$ substrate is identified to dominate the difference of observed surface free energy between exfoliated and CVD-grown graphene on SiO$_2$. Moreover, in addition to quantitatively estimation of surface energy change with different number of graphene layers, two levels of theoretical analysis using ab initio density functional calculations support our experimental observations.

8:00 AM *CP04.05.01
**Triple-Junction Dynamics During Grain Boundary Migration**
David J. Srolovitz$^{1,2,3}$, Spencer L. Thomas$^2$, Jian Han$^2$, Chaozhen Wei$^3$ and Yang Xiang$^3$; $^1$Materials Science and Engineering, City University of Hong Kong, Kowloon, Hong Kong; $^2$Materials Science and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; $^3$Institute for Advanced Study, The Hong Kong University of Science and Technology, Kowloon, Hong Kong; $^4$Hong Kong Institute for Advanced Study, City University of Hong Kong, Kowloon, Hong Kong; $^5$Mathematics, The Hong Kong University of Science and Technology, Kowloon, Hong Kong.

Grain boundaries (GBs) move by the formation and propagation of disconnections; line defects with both dislocation and step character. During the evolution of a polycrystalline microstructure, disconnections pile-up against triple junctions (TJs). This implies that TJs accumulate a net Burgers vector, $\mathbf{B}$. As the GBs migrate, the net Burgers vector at the TJ grows, creating a back stress that effectively shuts off additional disconnection motion and stops GB migration. TJs have many options to relax the Burgers vector and back stress: (1) accumulation of cancelling disconnection from the other GBs meeting at the TJ, (2) emission of other defects (e.g., lattice dislocations, twins,...), and (3) formation of new types of disconnections along the GB with opposite sign Burgers vector. I will show molecular dynamics simulations, theoretical analysis, and continuum simulations that show what is going on at TJs during GB migration and examine its implications for microstructure evolution.

**Shear Induced Motion of Twin Boundaries in Mg via Disconnection Terrace Nucleation, Growth and Coalescence**
Douglas E. Spearot$^1$, Laurent Capolungo$^3$ and Carlos Tome$^4$; $^1$Univ of Florida, Gainesville, Florida, United States; $^2$Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Twinning is a common deformation mode in hexagonal close packed metals such as magnesium. This atomistic simulation study characterizes the relationship between the kinetics associated with motion of the \{10-12\} twin boundary in pure Mg and the nucleation, growth and coalescence of disconnection terraces on the twin boundary. This problem is resolved adopting both 2D and 3D simulation geometries. This study shows that the kinetics of twin boundary migration can only be addressed in 3D, as 2D simulations predict twin boundary migration rates at least an order of magnitude higher than 3D simulations. A simple constitutive relationship is extracted from the atomistic simulations. Such a model, accompanied by observations of disconnection terrace nucleation, growth and coalescence, reveals the existence of an autocatalytic terrace nucleation regime for the shear induced motion of the \{10-12\} twin boundary in Mg.

**A Machine Learning Exploration of Grain Boundary Mobility Mechanisms**
Leila Khalili$^1$, Eric R. Horner$^2$ and Srikanth Patala$^3$; $^1$Department of Materials Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States; $^2$Department of Mechanical Engineering, Brigham Young University, Provo, Utah, United States.

The mobility of grain boundaries plays an important role in governing the kinetics of microstructural evolution in every class of polycrystalline materials. Of particular interest is the role of bicrystallography, characterized by the macroscopic crystallographic degrees of freedom, on the underlying atomistic mechanisms governing grain boundary mobility. In this talk, I will present an algorithm to automatically identify the atomistic motion mechanisms that give rise to mobility of an interface. We use machine-learning methods, inspired by recent work in disordered solids, to correlate local structure with the susceptibility for rearrangement of grain boundary atoms. We show that it is possible to automatically identify mobility mechanisms of grain boundaries with a diverse range of crystallographic character.

**First Principle Study of the Protonation Effect and Active Sites Towards Oxygen Reduction Reaction on α-MnO$_2$(211) Plane**
Xium Shu, AM Kannan and Xihong Peng; Arizona State University, Mesa, Arizona, United States.

The most commonly believed oxygen reduction reaction path on α-MnO$_2$ plane in alkaline media is undergoing water uptake or protonation to form MnOOH, then adsorb the oxygen. In this study, first-principles density functional theory calculations were used to simulate the oxygen adsorption on the clean α-MnO$_2$(211) plane and the protonated plane. There are total four possible sites at which the proton will bond with oxygen, all the proton adsorption energy is ~2 eV with a tiny variation. Total eight possible configurations were considered for oxygen adsorption onto the α-MnO$_2$(211) plane, include O=O=O, O=O−O=Mn and Mn−O=O=Mn sites. All the configurations showed oxygen adsorbed to the surface, with the adsorption energy ranging from 0.27−1.76 eV. The theoretic optimized oxygen adsorption is ~1.8 eV. The Mn−O=O=Mn sites showed the best improvement with protonation among all the O=O−O, O=O=O=Mn sites. The bond length for Mn−O=O=Mn sites doesn’t change very much with protonation.
Semiconductor photoelectrodes for hydrogen generation in photoelectrochemical cells are a very good demonstration example for the role which defects can play in function of electrical devices.

We present an extensive study on metal oxide heterostructures synthesized by chemical deposition methods with soft x-ray spectroscopy and electroanalytical methods. The matching of substrate current collector and photoabsorber layer forms an interface with a malignant electronic defect state which can be "healed" by introduction of a buffer layer from a different metal oxide - to the extent that the performance of the photoelectrode increases considerably. The molecular origin of this effect is uncovered by using oxygen ligand spectroscopy with soft x-rays. Specifically, a malignant state in the valence band at the interface is removed upon introduction of the buffer layer. The charge transport increases accordingly.

Different roles of defects are necessary at the surface which is in contact with a liquid electrolyte. Here the electrocatalytical properties are relevant, and correspondingly the absorber material is facing a challenge which its stoichiometry can not perform well. But a chemical after processing step, specifically gas phase reduction alters the oxidation state of the surface of the absorber to an extent that it can increase the photocurrent and hydrogen production efficiency considerably. This is evidenced both with soft x-ray spectroscopy and electron spectrscopy.

With this study is shown how the proper processing of components in heterostructures can yield better component performance in a device and thus better device performance.

10:30 AM CP04.06.03
Time Resolved Ambient Pressure X-Ray Study of Li$_2$CO$_3$ Formation on Garnet Electrolyte in CO$_2$ Melling Sun 1, 2; Yierpan Aierken 1, 3, Ane Etxebarria 1, 3, Hao Shen 1, David Prendergast 1, 2, Marca M. Doet 1 and Ethan J. Crumlin 1; Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3CIC Energigune, Parque Tecnológico de Álava, Múgica, Spain; 4Energy Storage and Distributed Resources Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Garnet Li$_2$La$_2$Zr$_2$O$_7$ (LLZO) has been considered as one of the most promising solid-state electrolytes that could enable solid-state-batteries employing metallic Li anodes. However, most Li$_x$A$_2$M$_2$O$_7$ garnets have been reported to react with air or moisture, which results in the loss of Li and also in the appearance of a main Li$_2$CO$_3$ secondary phase that is detrimental to the Li$^+$ conductivity at the Li$_2$-LLZO interface. Interestingly, different to other garnets, cubic LLZO was recently reported to be more stable in humid atmosphere regarding no structure change and conductivity degradation upon exposure to humid atmospheres. Although it is known that generally Li$^+$/H$^+$ exchange took place when garnet expose to moisture, the mechanism of how Li$_2$CO$_3$ forms on the interface is still unclear, especially for cubic LLZO. There is also lack of study on the independent role which CO$_2$, H$_2$O and O$_2$ play roles in Li$_2$CO$_3$ formation. Here we performed time resolved Ambient-Pressure X-ray Photoelectron Spectroscopy to monitor Li$_2$CO$_3$ thickness growth kinetics on Al-doped cubic LLZO in the presence of dry CO$_2$, O$_2$ assisted CO$_2$, and H$_2$O. CO$_2$ moisture under different gas pressures (0.01 mTorr, 1 mTorr, 100 mTorr). We elucidated that small amount of O$_2$ significantly catalyzes the Li$_2$CO$_3$ formation on cubic LLZO. Moreover, the minimal Li$_2$CO$_3$ formed in humid CO$_2$ when expose to three atmospheres of 100 mTorr, probably went through COOH$^-$ generation and is due to proton blocking effect. We hope this kinetic spectroscopic study would shed light on protecting carbonation of LLZO during processing and help to further understand the Li$_2$CO$_3$ formation mechanism in different gases.

ACKNOWLEDGEMENTS: The authors thank funding from the Energy Biosciences Institute and Shell International Exploration and Production Company. This research used resources of the Advanced Light Source, which is a U.S. Department of Energy, Office of Science User Facility under contract no. DE-AC02-05CH1231. The synthesis used the facilities supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division. Portions of the calculation work were supported by a User Project at The Molecular Foundry and its compute cluster (vulpus), managed by the High Performance Computing Services Group at Lawrence Berkeley National Laboratory (LBNL), and portions of this work used the computing resources of the National Energy Research Scientific Computing Center, LBNL, both of which are supported by the Office of Science of the United States Department of Energy under Contract DEAC02-05CH1231.

Coupling Chemistry and Mechanics in Nanomaterials Joerg Weissmüller 1, 2; Hamburg University of Technology, Hamburg, Germany; 1Helmholtz-Center Geesthacht, Geesthacht, Germany.

Many materials phenomena contain signatures of the coupling between chemistry (or electrochemistry) and mechanics. The coupling in the bulk of alloys is well acknowledged, for instance in studies of coherence phase transformations or of damping phenomena. Yet, strong coupling phenomena can also be found at interfaces. This may be exploited in novel materials concepts that afford unexpected functional behavior. Nanoporous-metal based hybrid materials that behave similar to piezoelectric ceramics exemplify this concept: Bodies of nanoporous gold impregnated with electrolyte emit exceptionally robust electric signals when subjected to external load. The metal-based material may thus be considered as piezoelectric, in a literal interpretation of the term. A predictive understanding of the interfacial stress-charge coupling, as the underlying microscopic phenomenon, remains elusive even after systematic experimental and numerical studies. On the other hand, the concepts which have been established in the discussion of bulk chemo mechanical coupling provide useful insights into a related phenomenon, namely the coupling between adsortion enthalpies and strain. This topic is of high interest to the field of strain-modulated catalysis. The talk will discuss relevant issues from the perspectives of experiment, phenomenological thermodynamics, and atomistics.

Surface Dominated Deformation in Sub-10 nm Au Nanocrystals at High Pressure Wendy Gu and Abhinav Parakh; Stanford University, Stanford, California, United States.

Sub-10nm metallic nanocrystals are expected to have unique elastic properties, strength and deformation due to the close proximity of surfaces, but are challenging to study due to the small forces and dimensions involved. Here, we use a diamond anvil cell to deform metallic nanocrystals under quasi-hydrostatic, and non-hydrostatic pressure up to 20 GPa in order to determine deformation mechanisms in this size regime and their dependence on microstructure. In particular, we are interested in the processes that lead to pseudoelasticity, or reversible shape recovery from large strain, that have been observed previously in small noble metal nanocrystals. Au nanocrystals with sizes from 4-10 nm are synthesized using colloidal methods. Structural changes under pressure are measured using optical absorbance spectroscopy and high pressure X-ray diffraction. Optical absorbance spectroscopy is used to monitor plasmonic resonance, which is highly sensitive to nanocrystal size and shape. High pressure X-ray diffraction reveals changes in the position and breadth of diffraction peaks, which reveals elastic strain, microstrain and the formation of crystalline defects. These measurements are corroborated by transmission electron microscopy on nanocrystals after compression. We find that 4nm Au nanocrystals are able to reversibly recover their size and shape after load is removed, even after compressed of ~20% along one axis. Crystalline defects remain in the nanocrystals after recovery. Larger Au nanocrystals do not exhibit this pseudo-elastic shape recovery.

11:30 AM CP04.06.06
Multi-Resolution Characterization of Surface Topography for Improved Prediction of Surface Properties Tevis D. Jacobs1, Abhijeet Gujrati1, Luke A. Thimons2, Subarna R. Khanal1 and Lars Pastewka1; 1Mechanical Engineering and Materials Science, University of Pittsburgh, Pittsburgh, Pennsylvania, United States; 2University of Freiburg, Freiburg, Germany.

Surface topography strongly affects the functional performance of free surfaces. For example, in electromechanical switches and other applications that make and break contact, surface topography affects the mechanical and transport properties of the contact. Further, in coatings applications, the adhesion of thin films depends strongly on the surface topography of the coated surface. However, many experimental investigations to quantify the effect of surface topography on properties are inconclusive. This is because most surfaces have multi-scale fractal-like roughness, such that the values of measured topography parameters depend on the characterization size and method.
Here we use nanocrystalline diamond films of varying grain size as model systems to investigate the quantitative connection between surface structure and surface properties. In the first part of the talk, we demonstrate the quantitative characterization of surface topography using transmission electron microscopy and its combination with conventional techniques for multi-resolution characterization. Specifically, more than 100 individual measurements at scales from Ångströms to centimeters are combined using spectral analysis to yield scale-dependent information on surface and interface topography. In the second part of the talk, we discuss multi-resolution measurements of adhesion as a function of topography. Results are analyzed in the context of multi-scale continuum mechanics models. The investigation demonstrates that this multi-resolution approach to topography characterization is far more effective than any conventional (single-scale) roughness descriptors at predicting adhesion and other surface properties.

Grain Boundary Metastability Under Irradiation—Toward Tunable Sink Efficiency
Mitra Taheri, Department of Materials Science and Engineering, Drexel University, Philadelphia, Pennsylvania, United States.

Understanding the sink efficiency of interfaces under irradiation is of paramount importance to tailoring materials for radiation tolerance. Using in situ irradiation coupled with precession electron diffraction analysis, defect absorption was tracked for increasing dose. Denuded zones were found to collapse, but in the absence of any detected change in macroscopic degrees of freedom of the grain boundaries. Each grain boundary denuded zone experienced changes different doses, indicating a direct observation of the difference in grain boundary “immunity” to irradiation depending on character. Since a change in sink efficiency is likely due to a change in point defect absorption at the boundary, this indicates that something about the structure of these boundaries has changed. The grain boundary macroscopic character remains the same, however, leading to the conclusion that a change in microscopic character has occurred, possibly due to the formation of extrinsic defects in the boundary. To analyze this further, simulations were used to explore grain boundary microstates loaded with defects (mimicking a collision cascade) and assessed for vacancy formation energies. Overall, the results present a foundation for improving sink efficiency descriptions under irradiation, and take a step forward in understanding complex interfacial dependencies. Additionally, results will be shown for studies of grain boundary structure and stability, including facetting, in the context of grain boundaries acting as “phases.” These advances present the possibility that the extent to which a grain boundary’s microscopic degrees of freedom change controls sink efficiency, and thus presents an opportunity to tune such efficiency as the defect scale.

2:00 PM CP04.07.02
Atomicistic Multiscale Modeling of Compositional and Defect Dynamics for Ion Irradiation Synthesis of III-V Semiconductor Quantum Dots
Michael Lively1, Michael Toriyama1, and Jean Paul Allain2,1; Nuclear, Plasma, and Radiological Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Materials Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Directed irradiation synthesis (DIS) and directed plasma nanosynthesis (DPNS) are robust, scalable approaches to design and fabricate surfaces and interfaces with unique, multi-functional properties at the nanoscale. In particular, DIS/DPNS can be used to rapidly fabricate hexagonal arrays of semiconductor quantum dots at III-V semiconductor surfaces in a single process step [1]. These are desirable for their excellent optoelectronic properties, including sharply-peaked density-of-states and sharp luminescence lines [2]. However, the ion irradiation process introduces significant damage and disorder to the surface, leading to the formation of a nanometers-thick, compositionally-complex amorphous layer at the interface [3], which significantly degrades the optoelectronic properties of the III-V quantum dots. Therefore, a fundamental atomicistic understanding of the irradiation-driven defect dynamics and structural-compositional disorder is crucial for optimized fabrication of these nanostructures.

We have carried out large-scale molecular dynamics (MD) simulations of low-energy (500 eV) Kr++ ion irradiation of GaSb surfaces on the Blue Waters supercomputer at the University of Illinois [4]. These simulations have shown that the irradiation-induced altered compositional depth profile drives phase separation into clusters of the enriched component (Ga or Sb) at a given depth, with characteristic sizes of a few nm, surrounded by 50/50 amorphous GaSb. The nanoscale interface between these clusters and the "bulk-amorphous" 50/50 GaSb are a region of elevated potential energy, which can function as diffusion sinks or as pathways for accelerated transport at the atomic scale. From MD simulations of ion irradiation from the initial (pristine) surface to the structure formation threshold fluence, we observe the formation of small, unstable “protoclusters” of Sb throughout the surface from prompt ion effects. The Sb protoclusters are usually <1 nm in size and contain ~4% of all Sb atoms in the GaSb. However, no evolution of a global compositional gradient emerges from these simulations, indicating that long temporal scale effects such as defect-mediated diffusion are necessary to model the complex compositional evolution of the surface. Analysis of the atomic bonding in the irradiated surface indicates a strong preferential mobility of Sb atoms, suggesting accelerated Sb diffusion to the cluster/bulk interface as the protocluster growth mechanism.

To elucidate the defect dynamics and atomic diffusion mechanisms, we have developed a hybrid MD/KMC model to connect short and long temporal scales in a single simulation framework. The KMC component models atomic diffusion through the disordered layer via a lattice-free method which relies on “in-situ” characterization of the point defects generated by cumulative ion impacts into the GaSb surface. Using this hybrid model, we test the hypothesis that irradiation-enhanced diffusion of Sb atoms towards the Sb protoclusters interfaces provides the growth mechanism to stabilize Sb protoclusters at 2-3 nm diameters. This mechanism connects the prompt ion-induced structural changes and defect production to three-dimensional compositional evolution and surface morphology of III-V surfaces. We study the influence of the surface temperature on the defect dynamics and recovery rates, showing how manipulating the ratio between ion flux and surface temperature during DIS/DPNS processing offers a route towards minimizing damage and optimizing the properties of the resulting III-V quantum dots.

2:15 PM CP04.07.03
Atomic-Scale Mechanisms for Interfacial Radiation Damage Resistance of Oxide Heterostructures
Steven R. Spurgeon, Michel Sassier, Tiffany Kaspar, Weilin Jiang and Vaithiyalingam Shutthanandan; Pacific Northwest National Laboratory, Richland, Washington, United States.

Functional oxide interfaces exhibit useful emergent properties for electronics and sensors, but little work has been done to examine their degradation in high-radiation environments, such as in spacecraft and nuclear reactor cores. While grain boundaries in metals are known to respond much differently than the bulk, less attention has focused on the behavior of engineered oxide interfaces, which offer the potential to finely control structural, chemical, and electronic parameters. Here we examine the damage response of La2TiO4/SrTiO3, and related heterojunctions using a combination of advanced scanning transmission electron microscopy (STEM), electron energy loss spectroscopy (EELS), and ab initio theory calculations. We observe that the interface can exhibit markedly improved damage resistance to 1 MeV Zr+ ion bombardment, in contrast to the bulk of the film or substrate. We discuss possible atomicistic damage mechanisms and identify unique features of the interface that can influence the damage process. This work suggests that engineered oxide interfaces may offer a means to tune both functional properties and damage resistance, with potential implications for device design in extreme environments.

2:30 PM BREAK
Laser-assisted probe tomography (LAPT) is a powerful tool for materials characterization due to its desirable combination of high spatial resolution and analytical sensitivity. In state of the art LAPT the thermal transient from a near-UV laser (E = 3.5 eV to 3.6 eV; 343 nm to 355 nm) provides the energy to overcome the activation barrier for field ion evaporation. This technique is generally superior to voltage pulsing, which is limited strictly to conductors, and has allowed APT to expand its capability to effectively analyze a wide-range of materials including semiconductors and insulators. However, the thermal process is not without drawbacks. For example, LAPT data quality can be degraded due to thermal tails that limit sensitivity, formation of cluster ions that may have isobaric overlap with elemental species or dissociate into undetected neutral species which can adversely influence composition measurements. This is especially true for many ionic and covalent materials and can limit the recovery of bulk stoichiometry or composition to a narrow range of experimental conditions, if at all [1,2].

Ionizing radiation in the extreme ultraviolet (EUV) region of the electromagnetic spectrum (10 eV to 100 eV; 124 nm to 12 nm) may offer a potential athermal field ionization pathway. Dependent on the particular photon energy used, EUV radiation is above the band gap, work function and ionization potential of any naturally occurring element. Photoionization cross-sections peak in the EUV band across the entire periodic table, and EUV is highly absorbed within the first few nm of the sample surface [3]. Coherent EUV radiation may also offer a potential in situ method for imaging the evolving specimen shape in real time through simultaneous coherent diffraction imaging or related methods [4].

This finding has significant consequences. For example, EUV-APT may be able to measure nanoscale composition measurements in materials systems where the functionality depends critically on an unknown composition or stoichiometry at the local level, or where non-equilibrium phases play a role. This can be as simple as measuring and mapping the variation of a known reaction layer or compound formed during thin film deposition. Another example is in resistance switching oxides that have potential use in non-volatile memory and memristors in neuromorphic computing elements for beyond-CMOS quantum information systems. In these materials, oxygen deficiency (e.g. the oxygen vacancy concentration) plays a critical role in the nanoscale, conductive filaments responsible for the desired functionality. Other applications include hydrogen separation membranes, oxidation catalysts, ion conduction materials, and superconductors.

Sub-Nanoscale Chemistry Across an Abrupt SiO2/Si Interface Using Vibrational Electron Energy-Loss Spectroscopy Kartik Venkatraman1, Barnaby D. Levin1, Katrina March2, Peter Rez2 and Peter Crozier1, 1School for Engineering of Matter, Transport and Energy, Arizona State University, Tempe, Arizona, United States; 2Eyring Materials Center, Arizona State University, Tempe, Arizona, United States; 3Department of Physics, Arizona State University, Tempe, Arizona, United States.

Interfaces are frequently the site of reactions and phenomena that dominate macroscopic properties, even though they are fractionally present relative to the bulk. Widely used vibrational spectroscopies like Raman and Fourier-transform infrared (FTIR) spectroscopy provide chemical fingerprints of bonding arrangements for materials characterization. However, only a few vibrational spectroscopies are effective to probe interfaces at the molecular level, viz. second-harmonic generation spectroscopy and sum-frequency generation spectroscopy. Advances in monochromation in the modern scanning transmission electron microscope (STEM) has made it possible to detect vibrational excitations using electron energy-loss spectroscopy (EELS) [1]. This new capability can be used to investigate the delocalized behavior of bulk as well as the localized behavior of surfaces and interfaces [2]. For a comprehensive understanding of the technique, experiments need to be performed on simple model systems. We explore the spatial variation in different vibrational modes when an electron beam is scanned across an abrupt SiO2/Si interface. This investigation provides baseline data which can be used to further explore the influence of more complex interfaces on vibrational modes in materials.

A 3 μm layer of SiO2 on a Si wafer was prepared for STEM EELS analysis by lifting out a focused ion beam (FIB) lamella using a Nova 200 NanoLab (FEI) FIB. A NION UltraSTEM 100 aberration-corrected electron microscope was operated at 60 kV and equipped with a monochromator that was used to perform EELS linescans across the SiO2/Si interface. The electron interactions in vibrational EELS can be discussed in terms of dipole and impact scattering as done in surface vibrational spectroscopy using high-resolution EELS [3]. The energy-loss spectrum from amorphous SiO2 shows the thin-film bond-stretch mode at 144 meV, a dipole scattering dominated signal, and the bond-stretch plus bend mode at 100 meV, an impact scattering dominated signal. We show that, in practice, the SiO2 thin-film signal at 144 meV is delocalized to ~20 nm and that nanometer resolution is possible when selecting the SiO2/Si interface signal at 136 meV. We also show that the 100 meV vibrational mode in SiO2 was used to measure the interface abruptness to 0.5 nm. Finally, we demonstrate that with vibrational EELS in crystalline Si, which has only impact scattering dominant vibrational modes, a resolution of better than 0.2 nm was achieved with both optical and acoustic phonons [4]. Further experiments on the effect of interfaces such as grain boundaries and twin boundaries on the chemistry in Si will be presented.

conditions to 5% and 20% strain. Using nanobeam scanning diffraction, with a 3nm near parallel-beam probe, we acquired crystallographic information and measured volume fractions of deformation-induced twins and phases within the observed shear bands. We complemented the nanobeam diffraction measurements with atomic-resolution imaging to determine the structure of the interfaces between the martensite phases and the FCC-austenite matrix and to establish the configuration of dislocations at these interfaces. At 5% strain, the non-charged specimens show ample dislocation content from the initial as-forged microstructure with twin-laden shear bands apparent throughout the specimen. In the hydrogen-charged material, dislocation activity is planar at 5% strain, with shear bands containing far less twinning and instead forming ε-martensite. This trend continues up to 20% strain, with non-charged samples only showing general dislocation plasticity and twinning. At 20% strain, hydrogen-charged samples showed large amount of ε-martensite shear bands with α’-martensite within the intersections of the shear bands. Our observations support the strong-breaking notion that ε-martensite is a necessary intermediary in the formation of α’-martensite platelets, as has been described within the classical Olson-Cohen mechanism. However, detailed analysis of the observed structure of the shear-bands raises questions regarding the actual dislocation mechanisms underpinning this transformation. Atomic-resolution observations of an α’-martensite nucleus within an ε-martensite laden shear band shows low dislocation content surrounding the nucleus, indicating that the geometrically contrived distribution of shears of the conventionally invoked Olson-Cohen mechanism for α’-martensite nucleation are inconsistent with the experimentally observed shears. We will discuss alternative interfacial dislocation-based descriptions for the nucleation process and outline potential opportunities and needs for modeling to further clarify the transformation mechanism and its dependence on hydrogen.

**Atomic-Scale Chemical Analysis at Ceramic Interfaces by Advanced Scanning Transmission Electron Microscopy**

Naoya Shibata, The University of Tokyo, Tokyo, Japan.

In recent years, atom-resolved chemical mapping becomes possible by using aberration-corrected scanning transmission electron microscopy (STEM)-energy dispersive X-ray spectroscopy (EDS). STEM-EDS makes it possible to determine almost all the element atoms in periodic table at the same time, so it is advantageous to characterize material interfaces with local chemical inhomogenities. In this study, we applied this technique to understand complex local chemical structures at ceramic interfaces such as yttria stabilized zirconia grain boundaries. By using aberration-corrected STEM combined with high-sensitive silicon drift detectors (SDD), atomic-scale segregation profiles of solute and impurity atoms across ceramic interfaces can be clearly mapped. We demonstrate such chemical analysis elucidates very interesting atomic-scale segregation structures at ceramic interfaces. In this talk, the details of such ultra-high-resolution chemical mapping and new knowledge gained by such observations on ceramic interface segregation will be reported.

**Gallium-Based Liquid Metal Wetting Behavior of Tungsten Powder Facilitated via Electroless Silver Coatings**

Wilson Kong, Matthew Ralphs, Robert Wang and Konrad Rykaczewski, Arizona State University, Tempe, Arizona, United States.

Gallium-based liquid metals are stable liquids at room temperature that exhibit many excellent thermo-physical properties. Liquid metals are useful in applications that require high electrical and thermal conductivity in addition to mechanical deformation. Combining liquid metals with other thermally conductive metallic particles could potentially result in enhancements of these transport properties [1]. However, liquid metals are notorious for alloying with and/or embrittling metals under prolonged exposure due strong intermetallic chemistries. Refractory metals such as tantalum and tungsten are generally resistant to these detrimental processes. However, these metals are unable to directly wet with liquid metals, which prevents them from forming composite fluids. Depositing a thin metallic layer onto these metals can potentially enable refractory metals to be mixed in liquid metal via reactive wetting processes [2]. Electroplating and electroless deposition techniques have long been used to fabricate bi-metallic powders in literature [4]. We show that electroless deposition of silver coatings on tungsten powder can facilitate reactive wetting of these powders in liquid metals. This work demonstrates a relatively simple procedure of forming tungsten-silver core-shell powders and their reactive wetting behavior in liquid GaSn. In-situ focused ion beam (FIB) characterization is utilized for direct observation of this nanoscale wetting process. This work also investigates a time study of potential room temperature alloying processes of the silver layer in a gallium-rich environment under different volumetric fractions of liquid metal/powder. These studies can provide fundamental insights into liquid metal wetting phenomena and how to engineer material surfaces for thermal management, flexible electronics, and plasmonic applications.

**Characterization of Chemically Heterogeneous Metal-Metal Solid-Liquid Interfaces Using Atomistic Simulation**

Brian Laird, Yang Yang, J. Pablo Palacios-Hernandez, Jesse L. Kern and Mark Asta; 1Department of Chemistry, University of Kansas, Lawrence, Kansas, United States; 2Department of Physics, East China Normal University, Shanghai, China; 3Department of Chemistry, College of St. Scholastica, Duluth, Minnesota, United States; 4Department of Chemistry, Randolph College, Lynchburg, Virginia, United States; 5Department of Materials Science and Engineering, University of California, Berkeley, California, United States.

The properties of solid-liquid interfaces (SLIs) govern a wide variety of processes of technological import, e.g., wetting, heterogeneous nucleation, casting, and crystal morphology and growth. Here, we examine three chemically heterogeneous metal-metal SLIs, specifically Al(s)/Pb(l), Cu(s)/Pb(l) and Al(s)/Ga(l) to determine how interfacial structure and dynamics affect phenomena of experimental interest. For Al/Pb, transmission electron microscopy (TEM) experiments show that liquid Pb inclusions undergo Brownian motion within a solid Al matrix. Using molecular-dynamics (MD) simulations, we examine the role played by Al diffusion at the SLI interface in this phenomena and in the spreading of droplets. For Cu/Pb interfaces, earlier simulations predict a strong anisotropy in interfacial structure, with the (100) interface exhibiting surface alloying and the (111) showing a “pre-freezing” region. 2-3 lattice spacings thick, of crystalline Pb at the interface. Using an extensive series of MD simulations we show how this structural anisotropy contributes significantly to differences in the heterogeneous nucleation rates between these two interfaces. Finally, we examine the Al(s)/Ga(l) solid-liquid interface, an important material for the understanding of liquid-metal embrittlement, using both classical and ab-initio molecular-dynamics simulation.
Control of heterogeneous ice nucleation (HIN) is critical for applications that range from iceophobic surfaces to ice-templated materials. Multiple computational studies have been performed to study the effects of the substrate’s surface energy and topography and how their interaction determines phase transition temperature (PTT) and nucleation rates. Two particular well-studied substrates are graphene and silicon. In contrast to a considerable body of literature on computational approaches, few experimental studies have been reported concerning HIN on graphene and the extent of the effect of surface energy on the HIN on plasma-oxidized silicon. The study reported here focuses on the nucleation efficiency of ice on single layer graphene (SLG) deposited on three different substrates: single crystal silicon, fused quartz, and 300 nm SiO₂/Si, as well as plasma-treated silicon with multiple different surface energies. HIN was studied by placing a 1μL water drop on the substrate and observing the PTT using a freezing stage in a Raman spectroscopy system. After each freezing run, the WCA is measured, again. Findings are that the SLG displays surface transparency after only one experiment as indicated by the WCA changing from 95.4°+/−0.4° (a value typical for SLG), to values ranging from 60.9°+/−0.3° to 68.4°+/−0.3°. Such a significant decrease in surface energy was not predicted by computational models suggesting surface topography effects. To investigate the latter, the substrate surfaces were characterized by scanning electron microscopy (SEM) and atomic force microscopy (AFM). The surprising findings were prominent wrinkles, where the SLG would peel away during the sequential HIN experiments, explaining the change in WCA which occurs due to the lower surface energy substrate being exposed. As a second material system, plasma-oxidized silicon was tested in the same way: as-received, and after 30 s, 120 s, and 300 s plasma exposure with resulting WCA ranging from 32.2°+/−0.3° to −2°. In both systems, the range of observed PTTs was surprisingly small falling within a range from -18.6°+/−0.6°C for the SiO₂/Si substrate (contact angle from 2 to 33 degrees) and -22.5°+/−0.6°C for the graphene substrate (contact angle from 60 to 90 degrees). While the fact that the SLGs were compromised will have contributed to the results obtained for the SLG material systems, the independence from surface energy of the PTT in the case of the plasma-oxidized silicon is an important finding. Both outcomes are noteworthy: 1) The results from the SLG system illustrate the importance of a careful characterization of the substrate before and after nucleation experiments, as it may reveal, as in our case, the suboptimal quality of commercially available SLGs, which poses considerable experimental challenges for the experimental verification of computational results and puts into questions results obtained without such an analysis. 2) The results from the study of plasma-oxidized silicon, which suggest that surface energy or WCA alone are not good indicators of PTT, invite further exploration both experimental and computational.

9:45 AM CP04.09.05
Adsortion Transparency of Supported Graphene to Water Molecules
Morteza H. Baqheri1, Rebecca T. Loibl1, Yingchun Jiang1, Anibal Boscoboinik2, Manuel Smer4,3 and Scott N. Schiffer1,1,1
1,1Mechanical Engineering, Binghamton University, The State University of New York, Binghamton, New York, United States; 1Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States; 1Material Science and Engineering, Binghamton University, The State University of New York, Binghamton, New York, United States; 1,1Physics, Binghamton University, The State University of New York, Binghamton, New York, United States.

The effect of graphene conformal mapping on the wetting of a surface remains a controversial topic. Many groups have studied the wetting transparency of graphene coated surfaces by measuring the water contact angle on the surface, however, airborne contamination due to the exposure of the surface during contact angle experiment can alter the hydrophilicity/hydrophobicity of the surface. Here, we explore this controversy by comparing the interaction of water molecules with a surface through measurement of the adsorption energy of the water molecules on the surface with and without graphene coatings. Ambient-pressure X-Ray Photoelectron Spectroscopy and quartz crystal microbalance experiments will be reported.

10:00 AM BREAK
Diffusion-induced grain boundary migration (DIGM) - A Molecular Dynamics Simulation

Navjeet Kaur, Chung Deng and Olamrewaju A. Ojo; Department of Mechanical Engineering, University of Manitoba, Winnipeg, Manitoba, Canada.

Diffusion-induced grain boundary motion (DIGM) can be described as normal grain boundary migration phenomenon caused by lateral grain boundary diffusion. In this work, molecular dynamic simulations using Embedded Atom Method potentials and LAMMPS code are performed to investigate the physical origin of DIGM. A comprehensive approach constructed by combining various atomistic simulation techniques, i.e., the synthetic driving force method, the interface random walk method, and shear coupling, has been used to quantify the driving force that operates during DIGM. The driving force obtained from this method is then compared to those arising from coherency strain energy. The two values are consistent with each other, which shows that a key driving force for the phenomenon is that due to unbalanced coherency strain energy across the boundary.

The simulation results also show that segregation plays an important role in promoting DIGM once GB is in close contact with the solute atoms. All observations made during the simulations are supported by the atomistic configurations and graphical analysis at different stages of the process. This phenomenon is of immense technological importance because of its scientific and practical significance in materials.

11:45 AM CP04.10.05

Interface Energy and Orientational Dependence of Interface Velocities and Mobilities of an Austenite-Ferrite Interface in Pure Fe Using Molecular Dynamics Simulation

Pawan K. Tripathi and Somnath Bhownick; Material Science and Engineering, IIT Kanpur, Kanpur, India.

Austenite (γ-Fe, face-centered cubic (FCC)) to ferrite (α-Fe, body-centered cubic (BCC)) phase transformation in steel is of great importance from the point of view of industrial applications. In this work, using classical molecular dynamics (MD) simulations, we study the atomistic mechanisms involved during the transformation of the ferrite phase from an austenite phase. The kinetics of the transformations, classified as martensitic and massive, is defined in terms of the interface mobility, which depends on the interface migration velocity and Gibbs free energy change. The simulations are performed by creating an FCC region, sandwiched between two BCC regions (interface formed according to Nishiya-Wasserman (NW) orientation relationship, with [110] of BCC oriented parallel to [111] of FCC) and studying how the former transforms into the later phase at elevated temperature, ranging from 1000 to 1400 K. Three configurations of BCC-FCC phase were created by tilting FCC phase with respect to z-axis with an angle of 3.11°, 4.04° and 5.77° from the ideal NW, resulting into formation of steps or disconnections at the interface. Using MD simulations, the effect of the tilt on interface velocities, mobilities and activation energy followed by the interface migration mechanism in each of the orientation will be discussed.
a consistent understanding of the \( n_{\alpha} \) directionality and of the final thin film microstructure characterized by a comprehensive structure analysis. The mechanism of LE was studied in situ as a function of time and temperature by Rutherford backscattering spectrometry and Raman spectroscopy. The graphitization occurred simultaneously with the LE and is completed during the applied heating ramp to 700 °C. The temperature resolved measurements allowed the determination of the onset temperatures and transition rates as a function of the annealing temperature and the stacking order. Finally, the activation energy for both LE directions was estimated. In combination with the thermodynamic calculations, this in situ study allows to identify the metal-induced crystallization via wetting and diffusion along grain boundaries, instead of dissolution/precipitation as the responsible mechanism for graphitization of amorphous carbon with layer exchange in contact with Ni. The proposed model can potentially be used to estimate the catalytic transformation of group 14 elements in contact with transition metals.

Financial support by the Helmholtz Excellence Network DCM-MatDNA (ExNet 0028) is gratefully acknowledged.

3:30 PM *CP04.12.01
Oxide Scale Evolution on Ni and Ti Alloys Talaia Barth, Paul Chao, Kathleen Chou, Emmanuelle Marquis and Emmanuelle Marquis; Department of Materials Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States.

Lifetime of structural alloys used in high temperature applications is often limited by their vulnerability to oxidation. To address this issue, different alloying and/or coating strategies have been developed depending on alloy system and application. Alloy chemistries may be tailored so that a slow-growing, passive oxide scale forms on the alloy surface and protects it from further attack by oxidation. The addition of small amounts of dopants can further reduce oxide growth kinetics and enhance scale adherence. While the principles leading to scale growth are generally understood, the mechanistic roles of alloying elements and synergy between alloy and oxide scale are often less clear. High resolution characterization techniques provide a unique opportunity to uncover new insights into the structure and evolution of oxide scales, and ultimately quantify mechanisms of alloy oxidation. Using our experimental observations, we will discuss the mechanisms of scale growth and the contributions of alloying elements during controlled oxidation exposure of model Ni-Cr-Al and Ti alloys.

Morphological Stability and Breakdown of Passive Oxide Films Rohit Ramanathan and Peter W. Voorhees; Northwestern University, Evanston, Illinois, United States.

Most models describing the formation of a passive oxide film on a metal are formulated in one-dimension where the principle assumption is that any interfaces in the system are planar. These models fail to describe the interfacial evolution of morphologically complex oxide films because they neglect interfacial energy and curvature, which are important for self-consistently describing morphological evolution for non-planar interfaces. We extend the Point Defect Model for growing oxide films to multiple dimensions and have modified the boundary conditions to include capillary contributions to the defect chemical potentials at the film interfaces. We perform a morphological stability analysis of the 1D steady-state as a first step toward describing the full morphology evolution of the oxide. Our analysis predicts that a localized thinning instability is present at concave regions oxide-solution interface due to anodic dissolution of the oxide. This instability could be the first step of the formation of pitting corrosion. Our results provide insights to the important role that interfacial energy plays in the evolution of the oxide film and suggests that many 1D models may be inapplicable in a broad class of corrosion processes.

Ab Initio Prediction of Metastable Phases at Metal/Oxide Heterointerfaces Aakash Kumar1, Amit Sharma2, Eugen Rabkin1 and David Srolovitz3,4; 1University of Pennsylvania, Philadelphia, Pennsylvania, United States; 2Technion - Israel Institute of Technology, Haifa, Israel; 3City University of Hong Kong, Hong Kong, Hong Kong.

Heterophase interfaces such as metal/ceramic and ceramic/ceramic interfaces are ubiquitous to a wide range of technological applications, such as the all-solid-state-batteries (ASSB), Cu(In,Ga)Se2 (CIGS) based photovoltaic cells and numerous other solid-state devices. Transport of atoms along these heterophase interfaces may lead to metastable phase formation at the interface. In this work, we report the experimental observation of two such cases a) HCP type Ni(Fe) phase (ground state is fcc structure) and b) FCC Fe (ground state is bcc structure), after the heat treatment of (solid solution) Ni95Fe5/O-Al2O3 and (solid solution) Ni95Fe5/O-Al2O3 respectively. Using ab initio calculations in conjunction with cluster expansion techniques, within the recently formulated meta Generalized Gradient Approximation - SCAN functional, we develop a general model (based upon interface energies) that can be readily applied to establish the conditions under which metastable phases will exist at/near heterophase interfaces, and then predict their minimum and maximum equilibrium thickness under specified conditions. Our experimentally observed thickness of the hcp-Ni(Fe) metastable phase is within the bounds predicted by the model. This implies that the occurrence of stable phases at these heterophase interfaces may not always be as predicted by the equilibrium thermodynamics but in fact is dependent on the interface energies of these heterophase interfaces.

Crystallization of Complex Oxides in Proximity of Semiconductor Surfaces with Non-Planar Geometries Divya J. Peakash1,2, Yajin Chen1, Christoph F. Denekel1, Paul G. Evans2 and Francesca Cavallo1,2; 1Center for High Technology Materials, The University of New Mexico, Albuquerque, New Mexico, United States; 2Department of Chemical and Biological Engineering, The University of New Mexico, Albuquerque, New Mexico, United States.

The crystallization of sputter-deposited amorphous strontium titanate (SrTiO3, STO) films is affected by the proximity of free-surfaces and interfaces with other materials. We have crystallized STO films with a thickness of ~12 nm sandwiched between two Si and SiGe-alloy semiconductors in non-planar geometries. The amorphous STO films were obtained by sputtering onto a room-temperature Si-SiGe heterostructure with a built-in stress imbalance. The released STO/Si/SiGe heterostructure rolls into tubes with diameters of a few microns, placing the STO layers in the proximity of two non-planar (or curved) semiconductor surfaces. The effect of the oxide/semiconductor interfaces on the crystallization process is investigated by heating the rolled-up structures to induce crystallization. X-ray diffraction and Raman spectroscopy provide insight on how the proximity of interfaces may determine the balance between nucleation probability and growth of the crystalline phase. Additional effects associated with heating include a restructurization of the amorphous layer and a change in the tube diameter due to changes in the stress distribution within the rolls.

Revealing the Role of Interfacial Stress on the Polarization Stability of Lead-Free Relaxor Ceramics Julia Glum1,2, Yoon Heo3, Matias Acosta1, Pankaj Sharma1, Jan Seidel1 and Manuel Hinterstein1,2; 1Norwegian University of Science and Technology, Trondheim, Norway; 2UNSW Australia, Sydney, New South Wales, Australia; 3Technische Universität Darmstadt, Darmstadt, Germany; 4Karlsruhe Institute of Technology, Karlsruhe, Germany.

The unique properties displayed by canonical relaxor ceramics, such as the electric field induced transformation from a pseudo-cubic relaxor state to a polar ferroelectric state[1], the associated huge strain[2] and the phase transition mediated polarization reversal mechanism[3], make these materials highly interesting objects for fundamental studies as well

*CP04.12.01

as versatile components for industrial applications. Especially, the achievement of high strains has drawn significant attention, the origin of which is based on the reversibility of the phase transformation between the ferroelectric and the relaxor state [4]. Many relaxor-ferroelectric systems exhibiting high actuating performance are located in the morphotropic phase region leading to the appearance of multiple crystallographic phases even within single grains. Their ability to take on different phases simultaneously and to change the phase ratio to adapt to external stimuli [5], is another important factor contributing to their exceptional electromechanical performance.

Here, we report on the thermal evolution of the different crystallographic phases in a multiphase (Bi1/2Na1/2)TiO3-BaTiO3 relaxor ceramic and the associated development of interfacial stresses. Upon electric field application, this system exhibits an “intrinsic core-shell structure” of a polar minority phase embedded into a polar majority phase. While the majority phase stays stable with increasing temperature up to the transition into the relaxor state, a gradual de-texturization of the minority phase is observed over the whole temperature range. The surface domain structure was found to decay already at significantly lower temperatures than expected from bulk observations. Development of interfacial stresses due to thermal expansion mismatch between majority and minority phases as well as differences in local stress state between surface and bulk are discussed as driving factors of the phase transition dynamics.

Tailoring of interfacial stresses through adaption of phase fractions opens up a pathway to optimize the strain performance of actuators and materials and can become a useful tool for the stabilization of usually metastable crystallographic phases as well as for property tuning in piezoelectrics and multiferrics.

Controlling the micro/nanostructure of thin films would enable us to explicitly tailor their mechanical behavior. Here, we describe a new process to synthesize thin films with precise microstructural control via systematic, in-situ seeding of nanocrystals, and subsequent crystallization of amorphous precursor films. It was found that varying the seed element affects the final phase of the films once annealed, such as NiTi forming an austenite or martensitic phase when seeded with Cr or Ti, respectively. This gives the ability to control grain size, dispersion, and phase composition of thin films. Additionally, crystallization temperatures potentially decrease with the presence of these nanocrystals, reducing precipitate formation and enhancing mechanical properties.

Austenitic 316L stainless steel is presently used for orthopaedic implants due to its biocompatibility and high corrosion resistance. One issue, however, with the use of this material in such applications concerns its low wear resistance. Surface properties can be modified through case hardening treatments in order to improve wear resistance and fatigue life as well. In this study two such treatments were applied on stainless steel 316L. The first treatment was Surface Mechanical Attrition Treatment (SMAT) which is a severe plastic deformation (SPD) process that enhances the surface properties and the performances of a material without changing its chemical composition by creating a nanostructured layer on the top surface of the material. The hardness evolutions below the treated surfaces were measured using micro- and nano-indentation and it was shown that at the top surface an increase of 75% in the hardness can be obtained after SMAT. The effect of SMAT can extent deep beneath the treated surface with the creation of a high deformation zone following the nano-grained layer. This high deformation zone contains larger grains where local misorientations are present, and the material in that region is seeing strain hardening as well. Further to SMAT, some specimens underwent a second case hardening treatment, plasma nitriding, to further enhance their surface properties by the diffusion of nitrogen atoms in interstitial positions in the iron lattice creating additional residual strains at the top surface of the material. Using different microstructure characterization techniques, we were able to determine the microstructural evolution of the stainless steel after these different surface treatments and to determine the effects of creating new grain boundaries by SMAT on the nitriding process. The microstructure features investigated here include thickness of the nanocrystalline layer, size of the grains within the nanocrystalline layer and depth of diffusion of the nitrogen atoms within the material. The microstructure changes are here correlated to the improvement in hardness and wear resistance.

Significant interest has arisen in the use of solutes to provide thermodynamic and/or kinetic stabilization of nanocrystalline grains. Much of this work has primarily focused on their ability to mitigate grain growth under thermal annealing. In this work, we explore both the grain boundary specificity of such segregation under annealing as well as the mechanical responses of these stabilized nanocrystalline grains under mechanical loads. Using Ni(P) as a case study, we demonstrate a cross-correlative precession electron diffraction – atom probe tomography technique where the P solute segregation to specific grain boundaries was quantified. It was found to be relatively homogeneous on high angle grain boundaries, particularly with an increase in annealing temperature. Where variation was noted, the interfacial excess concentrations varied from zero to upwards of tens of atoms/nm². Subsequently, the alloy film was in situ mechanical loaded in a TEM where the granular evolution was characterized. The experimental results are coupled to atomistic simulations to predict the specific boundary segregation behavior as well as simulating how such partitioning is influencing the granular stability under loads in a thermally stabilized nanocrystalline alloy.

**Thermal Processes and Mechanisms in Sputtered Nanostructures**

Andrea Hodge

Mork Family Department of Chemical Engineering and Materials Science; Aerospace and Mechanical Engineering Department, University of Southern California, Los Angeles, California, United States.

Nanomaterials, nanolayers (NMMs) are of considerable interest due to their high density of interfaces which lead to unique mechanical, chemical, and thermal properties. Additionally, NMM systems have been shown to undergo several microstructural transitions when annealed at elevated temperatures while still retaining nanoscale features. The microstructural evolution of these materials and the nanostructures that develop after annealing are not well understood but can provide insight of active thermal processes and stabilization mechanisms. To further understand the thermal evolution of these materials, several sputtered NMM systems including Mo-Al, Hf-Ti, W-C and Ta-Hf were annealed to critical temperatures determined by DSC. A wide range of characterization techniques including TEM and APT were utilized to examine compositional changes and gain insight into thermally activated events such as layer roughening, solute grain boundary segregation and phase separation.
Oxygen has been known to have a strong hardening effect on titanium alloys, while also inducing serious embrittlement when its concentration exceeds a limited amount. Yet, commercial purity Ti (CP-Ti) doped with a high oxygen content has been produced recently with both high strength and moderate ductility. To explore the mechanism that controls the superior property, we studied the microscopic deformation of the alloy with microstructural observation using electron microscopes after quasi-static and dynamic loading. The effect of loading rates on the deformation behavior, as well as the role of oxygen content, was examined. The high strain rate sensitivity shown in the alloy was carefully investigated and correlated to its microstructure and oxygen content. As well, the effect of oxygen on deformation and fracture modes was studied in relation to the grain size.

Mesoscale Crystal Plasticity Modeling of Buckling Behavior of Nanoscale Al-Al$_2$Cu Eutectic Alloy Guisen Liu, Shujuan Wang, Amit Misra and Jian Wang; 1Mechanical and Material Engineering, University of Nebraska–Lincoln, Lincoln, Nebraska, United States; 2Materials Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States.

Al-Al$_2$Cu eutectic alloy with nano-laminated microstructure exhibit high strength and good plasticity. Due to the significant difference in elastic properties and plastic deformation capability between Al and Al$_2$Cu phases, structural instability occurs in Al$_2$Cu lamellae associated with elastic buckling when a compression stress is applied parallel to the lamellae. Al lamellae plastically deform via dislocations motions. Al-Al$_2$Cu interfaces play strong barriers for blocking dislocation motions in Al lamellae. Thus, elastic buckling in Al$_2$Cu lamellae is constrained by the elastic-plastic deformation of Al lamellae. To understand buckling behavior of nanoscale Al-Al$_2$Cu eutectic alloy, we developed a mesoscale crystal plasticity model and implemented it into finite element analysis. Plastic deformation in Al lamellae is described by the confined layer slip (CLS) mechanism. The critical resolved shear stress for dislocation slip varies with layer thickness, estimated by CLS mechanism. The strain hardening is described by a phenomenological power law. To capture the essential features of confined layer slip in Al lamellae (dislocation loops glide through the layer and depositate at interfaces), plastic deformation in Al lamellae should be the same through the thickness. However, interface constraints will cause different elastic deformation through the thickness of Al lamellae. We thus divided each Al lamella into three voxels that have the same plastic deformation but may develop different elastic deformation. In comparison, we also conducted a traditional CP analysis in which plastic deformation in three voxels through the thickness of the lamella is calculated individually according to phenomenological power law. In these simulations, plasticity in Al$_2$Cu voxels that have the same plastic deformation but may develop different elastic deformation. In these simulations, plasticity in Al$_2$Cu voxels that have the same plastic deformation but may develop different elastic deformation. In these simulations, plasticity in Al$_2$Cu voxels that have the same plastic deformation but may develop different elastic deformation.

Twinning in Multiple Principal Element Alloys—Atomistic Simulation Studies
Jun Ding1, Mark Asta2,3, Robert Ritchie2,3, University of California, Berkeley, California, United States; 2Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

High-entropy alloys (HEAs) are an intriguing class of metallic materials due to their unique mechanical behavior. Achieving a detailed understanding of structure-property relationships in these materials has been challenged by the compositional disorder that underlies their unique mechanical behavior. For instance, extensive nanotwinning occurs at room temperature in the medium-entropy CrCoNi alloy, whose combination of strength, ductility and toughness properties approach the best on record. We present results of employing atomistic computer simulations to investigate twinning behavior in the medium-entropy CrCoNi alloys, considering model systems with random substitutional disorder as well as systems with a high degree of local chemical short-range order (SRO). The planar energetics associated with the twinning as well as parameter related to twinability are found to be strongly influenced local chemical SRO. Furthermore, the migration mechanism of twin boundary under deformation have been studied in the CrCoNi alloys with varying SRO.

Atomic Level Mechanism for the Formation of Long Period Stacking Order (LPSO) in Magnesium Alloys
Yiqian Chen, Huan Zhao, Blazej Grabowski, Jing Su, Christian Liebscher, Baptiste Gault and Dierk R. Raabe; Max-Planck-Institut für Eisenforschung, Düsseldorf, Germany.

The atomic-level mechanism for long period stacking order (LPSO) in magnesium alloys has been a challenge over the past decade. Here we show that LPSO structure is a result of impeding phase transition pathway from coherent (C) Guinier–Preston zone precipitation to semi-coherent (SC) intermetallic precipitation due to elemental interactions in magnesium alloys. By incorporating first principles calculations and atomic resolution Z-contrast electron microscopy imaging and energy-dispersive spectral (EDX) imaging with the scanning transmission electron microscopy (STEM) for heterophase interfaces in Mg-Zn-Y system, we have demonstrated that C-SC transition is reversed over a certain range of compositions and as a result, the transition from Guinier–Preston zone to LPSO structure is both thermodynamically and kinetically favorable. These results were then combined with atom probe tomography (APT), therefore providing a quantitative analysis of forming different phases and/or structures at the sub-nano scale. This discovery gives a clear picture of how LPSO structure forms at the atomic level and potentially may provide robust information for economical LPSO structured magnesium alloy designs without rare earth elemental additions.

2:15 PM CP04.15.03
On the Different Relaxation Schemes During Generalized Stacking Fault Energy Analysis in Hexagonal Close-Packed Metals—A Case Study of Magnesium
George Voyiadjis1,2, Reza Namakian1; 1Civil and Environmental Engineering, Louisiana State University, Baton Rouge, Louisiana, United States; 2Computational Solid Mechanics Laboratory, Louisiana State University, Baton Rouge, Louisiana, United States.

Generalized stacking fault energy (GSFE) analysis is a valuable technique to provide some insights and information on dislocation core structures and mobilities which are controlled by crystal resistance to shearing along a specific crystallographic plane. This technique is composed of the following steps: 1) cutting a single crystal along a fault plane, 2) shifting rigidly the upper half of the newly created bi-crystal along an arbitrary fault vector which belongs to the fault plane, 3) releasing the shifted crystal on the top of the lower half crystal, 4) relaxing the bi-crystal atoms in the direction perpendicular to the newly generated fault plane. By generating GSFE profile, one should be able to recognize the local minima on the profile correspond to stable stacking faults (SFs).

However, the stability of the SFs should be checked once the atoms are allowed to relax in all directions. This issue could be heightened in metals with hexagonal close-packed (HCP), like magnesium or Mg, due to the unsymmetrical feature of atomic configuration on the two sides of the slip direction. In this work, two relaxation directions are considered, out-of-plane (N-direction) and in-plane (P-direction). N-direction is normal to the slip plane which is [10-11], the first pyramidal or compression twinning plane in HCP metals. P-direction is parallel to the slip plane and perpendicular to the slip direction which is <-1012>. Accordingly, N-direction relaxation (one direction relaxation) and N-P-directions relaxation (two directions relaxation) schemes are used here.

To study the effect of different relaxation schemes on GSFE profile for [10-11]<-1012> system, a sample with 80,000 atoms is constructed in which the height of the sample is large enough to minimize the effect of free surface on the fault plane. Four different empirical potentials, three of which designed by embedded-atom method (EAM) and one with modified EAM (MEAM), available in the literature for Mg are employed in Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS) to generate GSFE profile as described above with N-direction and N-P-directions relaxations.

We report here that results of N-direction and N-P-directions relaxations both coincide partly along direction, however, N-P-directions relaxation shows significant oscillations in the GSFE profile for all four potentials. This deficiency could be attributed to the following reasons. First, GSFE is a nonphysical projection of crystal slip. Dislocation emission and motion incorporate two energy components: 1) initial elastic deformation and 2) breaking of atomic bonds. While the second term can be assessed by the GSFE, the contribution of elastic deformation is absent from the rigid GSFE model. Second, the traditional way of cutting, shifting, releasing, and finally relaxing the atoms to generate GSFE profile due to the unsymmetrical feature of atomic configuration on the two sides of the slip direction causes a force along the P-direction, which influences not only the value but also the location of the calculated GSFE. Therefore, one may observe the fluctuations in the GSFE profile.

To resolve all the above mentioned issues related to the rigid GSFE profile, nudged elastic band method (NEBM) as a minimum path energy finder (MEP) is employed to find precise values of the saddle points in the GSFE profile. The SFE profile obtained by NEBM alignment shows a completely different energy profile in shape and magnitudes with respect to the rigid GSFE such that the magnitude of the energy barriers are reduced significantly thanks to the incorporation of elastic deformation energy in NEBM and non-straight path of the slip trace obtained by NEBM. Therefore, NEBM can provide more accurate and robust results about SFs compared to GSFE method.

2:30 PM CP04.15.04
The Role of Twin Boundaries on Failure Mechanisms in Nickel-Based Superalloys
Zhongbo Zhang1, Yiqiang Chen1 and Michael Preuss1; 1University of Manchester, Manchester, United Kingdom; 2Max-Planck-Institut für Eisenforschung, Düsseldorf, Germany.

Most polycrystalline Ni-based superalloys used in demanding environments contain a high concentration of annealing twins. In contrast to the concept of grain boundary engineering, where low ζ coincidence-site-lattice boundaries are essential to mitigate the intergranular cracking, coherent ζ twin boundaries (TBSs) in Ni-based superalloys are found to be vulnerable for fatigue crack and hydrogen (H)-induced crack initiation. Despite recent extensive studies, the physical mechanism is still elusive, which hampers the alloy optimisation and performance prediction. Here we use multiscale microstructural characterisations and strain analysis, coupled with density functional theory calculation, to achieve a bottom-up understanding in the role of TBS on failure mechanism of γ"-strengthened Ni-based superalloys. We find that during mechanical loading much earlier dislocation plasticity and pronounced strain localisation happen at TBS, and H-induced cracks nucleate and extend along TBS. Multiscale characterisations, from centimetre scale down to sub-nanoscale, and DFT calculations demonstrate that the abnormal response from TBS originates from the distinctive precipitates formed along the TBS. Our work not only uncovers the mechanistic origin of TBS-related failure but also provides a practical method to alleviate the adverse effect of TBS on the performance of Ni-based superalloys in aggressive environments.

2:45 PM CP04.15.05
Preferential Intergranular Corrosion Along Coherent Twin Boundaries in Pure Ni
Mengping Liu1, Matteo Seita2 and Michael Demkowicz2; 1Materials Science and Engineering, Texas A&M University, College Station, Texas, United States; 2Mechanical and Aerospace Engineering, Nanyang Technological University, Singapore, Singapore.
We describe an investigation of intergranular corrosion on the surface of pure Ni after cathodic charging. The intergranular corrosion takes the form of long trenches along coherent twin boundaries (CTBs). These trenches are formed by the growth and eventual overlap of conical cavities along <110>-type directions within the CTB planes. We propose that the corrosion cavities initiate at high energy, symmetric incoherent facets along CTBs and deepen due to their local anodic polarization relative to the sample surface. Our observations show that cathodic protection is not guaranteed to prevent corrosion. They also reveal that—for being corrosion resistant—CTBs are especially susceptible to localized corrosion under some conditions.

Nano-Scale Effects on Grain Growth—Grain Boundary Energy and Velocity in Magnesium Aluminate Ricardo H. Castro and Derek N. Muche; University of California, Davis, Davis, California, United States.

Grain boundary mobility is affected by thermodynamic driving force and local velocity of atomic movement. It has been a long-time challenge to separate each individual contribution as they are intimately connect, but such understanding could help provide more reliable strategies for coarsening inhibition in nanocrystalline materials. Here we experimentally demonstrate the individual contribution of kinetics and thermodynamics in magnesium aluminate grain growth, in particular highlighting the nano-scale effects. Fully dense nanocrystalline MgAl2O4 grain growth was studied at different temperatures and a mobility shift - i.e. from a high mobility at small grains to lower mobility for larger grains - was observed below a critical nano-scaled grain size. By combining experimental grain boundary energies and kinetic analyses, we showed that the excess energies associated with grain boundaries at the nanoscale are increased due to the spinel inversion parameters, but there is also a change in grain boundary velocity, likely attributed to a complexion transition associated with the segregation of aluminum to grain boundaries.

4:00 PM CP04.16.02
Enhancing Grain Boundary Ionic Conductivity in Ceramics via Local Solute Enrichment and a New Data-Driven Interacting-Defect Model Describing Nanoscopic Interface Compositions William J. Bowman1, Xiaorui Tong2, David Mebane3 and Peter Crozier4; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Department of Mechanical and Aerospace Engineering, West Virginia University, Morgantown, West Virginia, United States; 3School for the Engineering of Matter, Transport and Energy, Arizona State University, Tempe, Arizona, United States.

High ionic conductivity is desired to optimize electrolyte performance, though it is significantly degraded by grain boundaries (GBs), which act as ionically-resisting block layers in polycrystalline electrolytes. Given the rich diversity in GB types, and the complex interplay between structure, composition, and chemistry at the atomic and nanoscale [1-3], there is considerable opportunity to elucidate fundamental science and performance optimization of GBs. Hence, studies should rely on GB datasets correlated across many length scales, with the aim of generalizing high spatial resolution observations to an entire GB population. This should facilitate bottom-up design of GBs with optimized properties, which remains a considerable challenge. By combining suitable modeling approaches with experimental measurements interrogating materials over different length scales, it becomes possible to estimate the electrical properties of individual GBs.

Here, we show that the enhancement of oxygen ionic conductivity by over two orders of magnitude in an electroceramic oxide is explicitly shown to result from nanoscale enrichment of a grain boundary layer or complexion with high solute concentration. A series of Ca1−xCexO2−δ polycrystalline oxides with fluoride structure and varying nominal Ca2++ solute concentration elucidates how local grain boundary composition, rather than structural grain boundary character, primarily regulates ionic conductivity. A correlation between high grain boundary solute concentration above ~40 mol6%, and four orders of magnitude increase in grain boundary conductivity is explicitly shown. A correlated experimental approach provides unique insights into fundamental grain boundary science, and highlights how novel aspects of nanoscale grain boundary design may be employed to control ion transport properties in electroceramics.

Additionally, we present a new data-driven interacting-defect model that has quantitatively described the nanoscopic composition of high solute concentrations at grain boundaries in ion-conducting ceramics. The successful model is a Cahn-Hilliard methodology for interfaces, introduced and demonstrated in this report. The model is applied to high spatial resolution composition data gathered at grain boundaries in calcium-doped ceria. The statistical methodology for the data-driven procedure shows definitively that gradient terms are required to model defect interactions to quantitatively describe the local grain boundary composition data. The model additionally predicts co-aggregation of negatively-charged acceptor dopants and positively-charged oxygen vacancies at the interface, which is in accordance with atom probe tomography in acceptor-doped ceria.

Atomistic Studies of Effects of Alloying Element Segregation on Grain Boundary Cohesive Strength in Fe-Based Alloys Axel E. Alcocer Seoane and Xiao-Ming Bai; Department of Materials Science and Engineering, Virginia Polytechnic Institute and State University, Blacksburg, Virginia, United States.

Fe-based alloys are important structural materials for many engineering applications. Segregation of alloying elements and impurities to grain boundaries (GBs), either due to radiation induced segregation (RIS) or thermal segregation, can alter the GB cohesive strength and thus affect the fracture resistance of these alloys. Therefore, it is important to understand how the segregation of different alloying elements and impurities influences the GB cohesive strength. In this work, we use molecular dynamics simulations to study the changes of GB cohesive strength due to the substitutional segregation of P, Al, V, W, Cu, Ni and Cr at $\Sigma 3^{<111>}$, $\Sigma 3^{<112>}$, $\Sigma 5^{<012>}$ and $\Sigma 5^{<013>}$ GBs in body centered cubic (bcc) Fe. It is found that V, W increase the GB cohesive strength while P, Cu reduce it and Al, Cr, Ni have small effects. Additionally it is found that $\Sigma 3^{<111>}$ GB is influenced the most by segregation and the alteration in GB cohesive strength is correlated to substitution energy in the bulk.

4:30 PM CP04.16.04
First-Principles Studies of Effects of Oxygen Impurity on Grain Boundary Strength in Nickel Zisi Xiao and Xiao-Ming Bai; Materials Science and Engineering, Virginia Polytechnic Institute and State University, Blacksburg, Virginia, United States.

Grain boundary (GB) is one of the most important microstructures that govern the physical properties of materials. In many metallic systems such as nickel-based alloys, GBs are susceptible to intergranular fracture and stress corrosion cracking. Using first-principles calculations, we have investigated the strength of $\Sigma 5^{(012)}$ and $\Sigma 3^{(111)}$ GBs with different oxygen concentrations in both substitution and interstitial sites. As expected, our results show that oxygen is an embrittling element at both two sites. For each case, we compare the energy difference between mechanical distortion effect and chemical bond influence. Electronic analyses such as density of states (DOS) and charge density distribution are conducted to study the role of chemical bonds on GB strength.
Ceramic oxides are used for a wide variety of technologically relevant applications from electrochemical devices, novel resistive switching devices and oxygen sensors. Applications such as these typically rely upon the ability of oxides to conduct ions efficiently through the lattice. For oxides, such as CeO$_2$ (ceria), it is common to dope with aliovalent elements to increase the number of available charge carriers. While bulk-doping methods developed to optimize ionic conduction in the bulk have been successful, they have provided little insight when optimizing the grain boundary (GB) conductivity in these polycrystalline oxides. Unlike the bulk, GBs are often subject to complex segregation behavior, structural disorder, space charge effects as well as the standard defect-defect interactions typically present in the bulk. Recent nanoscale compositional characterization has shown different nominal concentrations could result in orders of magnitude increase in GB ionic conductivity relative to the undoped samples [1]. This effect has been attributed to increases in local dopant/solute concentrations at the GB. This study aims to understand how high concentrations of dopants, namely Ca, present at the GB increases the ionic conductivity.

To understand the key factors influencing the ionic conductivity, computational modeling is employed using molecular statics to optimize the GB interfacial structure for three the ionic conductivity.

In order to capture the changes in conductivity for various GB models, Migration energies, local strain and various oxygen migration pathways across each GB are compared to elucidate the role of local composition in modulating oxygen migration across GBs. Energetics and structural stability trends obtained using molecular statics/dynamics are validated using density functional theory calculations. This study further develops our understanding of the interplay between nanoscale composition and structure with high dopant concentrations enabling the development of methods such as selective doping to improve macroscopic ionic conductivity for both the grain and GB.

**10:30 AM *CP05.01.01 In Situ Observations of Nanotribology Evolution Laurence Marks:** Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States.

An important, and also sometimes controversial issue in nanotribology is how does a microstructure evolve? Is it purely stochastic, or are there some systematics underlying the science which occur naturally and/or can be exploited to reduce friction and wear. Over the last decade there has been a slow increase in the use of in-situ sliding within transmission electron microscopes. While these instruments normally are less sophisticated than dedicated scanning probe instruments or aberration-corrected microscopes, by combing the two one can obtain information about what matters, what does not which is often obscured by the buried interface in less direct experiments. This talk will focus on some older and some new results from in-situ observations inside electron microscopes. We find that the evolution is not purely stochastic, but instead involves fracture of weak links and the reduction of high friction local structures.

**11:00 AM *CP05.01.02 Atomic-Scale Insights into Contacts Between Nanoscale Bodies—In Situ Experiments and Matched Atomicistic Simulations Tevis D. Jacobs,* Sai Bharadwaj Vishnubhotla, Subarna R. Khanal, Rimei Chen, Xiaoli Hu and Ashlie Martini; Mechanical Engineering and Materials Science, University of Pittsburgh, Pittsburgh, Pennsylvania, United States; *University of California, Merced, Merced, California, United States.**

In probe-based microscopy, nanomanufacturing, and small-scale devices, the performance and reliability often depend on the size and nature of contacts between nanoscale bodies. However, conventional models of contact based on continuum mechanics rely on assumptions that may not hold at the nanometer length scale. Here we used a combination of in situ experiments and atomistic simulations to quantitatively investigate nanoscale asperities during formation, loading, and separation of contact. Experimentally, contact tests were performed inside of a transmission electron microscope, with in situ measurements of load and contact properties taken simultaneously with high-resolution characterization of the materials structure and geometry. In simulations, molecular dynamics modeling was performed on identical nanocontacts that were precisely matched in terms of materials, geometry, and loading conditions. The results demonstrate that important contact properties such as adhesion, contact size, and electrical current flow deviate significantly from the predictions of conventional models. The physical origin of the deviations is shown to be chemical and mechanical interactions at the atomic scale.

**11:30 AM CP05.01.03 Micro-Mechanical Investigation of Microstructure Effects on Dry Friction Gianluca Roscioli and C. Cem Tasan; Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.**

In absence of physically-based constitutive relations describing mechanisms of abrasive wear, design of wear-resistant materials has been driven either by (i) trial-and-error based alloy screening approaches, or (ii) following the Archard equation that linearly relates wear resistance to the hardness of the annealed material. There are, however, observations in literature that demonstrate that hardness is not the only factor controlling abrasive wear response. In an effort to unravel the key constitutive relations, a systematic study on the role of crystal structure and orientation has been performed. Grains with specific orientations of IF steel and pure nickel, heat treated to obtain similar micro-hardness values, have
been selected using EBSD to perform in-situ SEM scratch tests with the same applied force. Focused Ion Beam has been used in order to confirm that the dry friction tests were conducted in ploughing mode, and Atomic Force Microscopy as a way to quantify wear from the surface profile. Comparing the results for the two different crystal structures and for grains with different crystal orientations enabled the identification of guidelines for design of advanced wear-resistant materials.

In Situ Atomic-Scale Observation on Friction Between Metallic Contacts Scott X. Mao1, Yang He2 and Chongmin N. Wang2; 1University of Pittsburgh, Pittsburgh, Pennsylvania, United States; 2Pacific Northwest National Laboratory, Richland, Washington, United States.

Atomic friction is imperative to the performances and reliability of micro-/nano-electromechanical systems and magnetic storage devices. Nevertheless, the atomic mechanisms underlying friction are still elusive, primarily due to a lack of direct observation on the contacting interface during the process. Here, by combining in situ atomic-scale transmission electron microscopy (TEM) and atomic force microscopy (AFM), we discovered diffusion-mediated formation of an interfacial layer between two metallic asperities under trivial normal forces, which was responsible for ultra-low friction. In addition, the atomic friction mechanism was found to depend on the mutual orientation of the contacted crystals. The work demonstrates fundamental insights and a new avenue for atomic friction.

SESSION CP05.02: Tribology of 2D Materials
Session Chairs: Martin Dienwiebel and Laurence Marks
Tuesday Afternoon, April 23, 2019
PCC West, 100 Level, Room 102 B

1:30 PM CP05.02.01
Fundamental Insights into Dry Friction, Adhesion and Wear via Nanoscale and In Situ Approaches Robert Carpick; University of Pennsylvania, Philadelphia, Pennsylvania, United States.

New insights into friction and lubrication from atomic force microscopy (AFM) are presented. First, nanocontacts with 2-dimensional materials including graphene and MoS2 are discussed. Friction between nanoscale tips and 2D materials has been repeatedly shown to depend on the number of layers. An initial model attributing this to puckering [1] is now enhanced by molecular dynamics (MD) simulations showing a strong role of energy barriers due to interfacial pinning and commensurability [2]. New results where 2D materials are used on both the tip and the sample will also be presented. Then, nanoscale asperity-on-asperity sliding experiments conducted using a nanoindentation apparatus inside a transmission electron microscope will be discussed. This experiment is used to obtain atomic-scale resolution of contact formation, sliding, and adhesive separation of two silicon nanosuperlattices. Forming and separating the contacts without sliding revealed small adhesion forces; separating during sliding resulted in a nearly 20 times increase. These effects were repeatable multiple times, and increased with both the sliding speed and the applied load used. We attribute this surprising sliding-dependent adhesion to the removal of passivating terminal species (likely hydrogen atoms) from the surfaces, followed by re-adsorption of these species after separating the surfaces. This helps explain mechanisms of nanoscale dry adhesion, and demonstrates that adhesion can be reversibly varied, which offers potential applications for nanoscale manipulation.

2:00 PM CP05.02.02
Atomic Origins of Temperature-Dependent Shear Strength in 2D Materials Adam R. Hinkle1, John Curry1, Tomas Babuska1, Michael T. Dugger1, Brandon A. Krick2, Nicolas Argibay2 and Michael Chandross3; 1Sandia National Laboratories, Albuquerque, New Mexico, United States; 2Lehigh University, Bethlehem, Pennsylvania, United States.

We present a model that predicts the macroscale temperature-dependent interface shear strength of 2D materials like MoS2 based on atomistic mechanisms and energetic barriers to sliding. Atomic simulations were used to systematically determine the lamellar size-dependent rotation and translation energy barriers, that were used to accurately predict a broad range of experimental data. This framework provides insight about the origins of characteristic shear strengths of 2D materials.

2:15 PM CP05.02.03
Temperature and Speed Dependence of Nanoscale Friction for Mono- and Multilayer MoS2—A Combined Atomic Force Microscopy and Molecular Dynamics Study Kathryn Hasz1, Mohammad R. Vaziriserehsk2, Ashlie Martini2 and Robert Carpick1; 1University of Pennsylvania, Philadelphia, Pennsylvania, United States; 2University of California, Merced, Merced, California, United States.

There has been a sustained interest in 2D and layered materials for use as solid lubricants due to their intrinsically low friction, and in advanced electronics applications including flexible electronics due to their intrinsic bendability and novel electronic properties. It is known that both temperature and sliding speed affect friction, but there is little understanding about the relative importance of these effects. We use matched ultrahigh vacuum atomic force microscopy (AFM) experiments and molecular dynamics (MD) simulations to study the atomic stick slip friction for nanoscale SiNx and Si tips sliding on monolayer and multilayer MoS2 from cryogenic to elevated temperatures, and over several decades of sliding speed. We observe that friction increases as temperature decreases and as speed increase. In agreement with the qualitative trends predicted by the thermal Prandtl-Tomlinson model, friction shows an approximately logarithmic increase with increasing sliding speed. In some cases, we observe dramatically decreases in friction as temperature increases, suggesting the effective role of thermolubricity. Similar trends are seen for monolayer and multilayer MoS2. However, the temperature dependence differs between different tip materials, potentially due to the difference in thermal conductivity of the tip and across the tip-sample interface. These new findings have important implications for macroscale and nanoscale solid lubrication, and for applications using layered and 2D materials including the assembly and functionality of flexible electronics.

2:30 PM CP05.02.04
Environmental Contamination Affecting Friction in Graphene Clara Almeida1, Felipe Ptk2 and Rodrigo P. Menezes2; 1Unimetro, Duque de Caxias, Brazil; 2Pontifícia Universidade Católica do Rio de Janeiro, Rio de Janeiro, Brazil.

Environmental contaminations are known to affect the use of nanoscale materials in devices. In this contribution, we show that friction in graphene is significantly altered by the presence of contamination that comes from air exposure. The influence of contamination in tribological properties was studied by friction force microscopy. It was observed that friction in graphene increases due to surface contamination, decreasing the difference in friction between mono and bilayer graphene. The physisorption of contaminants was observed to begin at the edges or mechanical defects in graphene monolayers. Time series of friction force images enable us to observe the kinetics of this contamination spreading over the surface.

2:45 PM CP05.02.05
Sliding Over 10,000 Times Faster—QCM Integrated Microtribometry to Probe Friction Fundamentals via Gold and Single-Crystal MoS2 Nikolay T. Garabedian1, Raymond Wieser2, Gabriel McAndrews2; 1University of Delaware, Newark, Delaware, United States; 2Physics, St. Olaf College, Northfield, Minnesota, United States.

A major focus of tribology research has been to understand the origins of practical-scale multi-asperity friction by dissecting it down to nano-scale single-asperity contacts. The Prandtl-Tomlinson model with thermal activation (PTT) has laid the theoretical foundations for understanding friction of single-asperity contacts. Experimentally, both molecular dynamics and friction force microscopy have agreed with PTT model’s prediction that friction increases logarithmically with velocity. Multi-asperity contacts’ velocity dependence, on the other hand, is much more challenging to describe theoretically and verify experimentally. In this presentation, we show an experimental setup that consists of a microtribometer that simultaneously uses two lateral motion devices with vastly different characteristic velocities: a piezo stage (<0.1 mm/s) and a quartz crystal microbalance (QCM) (up to 1 m/s). We also have two independent opportunities to measure the frictional responses of the contact: using either the capacitance sensor-based microtribometer
Fundamental Links Between Microstructure, Environment and Friction in Metals

understanding of the fundamental aspects of how shear stress may affect the microstructure and chemistry of PFA. The objective of this work is to link the chemical and physical aspects of fracture mechanics, which includes the tribological behavior of the polymer composite and the mechanical properties of the fillers.

Dry friction is commonly desired in extreme environments where traditional lubrication solutions such as oils and greases are precluded. Polytetrafluoroethylene is an excellent candidate material for dry sliding applications due to its low friction coefficient, high resistance to chemical attack, vacuum compatibility, and wide range of operating temperatures. Although it suffers from a notoriously high wear rate, k~7 x 10^-4 mm^3/(Nm), filler materials from microparticles to fibers provide modest to moderate improvements in wear resistance, typically by one to two orders of magnitude. The formation of a stable transfer film is largely believed to be a critical step towards attaining ultralow wear in sliding against metal counterfaces; however, the specific tribomechanical mechanisms of transfer film formation have only very recently been investigated. In this study, a “striping” experiment permitted spectroscopic analyses of PTFE/alumina transfer films in various stages of development. This study led to a proposed mechanism that details the formation of chemically-distinct films on both surfaces of the tribological pair. PTFE chains break due to the mechanical stresses generated during sliding and, in the presence of oxygen and water in the ambient environment, produce carboxylic acid end groups, which chelate to both the surface of the alumina filler and the exposed metal counterface and nucleate the formation of the transfer film. These tribomechanical reactions form a thin and robust polymer-on-polymer tribological system that after the initial run-in period can endure hundreds of thousands of reciprocating sliding cycles with virtually no polymer composite wear. The Hamaker model for van der Waals interactions between polymer fibrils and the countersurface provides mathematical support for the mechanical scission of carbon–carbon bonds in the backbone of PTFE under sliding contact conditions. Model experiments utilizing small molecules have confirmed the proposed reactions.

INTRODUCTION: Though it has similar mechanical, thermal, and chemical properties as polytetrafluoroethylene (PTFE), perfluoroalkoxy polymer (PFA) has rarely been evaluated in tribological (friction and wear) applications. In addition to its unique physical, thermal, and chemical properties, PFA can be melt-processed instead of the sintering-based methods of PTFE. This allows filler particles or fibers to be melt mixed with PFA and this mixture can be used to produce complex geometries via screw-injection molding. The wear rate of PFA was shown to improve nearly four orders of magnitude with the addition of 5-10 wt. % of α-alumina filler particles, highlighting the need for a better understanding of the fundamental aspects of how shear stress may affect the microstructure and chemistry of PFA. The objective of this work is to link the chemical and microstructural observations of unfilled PFA the observations seen in PTFE-alumina and PFA-alumina composite systems.

METHODS: Differential scanning calorimetry (DSC), x-ray diffraction (XRD), transmission infrared spectroscopy, and attenuated total reflection fourier transform infrared spectroscopy (ATR-FTIR) were used on bulk and worn samples of unfilled PFA and PFA-alumina composites were slid against stainless steel counterfaces at 6.25 MPa of applied pressure and a sliding velocity of 50 mm/s.

RESULTS & DISCUSSION: Tribological experiments revealed a 10,000x improvement in wear of PFA-alumina composites (K~4.0x10^-4 mm^3/(Nm)) compared to unfilled PFA (K~4.0x10^-2 mm^3/Nm)). Additionally, PFA-alumina composites were found to have similar friction (μ~0.25) which is surprising considering unfilled PFA (μ~0.12 has a friction coefficient nearly 2x lower than that of unfilled PFA (μ~0.24). Wear properties of PTFE-alumina composites (K~4.4x10^-4 mm^3/Nm) matched those observed in filled PTFE composites. The reduction in wear rate for PTFE-alumina and PFA-alumina composites has been attributed to tribochemical reactions of broken fluoropolymer chains, environmental constituents, and the metallic countersurface/aluminum oxide filler material. These reactions promote the development of running films and transfer films that protect the surface of the polymer composite and steel counterface.

To better understand this tribomechanical mechanism, tribological experiments of PFA compared to PTFE, the effects of sliding on the microstructure and chemical makeup of PFA were investigated. From observations of DSC endotherms, PFA wear debris had higher crystallinity compared to bulk PFA. Additionally, XRD of unworn and worn PFA showed an increase in crystallite size for the wear debris. Both these observations point to microstructural rearrangement of the PFA backbone due to stress applied during sliding, which have also been reported in the wear of unfilled PTFE and drawing of PTFE films. Higher concentrations of PAVE comonomer were seen in ATR-IR spectra of PFA wear debris, suggesting preferential crack propagation through the amorphous region of the microstructure of PFA during sliding. Similar repeated loading during MIT flex life experiments on PFA showed that PFA samples with lower crystallinity of PFA (higher % amorphous region) exhibited improved fatigue performance, suggesting that cracks preferentially travel through the amorphous region of PFA. Transmission IR spectra of PFA wear debris revealed the presence of free carboxylic acid endgroups that were not present in the bulk PFA surface. The presence of free carboxylic acids is due to the breaking of C-C bonds in the PFA backbone reacting with environment constituents. The formation of free-carboxylic acids endgroups is a critical intermediate step of the tribochemical reaction necessary to form robust transfer films and running films proposed for PTFE-alumina composites.
Are Tribofilm Properties Predictive of Wear Resistance?

In tribological systems, wear is a dynamic process that leads to adhesive transfer, material mixing, and oxidation. All of these phenomena, along with the mechanical deformation of the near-surface, lead to the formation of tribofilms, which are also called mechanically mixed layers. Microstructural and chemical modification of tribofilms lead to enhanced frictional behavior and wear resistance.

During sliding of surfaces, the near-surface undergoes significant changes in terms of topography, composition, and microstructure. These changes affect the wear properties of materials. The study of tribofilms is crucial for understanding wear mechanisms and developing materials with improved wear resistance.

The role of shear deformation on generating tribofilms is a topic of ongoing research. Shear force applied to metallic materials can induce deformation and microstructural changes which can be used to process materials in solid state, helping avoid melt processing and in achieving highly refined microstructures not achievable by conventional processing. In order to develop such solid phase processing methods for metallic alloys, we aim to better understand the fundamental atomic scale mechanisms of mass and energy transfer in materials under shear deformation. Formation of metastable interfacial states in metallic multilayer thin film systems with different miscibility between individual layers under shear deformation, unique deformation mechanisms and accelerated diffusion observed only under high shear deformation are crucial factors to be understood. We employ a pin-on-disk tribometer deformation of various thin film stacks based on Cu and Al systems followed by detailed microstructural characterization before and after shear deformation by transmission electron microscopy, atomic force microscopy and atom probe tomography to understand the structural and compositional changes near atomic scale resolution. Our results on structural and chemical modifications at interfaces and individual layers of thin films after shear deformation versus thermal annealing provide new insights on the unique role of shear deformation on modifying the phase transformation pathways of these alloy systems. These new insights will be presented and compared with what is currently understood about role of shear deformation on generating super saturated solid solution states or self-organized nanolayers in immiscible metallic alloys.

9:15 AM CP05.04.03 Shear Deformation Induced Intermingling and Structural Modifications of Metallic Multilayer Thin Films Arun Devaraj, 1, Aashish Rohatgi, 2, Peter V. Suzalco, 1, Sreen N. Mathadu, 3 and Cynthia Powell, 3 Physical and Computational Sciences Directorate, Pacific Northwest National Laboratory, Richland, Washington, United States; 3Department of Materials Science and Engineering, Mechanical Engineering, University of California, Riverside, Riverside, California, United States; 4Energy and Environment Directorate, Pacific Northwest National Laboratory, Richland, Washington, United States.

9:30 AM CP05.04.04 Microstructure Evaluation of Nanostructured Multilayer Ductile Cast Iron Under Dry Sliding Condition Kewen Dong, Wentao Zhou and Cheng Liu; Yangzhou University, Yangzhou, China.

Ductile cast iron (DCI) is becoming an increasingly important engineering material due to its remarkable strength, ductility, wear resistance and low production cost. However, the industrial heavy-loading components like gears and bearings require improved wear resistance with the wide application of DCIs. An investigation is carried out to examine the influence of austempering time on microstructures and tribological performance of a novel DCI under dry sliding conditions. A commercial unalloyed DCI is used to be austenitised at 900°C for 30min, then rapidly quenched into a patented water-based liquid at 200°C for a very short time, and isothermally held at 190°C (slightly lower than the starting temperature of martensite formation of DCI matrix) for 5, 30, 120, 600 or 720min. It is shown from the tribological test that the superior wear resistance with a minimum mass loss and a lower wear rate can be achieved at 190°C for 120min, which is mainly due to the multiphase synergy between prior martensite (PM), bainitic ferrite (BF), retained austenite (RA) and a unique nano-structure composed of nano-scaled BF and RA enriched with high carbon content (BF+RA)mono, during dry sliding conditions. Particularly, the region with (BF+RA)mono and a certain content RA, exhibits even a higher hardness after dry sliding. Because the normal force engaging during tribological test can induce the martensite transformation locally and give the structure a hard surface layer. The result shows a reasonable value of tribological performance which recommends the designed nanostructured multiphase DCI for more extensive application prospects.

9:45 AM CP05.04.05 Shear Melting of Silicon and Diamond and the Disappearance of the Polymorphic Transition Under Shear Giannietro Morosi, 1 Andreas Klemenz, 1 Thomas Reichenbach, 1 Adrien Gola, 2 Hiroshi Uetsuka, 3 Michael Moseler, 4 and Lars Pasteck, 1, 2 Fraunhofer IWM, MicroTribology Center μTC, Freiburg, Germany; 3Department of Microsystems Engineering, University of Freiburg, Freiburg, Germany; 4Asahi Diamond Industrial Co. Ltd., Chiba, Japan; 5Institute of Physics, University of Freiburg, Freiburg, Germany.

Molecular dynamics simulations of diamond-cubic silicon and carbon under combined shear and compression show the formation of an amorphous solid with liquidlike structure at room temperature. Consistent with the opposite density changes of the two crystals upon melting, the amorphous material is denser than the crystal in silicon and less dense than the crystal in carbon. As a result, its rate of formation is enhanced by pressure in silicon but suppressed in carbon. These results are particularly unexpected for silicon, whose amorphous structure is supposed to be liquidlike (high-density amorphous Si, HDA-Si) only when hydrostatically compressed above the polymorphic transition pressure (~ 14 GPa). Below this pressure, amorphous silicon is expected to have a low-density structure (LDA-Si) with density close to that of the diamond-cubic crystal. Our simulations show that this polymorphic transition disappears under shear and high-density, liquidlike amorphous silicon with metallic ductility forms even at low pressure. These results are potentially transferable to other diamond-cubic crystals, such as germanium and ice Ih, and provide insights into nonequilibrium materials transformations that govern friction and wear in tribological systems.

10:00 AM BREAK

10:30 AM *CP05.04.06 Are Tribofilms Properties Predictive of Wear Resistance? Richard Chronik; Materials Engineering, McGill University, Montreal, Quebec, Canada.

Wear of metals in dry sliding contacts is a dynamic process that leads to adhesive transfer, material mixing and oxidation. All of these phenomena, along with the mechanical deformation of the near-surface, lead to the formation of tribofilms, which are also called microscopically mixed layers. Microstructural and chemical modification of tribofilms lead to significantly different properties from the bulk material that is subjected to dry sliding wear. In some instances, tribofilms can be stable and resist wear and in other cases, there can be persistent wear flow related to tribofilm instability.

Recent advances in nanomechanical testing have made it possible to study mechanical properties of small volumes of materials. Tribofilms present an interesting and challenging vista for nanomechanical testing. In recent years, researchers have used nanoinindentation and pillar compression testing to determine the properties of tribofilms. While a limited number of studies of this type exist, and measurements are difficult to quantify, there is clearly a trend with tribofilms and the wear resistance of a metals and metal-matrix composites (MMCs). In this study, nanoindentation testing of tribofilms revealed that for a wide range of metals (Al, Cu, Ti, Ni) and their MMCs (Al-Al2O3, Ti-TiC, Cu-MoS2 and Ni-WC) that there is a trend of decreasing wear rate with tribofilms hardness. Metals and MMCs are tested in sliding wear and sometimes fretting wear test conditions. For all cases, post-characterization of cross-sectioned wear scars reveals microstructural evolution near surface leading to formation of tribofilms that provide wear resistance and friction control. Structure and properties of the tribofilms are determined with SEM, TEM, EDS, Raman spectroscopy and nanoindentation. Generally, tribofilms are found to be mixtures of the two components in the MMC, but with finer microstructure and some level of oxidation that leads to higher hardness. Using a wider range of test conditions
(e.g. sliding speed, normal load), one can establish additional relationships between tribofilm properties and wear resistance. Furthermore, using recently developed techniques for toughness measurements using nanomechanical methods, a better picture of the overall mechanical properties required for tribofilm stability and wear resistance can be established.

11:00 AM CP05.04.07
Chemical and Microstructural Evolution of Mechanical Contacts by Multiscale Simulations
Izabela Szlufarska, Zhuohan Li and Hubin Luo; University of Wisconsin, Madison, Wisconsin, United States.

One of the critical challenges in designing materials with superior tribological properties is that at present there is limited understanding of how the contact interface and the microstructures of contacting materials evolve during sliding. This evolution may include chemical reactions at the buried interface, grain growth and refinement, evolution of dislocation networks, interaction of dislocations with interfaces, chemical mixing etc. All these phenomena can contribute to energy dissipation (friction) and they can affect the dominant type and amount of wear. Changes taking place in the near-interfacial regions of the contacting materials are difficult to monitor experimentally in \textit{operando} because imagining techniques for buried interfaces under mechanical loads are still in their infancy. Computer simulations provide a powerful approach to investigating interfacial evolution and to discovering phenomena that control friction and wear. Here, I will discuss our developments of a multiscale simulation methodology to determine how materials evolve in sliding contacts.

In the first part of the talk I will focus on chemical evolution of frictional interfaces, a phenomenon referred to as chemical aging. Specifically, I will discuss the combined effects of chemical evolution of interfaces and of surface roughness on the origin of static friction, which is a highly debated topic in the field of tribology. Our approach combines density functional theory calculations of chemical reactions at interfaces, kinetic Monte Carlo simulations that extend simulation time scales to those that can be accessed in experiments, and boundary element method to extend simulation length scale and investigate multi-asperity contacts. For most solid/solid contacts, static friction increases logarithmically with time, a phenomenon known as aging. We discovered molecular mechanisms that are responsible for aging of silica/silica contacts in the presence of water and that are based purely on interfacial chemistry. By combing simulations with atomic force microscopy (AFM) experiments we identified the effects of contact pressure on both friction and aging, showing that aging is accelerated when the contact pressure is increased. Our model shows a quantitative agreement with AFM experiments on load-dependence of aging in single-asperity contacts. In addition, our model predicts that aging is a non-monotonic function of temperature and therefore the temperature can be used to control this phenomenon. Finally, we make predictions of how chemical aging will scale to large rough surfaces and how it will depend on the nature of the contact roughness.

In the second part of the talk I will discuss our developments of multiscale models of microstructural evolution of polycrystalline metals subject to mechanical loads. We combine molecular dynamics simulations with crystal plasticity and phase field models to determine microstructural evolution on experimentally relevant time scales. I will also discuss specific predictions from our models regarding the effects of grain size on chemical reaction mechanism of metal alloys. For instance, we have discovered an intermetallic alloy that can accommodate large plastic strain without help of dislocations due to formation of thin amorphous shear bands during deformation. This finding has important consequences for mechanical response because such intermetallics do not exhibit the classical Hall-Petch grain-size strengthening.

11:30 AM CP05.04.08
Icosahedral Quasicrystalline Nanoparticle Fabrication by Mechanical Approach
Samuel Showman,1,2 Anish Bhagwat,1 James Sanders,1 Kimmy Westover,1,2 Helen Hampkian2 and Chunfes Li3; 1Clarion University Department of Physics, Clarion, Pennsylvania, United States; 2Biology, Clarion University of Pennsylvania, Clarion, Pennsylvania, United States.

This paper reports our attempt to prepare icosahedral quasicrystalline nanoparticles (IQNP). It is well-known that, at the nanometer order, the properties of materials depend on their size. For example, the emission spectrum of quantum dots can be simply tuned by adjusting their size. Although nanoparticles of crystalline and amorphous structures have been reported, nanoparticles of icosahedral quasicrystalline structure, which combines a novel structure with nanometer size, have not.

It is believed that a mechanical approach is the easiest way to prepare IQNP. In our study, we proposed to grind alloy mechanically in to nanoparticles followed by size sorting using filtering. An alloy of Al\textsubscript{56}Cu\textsubscript{13}Fe\textsubscript{11} composition was used to experimentally establish this procedure. Alloy of this composition is closely related to the formation of pure icosahedral phase, although the alloy used in the present study is not of pure icosahedral phase. The alloy was ground for 40 hours and the existence of nanoparticles, particles smaller than 100 nanometers, was confirmed using Scanning Electron Microscopy (SEM). Such particles were suspended in methanol, forming a solution of 1 milligram per milliliter (1 mg/mL). This solution was then passed through a syringe filter. The passed solution was expected to contain particles with sizes smaller than the filter pore size and was subsequently passed through another filter with a smaller pore size. This filtering process began with filters of 5um pore size, and progressed through 1 um, and down to 0.45 um. The volume of the raw solution started with 1 mL and was maintained to this volume by adding extra methanol at different stages. SEM specimens were prepared by dispersing approximately 10 μL of the through-solution onto a silicon wafer and allowing to dry.

We were successful in filtering out nanoparticles, indicating that our procedure has been established, and is ready to be applied to an alloy of Al-Pd-Mn pure icosahedral quasicrystalline phase. During this process, we encountered the following problems and were able to establish effective solutions to overcome them.

We first began with hydrophobic polypropylene syringe filters. Upon examination of the specimen prepared with the flow through, it was frequently found that the desired particles were buried within unknown objects. The situation was worse with filters of a smaller pore size. The morphology of the objects resembled that of the filter fibers. This speculation was confirmed by Energy Dispersive X-ray Spectroscopy (EDS) analysis. The flow through of filter fibers is believed to be related to the presence of alloy particles in our solution, since repeated experiments with pure methanol did not cause this effect. With this knowledge, we switched to a stronger filter made of glass fiber. We found that the glass filter had little to no filter fiber flow through. The second problem we encountered is that the alloy particles obtained through filtering were mixed with salt (NaCl), which affected the examination of the nanoparticles by SEM. The effect became worse with filters of smaller pore size. We speculate that the salt is from the filter since salt was not observed on SEM specimens prepared from the raw solution prior to filtration. Several efforts were made to eliminate the salt. First, the filters were rinsed before use, although this turned out to also affect the integrity of the filters. Second, we scratched the silicon wafers with diamond paper and placed the particles on this relatively rough surface. Then we rinsed the sample with water with the aim of dissociating the salt, leaving the nanoparticles in the grooves. This was successful in removing almost all of the salt and allowing us to get a clear view of the desired particles.

11:45 AM CP05.04.09
Response of CuS Nanoparticle Additive in Ester Lubricant Under Electric Potentials
Ofir Friedman1, Chenxu Liu2, Yonggang Meng2, Yu Tian1 and Yuval Golan1; 1Ben-Gurion University of the Negev, Beer-Sheva, Israel; 2State Key Laboratory of Tribology, Tsinghua University, Beijing, China.

Nanomaterials have great potential as lubricating materials and for the development of advanced lubrication technologies. Moreover, applied electric field is considered to be of great interest and importance for controlling friction in systems with nanoparticle additives. Copper sulfide nanoparticles can be synthesized both as single nanoparticles and nanoplate arrays single by using single source, single surfactant technique and their surfactant coating can be re-organized in diferent structures by post synthesis thermal treatments.1 Surfactant coated CuS nanoparticle additives dispersed in diethyl succinate lubricant were studied in friction experiments under applied electric potential from -30 V to 30 V. A remarkable decrease in the coefficient of friction was observed upon application of an electric field perpendicular to the shearing interface. Friction tests indicate that the nanoparticles can reduce the friction coefficient of diethyl succinate lubricant by ~25%, from 0.24 to 0.18. When a negative potential lower than -14 V was applied, the friction coefficient markedly decreased to 0.05. Finally, different models were used for adsorption-settlement kinetics of nanoparticles implied that both the adsorption and settlement of CuS nanoparticles play an important role in the mass changes on the solid surface in the suspension of the nanoparticles. According to this research, shape controlled nanoscale lubricant additives are likely to have important technological importance in reducing and controlling friction in engineering systems.

The energy dissipated in a metallic frictional contact is largely converted into plastic deformation. The subsurface material is thereby exposed to extreme amounts of shear deformation and often forms layered subsurface microstructures with reduced grain size. We analyze the early stages of these processes with the aim of elucidating the elementary mechanisms for the formation of the subsurface microstructures by systematic model experiments and Discrete Dislocation Dynamics simulations. The simulations show how preexisting dislocations transform into dislocation structures within the stress field underneath a moving spherical contact. The crystallographic orientation is decisive for the formation of these structures and for dislocation transport with the moving contact[1]. Experimentally, we find a localized dislocation structure at a depth of ∼100-150 nm already after the first loading pass[2]. This dislocation structure is shown to be connected to the inhomogeneous stress field under the moving contact. Its generation and evolution under different conditions of load and loading rate are investigated. All subsequent microstructural transformations and the mechanical properties of the surface layer to some extent depend on this structure.

2:00 PM CP05.02 Microstructure Evolution and Deformation Mechanisms During High Rate and Cryogenic Sliding of Copper Xiang Chen1, Reinhard Schneider2, Peter Gumbsch1,3 and Christian Greiner1,4
1Institute for Applied Materials, Karlsruhe Institute of Technology, Karlsruhe, Germany; 2Laboratory for Electron Microscopy, Karlsruhe Institute of Technology, Karlsruhe, Germany; 3Fraunhofer IWM, Freiburg, Germany; 4MikroTribologie Centrum μTC, Karlsruhe, Germany.

Frictional sliding induces a distinct discontinuity in the microstructure between a subsurface layer and the underlying bulk material, which strongly influences the tribological performance. Here, the strain rate and temperature dependence of such tribologically induced microstructure evolution was systematically investigated during reciprocating sliding of copper. It was found that an increase in strain rate and a decrease in temperature each result in a transition in the dominating deformation mechanism from dislocation slip to twinning-mediated plasticity at the very beginning of sliding. A sequence of deformation mechanisms was revealed under high rate and/or cryogenic sliding: First, nanoscale dislocation trace lines form beneath the surface during the first forward pass; Second, partial dislocation nucleation from the sliding surface accompanied by nano-twinning and abundant stacking faults in the backward pass; Third, formation of a nanocrystalline layer upon further sliding. Sliding induced surface roughening is found to assist partial dislocation nucleation from the surface during high rate and cryogenic sliding. Our results suggest that the sliding surface can act as an effective source of dislocations to initiate and accommodate associated plastic deformation, which may be explored to model the microstructure evolution during sliding.

2:15 PM CP05.03 Dislocation Mediated Plasticity in Sliding Friction From 10,000 to 2 nm Darcy Hughes 1 and Niels Hansen 2
1Consultant, Fremont, California, United States; 2DTU, Roskilde, Denmark.

Microstructural evolution induced by plastic deformation during dry sliding and frictional contact is quantitatively examined via electron microscopy over several length scales. Individual dislocations, medium to high angle and dislocation boundaries, crystal orientation/texture, as well as local changes in chemical composition were measured as a function of depth from the sliding surface. These quantified structures are analyzed within a universal framework developed for metals and alloys undergoing different modes of plastic deformation. New and prior statistical scaling laws are used to evaluate structural evolution and the gradient in microstructural size scale that develops with increasing depth from the surface. In the near surface regions crystallite sizes with an average of 5 nm and a minimum of 2nm are observed. This average size scale coarsens with increasing depth and is measured as a function of depth. A new scaling law connects the microstructural evolution of two measured structural parameters. In turn those structural parameters are related to strength parameters that estimate the flow stress utilizing a linear addition of the classical Taylor and Hall-Petch formulations. The gradient in flow stress with depth is used to evaluate the overlapping stress fields created by sliding deformation.

Mechanisms that promote this refinement and counteract structural coarsening are examined. Solutes and dislocations, in addition to the applied stress field and deformation temperature, are all important elements in structural refinement. Solutes may be present both in the original alloy or introduced via mechanical mixing during deformation. Their presence is important to suppress dynamic recrystallization. In the absence of dynamic recrystallization, coarsening occurs by the migration of sharp triple junctions between deformation-induced boundaries that enclose lamellar regions. Attached dislocations and solutes can suppress junction migration via pinning mechanisms. Solutes hinder migration via both their presence within high angle boundaries and within the matrix as they stabilize dislocations and low angle dislocation boundaries. The observed and continuous presence of dislocations is a key point. Dislocation mechanisms remain the dominant deformation mechanism even below 5 nm.

Supercomputer Post-K Project “Challenge of Basic Science” in Japan and Its Recent Outcomes of Tribo-Wear Dynamics Induced by Chemical Reactions Momoji Kubo
Tohoku University, Sendai, Japan.

Supercomputer Post-K was constructed in 2011 in Kobe, Japan. Supercomputer K contains over 80,000 nodes and 700,000 cores and its calculation speed is 10^14 flops. Then, it won a championship in the supercomputer world ranking in June, 2011. However, in the supercomputer world ranking in June, 2018, supercomputer K ranks sixteenth. The ministry of education, culture, sports, science, and technology in Japan plans to construct new supercomputer post-K in 2021. The above ministry also started the “Post-K” projects for the development of Japanese-made simulation software on the supercomputer Post-K. Then, our proposed project “Challenge of Basic Science - Exploring Extremes through Multi-Physics and Multi-Scale Simulations” was adopted in June, 2016 and started in August, 2016. In this symposium, we introduce our supercomputer Post-K project and the recent outcomes of the tribology simulations by the supercomputer. The previous small-scale molecular dynamics simulations can clarify the super-low friction mechanism induced by the chemical reactions. However, the tribowear cannot be elucidated by the previous small-scale molecular dynamics simulations, because the tribo-wear simulations require huge amount of atoms. Super-large scale calculations by supercomputer and the molecular dynamics simulator optimized for supercomputer enable to simulate the tribowear dynamics induced by the chemical reactions. This is the paradigm-shift of the tribology simulation research. In the present presentation, we also discuss how the super-large scale simulations by the supercomputer “Post-K” will give the impacts on the tribology research.

Ideal adhesive and shear strengths of solid interfaces: A high throughput ab initio approach In printing, Computational Materials Science.

Tribo-oxidation is an often observed but far from fully understood phenomenon during friction and wear, taking place by tribochemical reactions of the tribo-partners or the surrounding medium. These reactions in most cases lead to a change in the surface properties such as the chemical composition and the mechanical properties and consequently result in a different friction and wear behavior. The aim of our research is to elucidate the elementary mechanisms of tribo-chemically induced oxidation by paring polycrystalline high-purity copper plates with sapphire spheres. The experiments are performed at room temperature in a strictly controlled atmosphere with reciprocating linear sliding under mild tribological loading.

Our results show the formation of amorphous oxygen-rich cuprous-oxide (CuO) islands which are formed below the surface and grow to hemispherical amorphous/nanocrystalline cuprous-oxide clusters. We relate the growth of the clusters to the diffusion of oxygen on and in copper but the exact pathways of the oxygen are still elusive. After the islands have grown, they coalesce and form a continuous oxide layer on the surface, determining from then on the tribological properties of the contact. This oxidation process takes place at rates order of magnitudes faster than the native oxidation of copper in contact with the same environmental conditions. This works aims to understand the influence of the sliding velocity on the formation of these oxide clusters. We systematically vary the sliding speed from 0.1 to 5.0 mm/s and investigate the resulting microstructure. Scanning electron microscopy techniques are used in order to reveal the fundamental mechanisms of tribo-chemically induced oxidation. Once understood, this will help for tailoring the materials properties in order to achieve superior tribological performance.

This project acknowledges funding by the European Research Council (ERC) under Grant No. 771237. Furthermore, it was possible through funding by the German Research Foundation under Project GR 4174/1.

Microstructure Analysis of Fretting Damage in Nickel-Based Alloy 617 Ahmed Darwish1, Arman Ahmadi2, Farshid Sadeghi2, Korukonda L. Murty3 and Jacob Eappen1 1Department of Nuclear Engineering, North Carolina State University, Raleigh, North Carolina, United States; 2School of Mechanical Engineering, Purdue University, West Lafayette, Indiana, United States.

Nickel-based alloys exhibit superior thermo-mechanical properties and are currently being considered for structural components of very-high-temperature gas-cooled reactors (VHTRs). During the operation of a VHTR, the structural components are exposed to extreme conditions including high temperatures and stresses; they are also susceptible to corrosion from moisture and impurity gases such as carbon dioxide and methane. Fretting wear occurs in several VHTR components such as valve stems and seats, control rod drive mechanisms, and fuel handling mechanisms.

Recently, a set of in-situ fretting wear measurements have been carried out on a nickel-based superalloy – Inconel 617 [Ahmadi, A., F. Sadeghi and S. Shaffer (2018)] in helium and air environment at elevated temperatures. In this work, we perform microstructural analysis of the samples from these tests using confocal laser microscopy and scanning/transmission electron microscopy techniques. The surface roughness measurements show that small amount of oxides, which are more prominent at higher temperatures, inhibit wear damage. The elemental mapping using energy-dispersive x-ray spectroscopy (EDS) also reveal enhanced oxygen presence on the wear scars. We will finally describe the possible formation of complex carbides that have a deleterious effect on the long-time integrity of the structural components.

References
Extraordinary tribological properties of diamond and tetrahedral amorphous carbon (ta-C) make them promising candidates for protective coatings in a variety of industrial products such as bearings and seals. Their ultra- (0.01 < μ < 0.1) and super-lubricity (μ < 0.01) have been observed under boundary lubrication with water and oxygen-containing organic friction modifiers. State-of-the-art spectroscopic measurements provided evidence for chemical and structural modifications of ultrathin carbon layers that play a role in establishing near-frictionless states. However, the tribochemical mechanisms behind the formation of superlubrious tribolayers have not been fully understood yet. Here, we will present recent results of atomistic tribology simulations of diamond and ta-C surfaces in contact with various lubricant molecules.

Large-scale quantum molecular dynamics simulations reveal five different friction regimes for water-lubricated diamond (111) surfaces [1]. While water starvation gives rise to cold-welding and amorphization of the tribological interface, traces of water are sufficient to preserve crystallinity. This can result either in high friction due to cold-welding via ether groups or in ultralow friction due to aromatic surface passivation triggered by shear-induced Pandey reconstruction. As increasing amounts of water molecules, dense H/OH surface passivation also provides another ultralow friction state. For other low-index diamond surfaces [i.e. (110) and (100)], three additional friction regimes involving ether and keto oxygen were found [2]. The surface-orientation-dependent friction regimes are rationalized by the structural and energetic peculiarities of the different low-index surfaces. Experimentally observed superlubricity of ta-C under boundary lubrication with oleic acid and glycerol is explained by our atomistic model [1]. The presence of two reactive centers in the lubricants (e.g. carboxylic polar head and C=O double bond in oleic acid) allows them to concurrently chemisorb on both ta-C surfaces and bridge the tribogap. Sliding-induced mechanical strain triggers a cascade of molecular fragmentation reactions releasing passivating hydroxyl, keto, epoxy, hydrogen and olefinic groups. Similarly, glycerol’s three hydroxyl groups react simultaneously with both ta-C surfaces, causing the molecule’s complete mechno-chemical fragmentation and formation of aromatic passivation layers with superlow friction. Interestingly, our finding is not limited to oleic acid and glycerol, but applicable to other common friction modifiers.

Actuation, length, stroke and actuation temperature. Novel approaches include using springs for radial compression, innovative biasing configurations and using the R-phase cycling to temperatures above and below the phase transformation temperatures under constant uniaxial strain conditions. Additionally, spatially resolved information was obtained in the case of the torsion specimens. The second aspect of this work will address the methodology adopted to design shape memory alloy springs along with results from comprehensive testing. The design considerations included multiple springs in limited operating volumes with requirements of forces exerted prior to actuation and following actuation, length, stroke and actuation temperature. Novel approaches include using springs for radial compression, innovative biasing configurations and using the R-phase transformation in NiTiFe springs. The discussion will also highlight appropriate modification of the theory in cases where substantial plastic deformation occurs during fabrication of the springs.

We have recently designed, fabricated and tested shape memory alloy elements in spring, tube and sheet forms for use in thermal switches, connect-disconnect mechanisms, deployable membrane telescopes and torsional tube actuators. The work has benefitted from in situ neutron diffraction at Los Alamos National Laboratory and Oak Ridge National Laboratory at stress and temperature in carefully selected experiments. The first aspect of this work will address implications for training (thermomechanical cycling for stable strain recovery in use) these alloys for cyclic aerospace applications and rely on experiments performed under (i) isothermal (both uniaxial and torsional deformation at constant temperature), (ii) isobaric (thermal cycling to temperatures above and below the phase transformation temperatures under constant uniaxial stress), and (iii) isostrain (thermal cycling to temperatures above and below the phase transformation temperatures under constant uniaxial strain) conditions. Additionally, spatially resolved information was obtained in the case of the torsion specimens. The hybrid nanomaterials formed by nanoporous metal and aqueous electrolyte have been considered competitive actuators since the concept appears in 2003. Motivated by this, here we study the impact of externally applied load on the actuation behaviors of nanoporous gold impregnated with an aqueous electrolyte. At no load, we observe the well-documented trend for a more positive electrode potential promoting elongation of the nanoporous body. For pure capacitive electrode processes on the clean surface, we confirm that the elastic response to external load is simply superimposed on the potential-induced elongation so that the strain per electric charge is invariant with the load. This is consistent with linear elastic behavior. Surprisingly, however, actuation in the regime of oxygen electrosorption responds strongly to loading: as the load is increased, the strain per charge first decreases and then inverts its sign. Furthermore, we demonstrate that the length change in response to lifting the oxygen adsorbate layer depends on the load that was present at the instant of oxygen-adsorption. We suggest that this “load memory effect” is a signature of the reorientation of local surface domains with anisotropic surface stress. We suggest that this “load memory effect” is a signature of the reorientation of local surface domains with anisotropic surface stress.

Li Alloy-Based Non-Volatile Actuators

Myoung-Sub Noh1,2, Seung-Hyub Baek1, Sangtae Kim1 and Chong Yun Kang1,2, 3

Center for Electronic Materials, Korea Institute of Science and Technology, Seoul, Korea (the Republic of); KU-KIST Graduate School of Converging Science and Technology, Korea University, Seoul, Korea (the Republic of).

Actuators form the basis of the modern robotics industry, with applications ranging from microelectromechanical devices to medical or consumer electronics. Various actuator types including piezoelectric actuators, shape memory alloys and electrochemical actuators have been devised to meet the wide range of application needs. Especially, recent urge to develop humanoid robots and exoskeletons that mimic or aid human motions call for further development of a special kind of actuators called the artificial muscles. The requirements for successful artificial muscles include a large amount of strain (~10%) and large stress on the order of 100 MPa, preferably with low power consumption. Several novel actuator types have been suggested to serve as artificial muscles such as polymer-based actuators or electrochemical actuators. These actuators achieve successful integration into several robotics parts, with the characteristically large amount of strain, fast response time and below 3 V operation. Most artificial muscles developed so far, however, feature volatile actuation where voltage must be continuously supplied to maintain the actuated position; as soon as the input voltage is turned off, regardless of how big or small the operation voltage, the actuated position returns to its original position. Such volatile actuation is featured in most well-known actuators, including the piezoelectric, shape memory alloy-based, electrostrictive and ionic muscle actuators. For artificial muscles, this volatility indicates a significant loss of efficiency, as mimicking human motions involve a series of constant actuated positions. Such non-volatile actuation capability, however, has not yet been realized with many well-known artificial muscles. Here, we develop a non-volatile actuator with LiGe electrodes for artificial muscle. The novel actuator type consists of ion insertion electrodes so that the inserted ions pose stress on the electrodes that sustain even after power shut-off. The device consists of lithium germanide (LiGe) thin films deposited on both sides of a flexible polyimide (PI) substrate. The demonstrated device...
Bistable Electroactive Polymers and Compliant Electrodes

Bistable electroactive polymers (BSEPs) combine the properties of shape memory polymers and dielectric elastomer actuation at the rubbery state to generate rigid-to-rigid actuation. The variable stiffness could be obtained via glass transition or phase changing. The reversible melting-crystallization of polymer chains in the phase changing BSEP leads to a narrow temperature band to complete the stiffness change. A modulus change greater than 1000 fold can be achieved within a few degrees. Large actuation strains could be obtained. To drive the large-strain deformation, compliant electrode materials are also developed that maintain electrical conductivity at the large strains.

Heavy Lifting with Soft Materials—Layered Liquid Crystal Elastomer Actuators

Liquid crystalline elastomers (LCEs) are soft, anisotropic materials that exhibit large shape transformations when subjected to various stimuli. This shape morphing results when the net order of the material is reduced by external stimuli, such as heat, light, or electric fields. Here, we demonstrate a facile approach, lamination, to enhance the out-of-plane work capacity of these materials by an order of magnitude, to nearly 20 J/kg. Additionally, these materials can displace loads more than 2500x heavier than its own weight over 0.5 mm. The enhancement in force output is enabled by the development of a room temperature polymerizable composition used both to prepare individual films, organized via directed self-assembly to retain arrays of topological defect profiles, as well as act as an adhesive to combine the LCE layers. 1

Shape memory alloys such as NiTi intermetallic compounds exhibit a shape memory effect and a pseudoelastic effect owing to the transition between B2 austenite and B19(′) martensitic phases. Upon a large enough stress, dislocations will be formed and hinder the B2-B19(′)-B2 transformation that will diminish the shape memory effect. To improve the shape-memory and pseudoelastic performance, NiTi-based minor-doped, multicomponent and even in recent years high-entropy intermetallic compounds have been developed. However, because of the complex atom configuration and large lattice distortion in high-entropy materials, the structure, phase transition, mechanical response and deformation behavior of NiTi-based high-entropy intermetallic compounds need further investigations. Thus in this work, NiTi-based low-entropy (binary), medium-entropy (quaternary) and high-entropy (senary) intermetallic compounds were prepared by arc melting and casting (thereafter with homogenization), and their structures, mechanical properties and deformation behavior were then characterized. X-ray diffractions indicated that all the samples had a B2 austenite structure, but an expansion of unit volume was obviously noted in the high-entropy intermetallic compounds. Nanoindentation tests on different-orientation grains revealed the loss of anisotropy of mechanical properties in the high-entropy intermetallic compounds. The in situ SEM compression of low-entropy micropillars presented a pseudoelastic response and, upon yielding at a high load, typical long-distance slip deformation. However, the in situ SEM compression of high-entropy micropillars showed homogeneous barrel-like deformation without clear slip lines or plastic heterogeneity. The cross-sectional TEM observation revealed a short-distance activity of abundant partial dislocations rather than long-distance gliding of few complete dislocations in the deformed high-entropy micropillars.

Phase inversion techniques, commonly used to fabricate filtration membranes, offer a mechanism to induce micro and nanoscale porosity in polymer materials, reducing their stiffness and impacting their mass elongation. Particulate additives can then be used to further modify the structure, and impart electrical properties. Together, macroscale properties of the composite can be tuned by controlling both the composition of the final material and its structure.

We demonstrate this using evaporation induced phase inversion of PVDF and explore the impact of non-solvent concentration and nano-scale ceramic particle loading on morphology. Particulate size and material are also varied, and show a dramatic impact on the structure of the pores present within the materials. This structure can be controlled from nano-scale voids to micro-scale foam-like openings. Testing shows how this morphology impacts the mechanical properties of these composites, determining how the materials can deform. Similar materials have already been used as battery separators. We look to further develop these porous composites to act as functional materials in soft electronics, using the filler to impart desired electrical properties such as conductivity, permittivity, and permeability, while maintaining low stiffness and high elongation.

Electroresponsive Homogeneous Polyelectrolyte Complex Hydrogels from Naturally Derived Polysaccharides

Homogeneous polyelectrolyte complex (PEC) hydrogels made from chitosan and carboxymethylcellulose were prepared in the LiOH/KOH/urea aqueous system through a freeze-thawing method. Following the treatments of sequential hydrolysis and physical crosslinking, the resulting hydrogels with superpower mechanical strength can operate as fast response actuators under electrical stimulus in salt aqueous solutions. The electromechanical behaviors of the hydrogels are strongly dependent on experimental parameters such as electric voltage, solvent constituents, pH, and ionic strength. It is proposed that the electromechanical deformation of hydrogel originates from a dynamic osmotic equilibrium effect taking place at the interface between the hydrogel and the surrounding medium, which is induced by the migration of ions throughout the gel network. In addition, programmable 3D shape transformations were obtained by using the PEC hydrogel with designed 2D geometric patterns. Moreover, the bending actuation behavior of the PEC hydrogel can propel an adjacent object to move forward. These hydrogels are expected to be used as underwater actuators for soft robotics and other smart biomimetic systems.

van der Waals Oxide Heteroepitaxy for Transparent Flexible Electronics

Integration of Genetically Engineered Protein Fibers with Textile Scaffolds for Wearable Sensing Applications

The presentation will also discuss results from the various oxide based stretchable platforms for applications in sensing, optics, and memories. We have demonstrated a transfer process which is ubiquitous (can be used for any oxide coating), repeatable (and amenable to mass manufacture), scalable, capable of high integration densities (due to ability to micro/nano pattern) and which utilizes high performance oxide materials stretchable up to 15%. This process utilised the naturally weak adhesion of platinum to silicon, and this allows us to create electronics on a rigid substrate such as silicon and then peel off the layers to transfer onto a stretchable substrate. This process also results in a unique ‘micro-tectonic’ surface, creating opportunities to explore new stretchable device applications. This process has been successfully demonstrated using transparent indium tin oxide, zinc oxide, titanium dioxide, strontium titanate, and vanadium oxide.

This process also results in a unique ‘micro-tectonic’ surface, creating opportunities to explore new stretchable device applications. This process has been successfully demonstrated using transparent indium tin oxide, zinc oxide thin films, and titanium dioxide thin films with stretchability of up to 15% which is exceptionally high for a brittle oxide. With this process, we have also demonstrated room temperature gas and UV sensors, mechanically tunable diffraction gratings as well as optical metasurfaces. More recently, we have demonstrated stretchable memory devices. A stretchable non-volatile resistive memory is a fundamental element in realizing complex neuromorphic computing and compact logic application adaptable to wearable electronics. A room temperature deposited strontium titanate based resistive memory on stretchable substrate has been developed. The STO-based resistive memory does not require energy-intensive electroforming, exhibits stable complementary switching, long retention time, and reproducible endurance switching. The devices demonstrate the ability to operate under uniaxial tensile strain and extreme bending conditions.

The presentation will also discuss results from the various oxide based stretchable platforms for applications in sensing, optics, and memories.

van der Waals Oxide Heteroepitaxy for Transparent Flexible Electronics

Ying-Hao Chu1, 2; National Chiao Tung Univ, Hsinchu, Taiwan; 2Institute of Physics, Academia Sinica, Hsinchu, Taiwan.

Flexible electronics represents a fast-developing field and has a great potential to impact our daily life. In building up flexible electronics, the materials with controllable conduction, transparency, and good flexibility are required. van der Waals epitaxy (vdWE) involving two-dimensional layered materials can play a crucial role in the expansion of thin film epitaxy by overcoming the bottleneck of material combinations due to lattice/thermal matching conditions inherent to conventional epitaxy. Among the layered materials, mica is a well-known phyllosilicate mineral that can have a remarkable impact on flexible electronics. Due to the interplay of lattice, charge, orbital, and spin degrees of freedom, correlated electrons in oxides generate a rich spectrum of competing phases and physical properties. However, a generic approach to build up flexible electronics based on functional oxides is yet to be developed. In this study, we use a 2D material as the substrate. In this talk, we confine ourselves to the validity of vdWE of functional oxides on muscovite mica throughout this treatise. With such demonstrations, it is anticipated that MICAtronics, vdWE on mica, can reveal unusual properties and emergent phenomena in the realm of high-performance flexible device applications.

Integration of Genetically Engineered Protein Fibers with Textile Scaffolds for Wearable Sensing Applications

Dalia Jane Saldanha, Bita Janfeshan, Zahra Abdali and Noemie-Manuelle Dorval Courchesne; Chemical Engineering, McGill University, Montreal, Quebec, Canada.

Smart materials and textiles with abilities to interact and respond to changes in their environment are becoming a need of the hour. Apart from being light-weight, flexible and portable, their fabrication into easy-to-read sensing devices can make the arena of diagnostics more accessible to the end-user. Among the options available today, engineered living materials, comprising a hybrid of living components that utilize energy sources to produce and/or secrete the bulk of the material and non-living components that confer novel properties, are gaining widespread popularity. One promising protein-based biomaterial we have studied in this project is the curli fiber system of E.coli. In this study, we report methods for effectively integrating curli nanofibers into commercially synthetic textiles to create functional wearable devices.

Curli fibers, in nature, constitute the non-pathogenic proteinaceous components of bacterial biofilms and can be genetically engineered to create a diverse range of stable and sensitive devices. These fibers form a high surface area porous network exhibiting unique self-assembly properties. They can be produced in various forms like gel, film, and powder while maintaining their properties. These systems have an edge over conventional organic polymers in that they are biocompatible and biodegradable while also being stable to enzymatic activities, detergent action and harsh chemical treatments. With properties that can be modulated through genetic, chemical and mechanical means, these materials find applications such as optical sensors in the diagnostic (e.g. wound infection) and personal care (e.g. blood glucose, stress hormone level) sectors.

A technique that showed great promise for integration of curli fibers into fabrics is vacuum filtration. In this work, we investigated the integration of protein curli fibers into various types of synthetic textile fabrics through the vacuum filtration technique. The filtration of curli-producing bacterial cultures onto the fabrics was followed by suitable washing and purification to separate the micro-organisms from the hybrid materials. With this method, we were able to load porous textile matrices with protein fibers throughout their cross-section, to create functional textile-protein composites. We optimized parameters affecting the extent of curli fiber incorporation onto the scaffold such as volume of the bacterial culture, porosity of the filtering fabric, and expression levels of the wild type or genetically engineered curli fibers. We also studied the microstructure and mechanical behavior of the fabrics before and after filtration. Microstructural analysis showed that the curli fibers were uniformly incorporated into the polymeric fibers of the fabrics over a large area. In some samples, self-assembly of curli fibers on textile fabrics was also observed. For further optimization, we studied the viscosity and rheological properties of the curli fiber gel obtained via vacuum filtration, and we explored suitable printing techniques such as screen or ink jet printing, as an alternative method for incorporating protein fibers into textiles. Last but not the least, curli fibers expressing a fluorescent sensing moiety were incorporated onto the textile scaffold, and we studied changes in functional activities before and after integration for potential development of this system into a fluorescent and wearable textile-based biosensor that is both accurate and user-friendly.

Microstructured P(VDF-TrFE) Featuring Embedded Electrodes for Flexible Direction-Sensitive Strain Sensors

Philipp Schäffner1, 2; Jonas Grotten1, Maria Belegratis1, Andreas Tscheppe1, Martin Zirk1 and Barbara Stadlober1; 1Joanneum Research Forschungsgesellschaft mbH, Weiz, Austria; 2University of Graz, Graz, Austria.

Tomorrow’s Industry 4.0 environments raise a growing demand in self-sustained, flexible and low-cost sensors for versatile applications in process control as well as condition and energy monitoring. We present a new concept for direction-sensitive and flexible strain sensors based on the ferroelectric copolymer PVDF-TrFE and a single layer of interdigitated electrodes. Microstructured metal electrodes are formed on plastic substrates and embedded in the copolymer. Electric poling using the embedded electrodes (EE) allows the orientation of the ferroelectric domains primarily parallel to the P(VDF-TrFE)-substrate interface, thus having increased piezoelectric coupling with respect to lateral strains present in the surface plane. We employ a combination of (self-aligned) photolithography and electroforming to produce 2-10µm wide and up to 4µm high electrodes that are fully covered by screen-printed P(VDF-TrFE). Alternatively, we present a novel structuring method based on microfluidic channels hot embossed into P(VDF-TrFE) which are filled with conductive ink to form high aspect ratio EE.
Tensile tests with sensors having a footprint area of 1cm² were performed and compared with FEM simulations. The results show a highly linear charge response with respect to longitudinal strain, and the coupling strength depends significantly on the strain orientation in the surface plane. In conclusion, the use of the EE allows selectively resolving strain magnitude and orientation. Furthermore, bending at 90Hz excitation frequency yields an average power output of ~0.6µW per mm³ of active polymer volume, sufficient for stand-alone applications.

SESSION CP06.04: Poster Session: Smart Materials for Multifunctional Devices and Interfaces
Session Chairs: Shou-Yi Chang and T. Venkatesh
Tuesday Afternoon, April 23, 2019
5:00 PM - 7:00 PM
PCC North, 300 Level, Exhibit Hall C-E

CP06.04.01 Thermoplastic Magnetorheological Elastomer for Fused Deposition Modeling—Filament Extrusion, Mechanical Properties and Magnetic Properties
Andrew H. Morgenstern, Thomas Calascione, Nathan Fischer, T.J Lee and Brittany Nelson-Cheesenman; Undergraduate School of Engineering, University of St. Thomas, Saint Paul, Minnesota, United States.

Magnetorheological elastomers (MREs) are unique smart materials of high elasticity and magnetic susceptibility. MREs are prominent for the high degree of mechanical deformation or changes in stiffness that can be induced by applying magnetic fields. While most MREs are made with thermoset elastomers, this research focuses on the development and testing of a thermoplastic magnetorheological elastomer (TMRE) for potential use as fused deposition modeling (FDM) filament. FDM, also known as 3D printing, is an additive manufacturing technique that consists of 1D viscous thermoplastic extrusions that create 2D layers that build up to a 3D part. This method of creating parts produces underlying anisotropies which can be tuned to control the properties of the final part. Printing could bring new functionalities and applications for TMREs due to new sub-structures that are available through FDM. Proposed applications include but are not limited to use in actuators, dampers, soft robotics, smart sensors and actuators, wearable technology and biomedical drug delivery. The first step in realizing such applications is the development of functional TMRE filament for FDM. Our TMRE was created utilizing solvent casting techniques to disperse isotropic magnetic particulate within a thermoplastic polyurethane matrix. A range of materials were explored to highlight the effects of particulate type and loading. Samples were created spanning two different magnetic particulate types (150µm iron & 2–4µm magnetite) and each with three different particulate loadings (20, 30, 40 wt%). The material was then extruded into FDM filaments with a Filameter. Filament width of the extruded filament samples was tracked and compared to evaluate the consistency of the extrusion process within the lab setting. Mechanical stress vs. strain curves of the extruded filaments were obtained using an MTS tensile tester. Magnetic hysteresis loops were acquired with a vibrating sample magnetometer (VSM). The analogous pure PU filaments were also extruded and tested as a control. Our testing indeed shows that altering the magnetic particulate type and its weight concentrations impacts both the magnetic and mechanical properties of the overall material. In general, the filament samples with magnetite particulate had higher diametric consistency and were stiffer than those with iron particulate. The heightened stiffness is likely due to the particulates smaller size and larger volume percentage of the magnetite given its lower density than iron. Additionally, samples with magnetite had higher magnetic susceptibility and coercivity but lower saturation magnetization than those with iron. Normalization of the saturation magnetization to compensate for the scaling of the particulate percentage indicates a consistent particulate dispersion and integration despite changes in its volume. Lastly, increasing particulate percentage increases both the mechanical stiffness and saturation magnetization of the samples, as expected. Future efforts will focus on further data analysis, magneto-mechanical testing, initial FDM printing tests, and cross-sectional imaging of the extruded samples to develop a robust explanation as to why the material functions in the way it does for insight and understanding when used in FDM. Despite being only the first step in understanding the functionality of this smart material, this step is critical for optimal utilization and realization in future applications.

CP06.04.02 All-in-One Piezoresistive-Sensing Patch Integrated with Micro-Supercapacitor
Yu Song and Haixia Zhang; Peking University, Beijing, China.

Portable and wearable sensors have attracted considerable attention, which could perceive and respond to ambient stimuli accurately. For the sake of solving the limited power supply and low integration, it is critical to develop and combine functional electronics with flexible energy devices. In this work, we designed an all-in-one sensing patch integrated with piezoresistance sensor and micro-supercapacitor with the porous CNT-PDMS elastomer. Taking the advantage of porous structure with piezoresistivity and elastomer with electrochemical performance, the piezoresistance sensor shows high sensitivity (0.51 kPa⁻¹) and wide detection range as functional fraction, and micro-supercapacitor maintains excellent areal capacitance and cycling stability after 6000 cycles as energy storage fraction, respectively. Assembled with piezoresistance sensor and micro-supercapacitor, the sensing patch could be easily attached on the epidermal skin for joint and muscle monitor with the corresponding resistance response. With high sensitivity and mechanical robustness, such sensing patch could be further utilized as a 3D touch in user identification and safety communication through feature parameter extraction and signal decoding. After packaged into the sensing patch matrix, it could be achieved for static pressure sensing and dynamic tactile trajectory. Therefore, the all-in-one sensing patch shows feasibility in real-time pressure recognition and human-machine interfaces.

CP06.04.03 Preparation of Fabrics with Smart Directional Water-Transport Property
Lihong Lao, Dahua Shou, Yuen Shing Wu and Jintu Fan; Cornell University, Ithaca, New York, United States.

Clothing provides a microclimate between the body and the external environment, and acts as a barrier for heat and vapor transfer in between. In sweating conditions, in order to maintain the thermal comfort, fabric next to the skin should not only absorb liquid rapidly but also transport it through the fabric promptly to avoid the discomfort of the fabric sticking to the skin. On the other hand, in the raining weather, the fabric next to the environment is desired to prevent the water passing from the environment to the skin, and thus should possess water-resistant or water-proof properties. Therefore, there’s a demand to design a smart fabric material that has an asymmetric wettability and could directionally transport water from the skin to the environment, but minimize the transport in the reverse direction.

In this project, we worked towards this goal — endowing asymmetric wettability on breathable fabrics to enable directional (differential) water transport properties. We used a combination of superhydrophobic finishing and plasma selective treatment to create gradient wettability channels through the fabric thickness. While these channels were served for directional liquid transport, the untreated larger surface remained superhydrophobic, therefore could still provide thermal comfort and water-resistant properties next to the skin and environment, respectively. The directional water transport ability was confirmed by a home-made measurement device. Additionally, SEM, TGA, chemical analysis, and contact angle measurements were performed to determine the surface structure and wettability of the fabric after various modification conditions.

CP06.04.04 Hydrothermal Synthesis and Characterization of Cesium Lead Halide (cspbX3) Perovskites for Optoelectronic Applications
Sahaya D. Babu and Xavier Sahaya Shajan; 1Department of Physics, Chettinad College of Engineering and Technology, Karur, India; 2Department of Physics, PSN College of Engineering And Technology, Trurnveli, India.

The outstanding optoelectronic properties of inexpensive and solution-processable hybrid metal halide perovskites have brought them to the forefront in many research fields, such as solar cells, light-emitting diodes, photo detectors, and lasers. One of the main advantages of these materials is that its optical band gap can be easily tuned by altering the constituent elements. The success of these materials quickly led to the synthesis of organic/inorganic hybrid perovskites, and later also as purely inorganic cesium-based perovskites. Nanocrystals exhibit high photoluminescence quantum yields (PLQY’s) and offer an inherent way to tune the optical properties through size- and dimensionality-dependent quantum confinement. Currently, a limited number of synthetic methods are available for the preparation of CsPbX₃ NCs. In this regard, we have been made an attempt to synthesize cesium lead halide perovskites through simple hydrothermal method. The prepared nanomaterials were characterized by various analytical techniques. XRD and Raman analysis shows perfect crystalline nature of cesium perovskite and its morphology was obtained from FESEM and TEM analysis. Band structure properties of cesium halides were attained from XPS and UPS analysis. Details will be presented.
Dynamic Surface Topography in Micro-Objects and Films

Mustafa K. Abdelrahman, Hyun Kim, Patrick Ondruske, Jimin Maeng and Taylor Ware; The University of Texas at Dallas, Richardson, Texas, United States.

Strategies to induce dynamic surface topography may enable new engineering devices where friction, fluid flow, or cell attachment is a property that needs to be controlled on-demand. There are multiple ways to create polymeric materials where the surface topography can be induced to change in response to a stimulus. For example, shape memory polymers can switch from smooth to rough on heating, but require mechanical programming, limiting this effect to only objects that can be easily deformed such as films. Also,
liquid crystalline networks could induce surface topography changes without a programming step; however, they require a constant energy source in order to keep the surface topography from returning to its original state. They also require an initial alignment step, which further confines this ability. Here we describe a versatile strategy to significantly and permanently alter the surface topography of films, microstructures and microphones without any mechanical programming step or initial alignment. Specifically, we use a radical thiol-ene reaction to build semi-crystalline polymer networks from low molecular weight monomers. Crystallization of the network occurs concurrently with polymerization and produces a material with built-in stresses. On heating through the melting point of the network, these initially smooth materials, having an average roughness of 10 mm, form peaks and valleys, reaching an average roughness of 500 nm. We have been able to produce this effect in films, micro-molded structures, and microphones. The magnitude of the roughness can be controlled by altering either the melting point of the network, the crosslink density, and/or the polymerization temperature. For example, we show that the closer the polymerization temperature is to the substrate's melting temperature, the less rough the substrate becomes after being heated to its melting temperature. This allows us to pattern roughness by simply polymerizing different portions of the substrate under various temperatures. This control will allow us to tackle major engineering challenges in the areas of micro fluids, self-cleaning films, bio-adhesion and cell growth.

CP06.04.10
Effect of Zn Substitution on Structural, Dielectric and Magnetic Properties of Cobalt Ferrites and Their Applications

Tammam Mariani1, Kazu Haniu2, Nazru Islam Khan3, and Shamima Choudhury1
1: Department of Physics and Astronomy, University of Toledo, Toledo, Ohio, United States; 2: Department of Physics, University of Dhaka, Dhaka, Bangladesh; 3: Material Science Division, Bangladesh Atomic Energy Center, Dhaka, Bangladesh.

A series of Co1-xZnxFe2O4 ferrite with (x=0.0, 0.1, 0.2, 0.3, 0.4, 0.5) compositions were synthesized using the standard double sintering ceramic technique, sintered at 1050°C for 2 hours. Substituting Zn in place of Co influenced the structural, dielectric and magnetic properties of CoFe2O4 samples. Structural analyses were carried out using X-ray diffraction (XRD). The X-ray diffraction pattern confirmed the single-phase cubic spinel structure and the sharp peak revealed that the samples are in good crystalline form. The lattice parameters were calculated for each composition and found to increase with Zn substitution. A significant increase in density and subsequent decrease in porosity was observed with increasing Zn content. The grain size of the samples was reduced by enhancing the Zn concentration. The dielectric constant (ε') of the sample is found to decrease with increase in frequency exhibiting normal dielectric behavior. Dielectric relaxation peaks were observed for the frequency dependence of dielectric loss tangent curves. The observed dielectric properties were explained on the basis of electron conduction mechanism. The variation of the resistivity versus temperature was also studied and the dielectric constant of the system has a variation quite similar to that of the resistivity. VSM measurement confirmed that the magnetizations of all the samples were saturated. Saturation magnetization and coercivity were estimated with variation of Zn content. These effects are due to facilitation of demagnetization by substitution of the non-magnetic Zn ions. Permeability was found to decrease with increasing in Zn content. The characteristics of electromagnetic, excellent chemical stability, mechanical hardness, low coercivity, moderate saturation magnetization and high anisotropy constant suggested Cobalt Ferrite a good candidate for synthesizing and investigation to contribute as dielectric, magnetic, multifunctional material and in storage devices for the advancement of science and technology.

CP06.04.11
Outstanding Performance of CuCo2O4 as an Electro catalyst for Urea Oxidation

Camilla Zequine1, Fangzhou Wang2, Xianglin Li3, Khamis Siam4, Pawan Kabol5 and Ramkumar Gupta2
1: Pittsburgh State University, Pittsburg, Kansas, United States; 2: Department of Mechanical Engineering, University of Kansas, Lawrence, Kansas, United States.

Urea oxidation reaction (UOR) brings a possible solution to solve the energy crisis in the world. Fuel cells have been used UOR to generate hydrogen with lower potential compared with water splitting, decreasing the costs of energy production. Urea is abundantly present in waste agricultural, and in industrial and human wastewater. Providing a generation of Hydrogen, this reaction provides a pathway to eliminate urea as a hazard in the environment and people's health. Herein, nanostructure 3D flower like CuCo2O4 grown on Ni foam were synthesized as an electrocatalyst for urea oxidation to generate hydrogen as a green fuel. The synthesized electrocatalyst was characterized using X-ray diffraction, scanning electron microscopy and X-ray photoelectron spectroscopy. The electroactivity of this material toward the urea oxidation in alkaline solution was evaluated using electrochemical measurements. The results for UOR confirm the applicability of the electrode as promising electroactive material for hydrogen production. Nanostructured CuCo2O4 grown on Ni foam requires a potential of 1.36 V in 1 M KOH with 0.33 M urea to deliver a current density of 10 mA/cm2. The electrode is electrochemical stable for over 15 hours of continuous measurements. The high catalytic activities for hydrogen evolution reaction make CuCo2O4 electrode as a bifunctional catalyst. The two electrode electrolyzer demands a potential of 1.52 V which is 190 mV less than that for the urea-free counterpart. Our study suggests that CuCo2O4 electrode can be a promising pathway to efficient UOR catalysts used in fuel cells with low-cost hydrogen generation.

CP06.04.12
Polyampholyte Micgels as Ionic Traps for Proteins

Wenjing Xu1,2, Andrej Rudov1,4, Ricardo Schroeder2,1, Igor Potemkin3,1, Walter Richtering4,1 and Andrij Pich3,4
1: DWI-Leibniz Institute for Interactive Materials, Aachen, Germany; 2: Institute for Technical and Macromolecular Chemistry, RWTH Aachen University, Aachen, Germany; 3: Physics Department, Lomonosov Moscow State University, Moscow, Russian Federation; 4: Institute of Physical Chemistry, RWTH Aachen University, Aachen, Germany.

Polyampholyte microgels contain both acidic and basic functional groups and are able to change their charge as function of the pH. Their particle sizes under aqueous state swell at pH 4 due to electrostatic repulsion and collapse at pH 11 due to electrostatic attraction. Their swelling and shrinking can be controlled by changing the pH. Therefore we aimed to synthesize polyampholyte microgels as carriers to achieve a triggered uptake and release of guest molecules. Microgels as carrier systems to transport guest molecules have attracted great attention in the past years. Their ability to bind and release guest molecules upon changing the outer stimuli is making them interesting for a wide range of applications especially in biomedical fields. It is well established that microgels interact with guest molecules via different pathways as covalent binding, hydrophobic interactions and electrostatic forces. In case of the interaction between polyelectrolytes, electrostatic forces are of greater importance. Therefore we are trying to synthesize polyampholyte microgels as carriers to achieve a triggered uptake and release of guest molecules. Polyampholyte microgels contain both acidic and basic functional groups and are able to change their charge as function of the pH. Their particle sizes under aqueous state swell at pH 4 due to electrostatic repulsion and collapse at pH 11 due to electrostatic attraction. The existence of an isoelectric point is another important characteristic feature of polyampholyte microgels revealing at which pH the charges are equal and the overall net charge become zero. In this research we synthesized new microgels with defined charge localization and various architectures (random, core-shell and Janus-like microgels) with free radical precipitation polymerization. Together with the help of computer simulations, we investigated the swelling and collapse of the microgels with possible shape variation as function of different external stimuli. In addition we studied the interaction of the synthesized microgels with the model protein cytochrome c at different pH values and different internal structures.

Development of Thermal Insulation Materials for Buildings with X-Ray and γ-Ray Shielding Function

Teruyoshi O. Hirano1, Yuki Katakanai1, Satoro Hashimoto1, Ichiro Hatusumari1, Tsukaru Nishisunou1, Naoki Yamashita1, Takumi Iwasaka2, Yako Yamashita1 and Yasuyuki Mori2; 1: GGG Inc, Tokyo, Japan; 2: MAKUZO Co., Ltd., Fukushima, Japan.

In the accident at Fukushima Daiichi Nuclear Power Station, many radioactive materials were released into the environment field. In the future, materials with radiation shielding property will be required for a long period. We have developed and reported Anti-Sievert® Concrete with enhanced shielding function as construction material1. Anti-Sievert® Concrete has a shielding function of about 3 times as compared with ordinary concrete for X-ray (200 kV) and shows strength exceeding 40 N / mm2. For building materials other than concrete, the application of advanced shielding function is required. In this report, we improved the function of shielding effects of radioactive materials and radiation on Rock-Wool, which is a typical heat insulating material widely used for many buildings. This material is a blend of Anti-Sievert® (high density ceramics material) with shielding function with other materials with shielding function. For improving the shielding function, it is required to increase the content of Anti-Sievert®. However, in order to realize the heat insulating function, it is essential to be porous. We developed heat insulating materials with practical shielding function by properly balancing these conflicting design values. In the present formulation, it has a shielding function of about 0.2 to 0.3 mm (100 kV) equivalent to lead in Anti-Sievert® Rock-Wool with a thickness of 50 mm. This characteristic corresponds to the shielding functions used for medical X-ray transmission photography equipment. Continue to improve the shielding function and report materials with shielding function of practical level that can be widely used for buildings. We think that this material is extremely useful in the Fukushima area.

Shape memory materials traditionally utilize temperature or environmentally dependent phase transitions in order to return from a deformed state. Alternatively, magnetic shape memory alloys have long been investigated, as they can be deformed by magnetic fields rather than environmental conditions; however, these alloys suffer from the drawback that they exhibit very small strains. This has led to recent developments in magnetoreheological elastomers (MREs), which can exhibit significantly greater strains. Our research focuses on the processing of a thermoplastic MRE by solvent casting a polyelectrolyte (PE) elastomer with magnetic particulate for fused deposition modeling (FDM) applications. FDM, commonly referred to as 3D printing, is a valuable manufacturing technique that allows for the creation of parts with inherent anisotropies. For the case of an MRE, FDM allows for the production of structures with tunable magnetic susceptibility along different axes. In these composites, the degree of particulate dispersion significantly affects the isoropy of material properties, which becomes increasingly important when small material volumes are used, such as in FDM. Incorporating solvent casting as a versatile method of producing polymer composites will allow for greater control over the particulate addition method, leading to a higher degree of dispersion when compared to a polymer melt. For our purposes, composite thin films were produced in order to examine effect of wet vs. dry addition of particulate on dispersion, while thicker samples were produced to study the porous structures obtainable by utilizing different drying methods. The solvent used in producing the PU composites was dimethylformamide (DMF). Preparation of polymer solutions included dissolution of PU in DMF to 20 w/v% followed by addition of the magnetic particulate. The particulates used were <150 µm iron powder and 2-4 µm magnetite powder. Composites solutions were made to concentrations of 20, 30, and 40 w/w% particulate to polymer by addition of either dry particulate or particulate pre-suspended in DMF. Drying conditions included room temperature air drying, or a dehydrator, or drying in a vacuum oven. Wet addition of magnetic particulate led to smaller clump sizes and improved dispersion, while dry addition led to larger clump sizes and poorer dispersion. All drying techniques prominently affected the degree of porosity in the resulting composite. Future inquiry will focus on the effects that the porosity of the composite, as a result of drying technique, has on further processing and manufacturing; ensuring that the effect of addition method on the dispersion of particulate in thicker samples is equivalent to that found in thin films; and understanding the impact that each of these factors will have on components manufactured by FDM.

**3D Numerical Simulation on the Effect of Surface Morphology for Highly Sensitive Ion-Sensitive Semiconductor Nanowire Sensors**

Yunsung Cho, Jeong-Su Kim, Geon-Gu Ji, Jin-Tea Kim and Yeon-Ho Im; Chonbuk National University, Jeonju-si, Korea (the Republic of).

Semiconductor nanowire ion-sensitive field effect transistor (NW-ISFET) has attracted considerable attention as a next-generation sensor platform for a wide range of chemical and biological applications. Despite their potential applications, highly reliable sensing performance of NW-ISFET is regarded as one of the main bottlenecks for commercialization of this technology. This issue may be mostly due to a lack of understanding of sensing mechanisms. To address this issue, we have performed 3D device modeling to capture the detailed aspects of NW-ISFET sensing mechanisms with the change of nanowire surface morphologies in chemical and biological applications. At the electrolyte interface between nanowire and liquid, a specific site binding model and Gouy-Chapman-Stern theories were applied in order to consider the realistic ion-screening effects via the electrical double layer. Meanwhile, 3D electronic transports on the nanowires with different surface morphologies were coupled with the electrochemical models. Finally, the simulation results are verified through comparison of our previous experimental data. It was concluded that the main aspects of NW-ISFET sensing performances were captured with our 3D numerical simulation according to the change of nanowire surface morphology. Finally, the detailed origins of the NW-ISFET sensing mechanism will be discussed. We believe that this work can give better insights to improve the reliability of chemical and biological NW-ISFET sensors.

**CP06.04.16**

**3D Printing of Carbon Nanotube-Based Electrically Conductive Nanocomposites**

Rasool Bayvanjhangang, Michael Hilli and Parisa Pour Shahid Saeed Abadi; Michigan Technological University, Houghton, Michigan, United States.

3D printing is a novel fabrication technique for constructing structures with complex geometries and material characteristics. 3D printing of conductive structures could potentially create material systems with unique combination of properties including electrical conductivity, mechanical integrity, and electrochemical properties. Such unique properties render the structures excellent for applications such as micro-electronics, robotics, sensors, and actuators, etc. Carbon nanotubes (CNTs) are excellent candidates for filler in inks to be used in 3D printing of conductive structures. The high aspect ratio of 1D CNTs makes them superior to zero-D materials such as metal nanoparticles and 2D materials such as graphene in applications such as fibrous constructs or linear actuators. Here we report 3D printing of carbon nanotube-based inks into geometries not possible with methods other than 3D printing. Our fabrication process consists of preparing a printable mixture of a polymer such as polydimethylsiloxane (PDMS) or poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT) and CNTs by ultrasonication, and then printing in a medium such as gelatin. We report unique properties ranging from mechanical to electrochemical including stiffness, elasticity, and capacitance.

**CP06.04.17**

**Memristive Nanowire Neural Network for Neuromorphic Computing**

Nikita N. Gaur, Jack D. KendallIII, Suhas Kumar3 and Juan C. Nino3; ‘Rain Neuromorphics, Redwood City, California, United States; 2Hewlett-Packard Company, Palo Alto, California, United States; 3Department of Materials Science and Engineering, University of Florida, Gainesville, Florida, United States.

The traditional Von Neumann computing architecture is reaching fundamental limits in terms of energy efficiency and scalability, especially with increasing data-intensive applications. Hence, it is imperative to look for alternative computing paradigms with coellected computation and memory. One promising example is neuromorphic hardware. These architectures are inspired by the massively interconnected architecture of biological brains, and have so far demonstrated improvements in scalability, robustness, and computational efficiency over traditional architectures. Resistive memories such as memristors (RRAM) and PCRAM are well suited for the artificial synapses of neuromorphic architectures, since they are non-volatile and can store multiple resistance states, similar to biological synapses.

In this work, a novel neuromorphic architecture called the Memristive Nanowire Neural Network (MN3) is proposed.2,3 The MN3 consists of an array of neural nodes interconnected using a randomized network of memristive nanowires. Each nanowire comprises a conductive core, which transmits signals between neurons, and a memristive shell, which forms memristive synapses with the neural nodes in the array. The techniques for fabricating such an architecture have been demonstrated along with static and dynamical switching characteristics. Hafnium oxide (HfO2)-based RRAM memristors have been studied for this work. Detailed analysis using complementary techniques such as EDX, XPS, FE-SEM, and HR-TEM will be further presented to 1) understand how structural and microstructural properties are affected by the electrical characterization of such films and 2) identify important parameters to further improve the devices. Simulation results showing improvements in the scalability of the MN3 architecture over traditional crossbar architectures will also be presented.

**CP06.04.18**

**Defected-Activated Cobalt-Iron-Layered Double Hydroxide (Co-Fe LDHs) as Highly Efficient Electrocatalyst for Enhanced Oxygen Evolution Reaction**

Cui Ye; Zhejiang University of Technology, HangZhou, China.

Since the oxygen evolution catalysis process is vital yet arduous in the energy conversion and storage devices, engineering the earth-abundant nanomaterials with superior electro-catalytic activity remains desired and tough for effective oxygen evolution reaction (OER). Herein, we reports a prism-like cobalt-iron-layered double hydroxide (Co-Fe LDHs) utilizing a facile cation-exchange strategy accompanied with hierarchical nanoflake shell and well-defined interior cavity. Instead of the conventional LDHs commonly referred to as 3D printing, is a valuable manufacturing technique that allows for the creation of parts with inherent anisotropies. For the case of an MRE, FDM allows for the production of structures with tunable magnetic susceptibility along different axes. In these composites, the degree of particulate dispersion significantly affects the isoropy of material properties, which becomes increasingly important when small material volumes are used, such as in FDM. Incorporating solvent casting as a versatile method of producing polymer composites will allow for greater control over the particulate addition method, leading to a higher degree of dispersion when compared to a polymer melt. For our purposes, composite thin films were produced in order to examine effect of wet vs. dry addition of particulate on dispersion, while thicker samples were produced to study the porous structures obtainable by utilizing different drying methods. The solvent used in producing the PU composites was dimethylformamide (DMF). Preparation of polymer solutions included dissolution of PU in DMF to 20 w/v% followed by addition of the magnetic particulate. The particulates used were <150 µm iron powder and 2-4 µm magnetite powder. Composites solutions were made to concentrations of 20, 30, and 40 w/w% particulate to polymer by addition of either dry particulate or particulate pre-suspended in DMF. Drying conditions included room temperature air drying, or a dehydrator, or drying in a vacuum oven. Wet addition of magnetic particulate led to smaller clump sizes and improved dispersion, while dry addition led to larger clump sizes and poorer dispersion. All drying techniques prominently affected the degree of porosity in the resulting composite. Future inquiry will focus on the effects that the porosity of the composite, as a result of drying technique, has on further processing and manufacturing; ensuring that the effect of addition method on the dispersion of particulate in thicker samples is equivalent to that found in thin films; and understanding the impact that each of these factors will have on components manufactured by FDM.
both experimental and theoretical efforts are being directed to understand the gas-sensing properties of hydrogen (H2) gas on ZnO films. The theoretical study is based on a combination of density-functional theory (DFT) with non-equilibrium Green’s function (NEGF) formalism. A focus was given to assess the catalytic effects of noble metals versus other low-electronegativity transition metals (e.g., Au, Pt, Ag, Pd, and Fe) were put, separately, as ad-atoms on ZnO nano-ribbons (ZnO-NR) on the transport properties and thus gas-sensing. While the results are in favor of chemisorption to take place in all the instances of the studied catalysts, Pt and Pd in particular have shown more coordination with the ZnO bed (stronger binding energies). Consequently, they both enormously affect the density of states at Fermi level and yield the largest deviations in IV-curve, from before to after the landing of H2 molecule. In case of Pt catalyst, the sensor’s response is found to be the largest in detecting H2 gas molecule. Tests of chemisorption using Pt catalyst to other gases (e.g., O2, N2, CO2; and H2S) have confirmed its great selectivity toward the detection of H2 gas. The experimental findings are in excellent agreement with the theoretical predictions.

**CP06.04.20**

**Printing Direction Influence in Properties of Additively Manufactured Functional Ceramics**  
Luis Chavez1,2, Bethany R. Wilburn1,2, Luis C. Delfín1,2 and Yirong Lin1,2  
1 Department of Mechanical Engineering, The University of Texas at El Paso, El Paso, Texas, United States; 2 W. M. Keck Center for 3D Innovation, The University of Texas at El Paso, El Paso, Texas, United States.

An increasing trend in the use of “green” energy sources for electricity generation has been observed in recent years. Despite this, electricity generation continues to be highly dependent on fossil fuel energy sources all around the world. As a result, the efficiency of energy conversion systems is critical for low emissions. Meticulous monitoring of the operating conditions of these systems can aid in achieving higher efficiencies. Piezoelectric materials are great candidates for this type of application due to their pressure and temperature sensing capabilities as well as their ability to withstand harsh environments. Barium titanate, BaTiO3, is one of the most prominent piezoelectric ceramics. One of the main drawbacks of implementing piezoelectric ceramics in these systems is their geometry and size constraints. Current manufacturing methods of these ceramics do not allow for custom complex designs. A novel solution to this issue has been the implementation of additive manufacturing to fabricate piezoelectric ceramics with complex geometries. However, most of the recent efforts have yielded low density parts and therefore weak mechanical and electrical properties. The purpose of this research project was to fabricate BaTiO3 using an ExOne M-Lab binder jetting 3D printer to study its dielectric and piezoelectric properties as a function of the printing direction. The morphology of the samples as well as the dielectric and piezoelectric properties were characterized in the normal and parallel orientations to the printing direction. Samples achieved a density of 36.8% after sintering. Meanwhile, samples that were electroded in the parallel direction to the printing layers presented an average dielectric constant of 34.6% and a piezoelectric constant of 70.5% of the theoretical properties of BaTiO3. Additionally, improvements in dielectric and piezoelectric constants of 20% and 13.5%, respectively, were observed for the samples tested in the normal direction to the printing layers. These results show that despite low densities, ceramics with high piezoelectric coupling coefficients can be fabricated through binder jetting additive manufacturing. Further optimization in printing parameters and powder used for the fabrication must be performed to achieve higher densities in the final parts.

**A Solid-State Light Emitting Device with a Coplanar Structure**  
Yue Kuo; Texas A&M Univ, College Station, Texas, United States.

The solid state light emitting device (SSI-LED) was reported by the author's group recently (1). Upon the application of a gate voltage, the broad band warm white light is emitted from a large number of nano-sized conductive paths formed from the dielectric breakdown of a MOS capacitor on a p-type Si wafer. The light emission principle is the thermal excitation of the conductive path upon the passage of a current (2). In spite of the difference in gate dielectric materials and process conditions (3), all lights are emitted over the same visible to near IR wavelength range. The SSI-LED also shows unique electric characteristics similar to those of an antifuse or a diode (4). However, since all SSI-LEDs on the same substrate share the common ground electrode, the crosstalk is unavoidable, which is a potential problem in practical applications.

In this paper, a new coplanar structured SSI-LED is reported. Each device has its own gate and ground electrodes both of which are located on the same side of the substrate. Since devices can be isolated with LOCOS, trench, or other methods, there is no issue of crosstalks among different devices. The emission spectrum of the new device is the same as that of the device with gate and electrodes located on different sides of the substrate. The former has a higher intensity of the emitted light than the latter has due to the formation of more conductive paths. The structure of the new device and the pattern of the current flow will be used to explain the improvement of the light emission. Potential applications of the new device will also be examined.

Shumao Zhang is acknowledged for preparation and characterization of SSI-LEDs in this paper.

**Fabrication of Vanadium Dioxide Thin Films for Device Applications**  
Arun M. Umarij, Devanshi Bhardwaj and Inyalot J. Tadeo; Indian Institute of Science, Bengaluru, India.

VO2 being a transition metal oxide is the most fascinating material of research as it shows a semiconductor to metal transition (SMT) near to room temperature (T~68 °C). It undergoes a structural change from M1, monoclinic phase (Space group: P21/c) to R, tetragonal phase (Space group: P4/mmm). Due to this phase transition, it is used for various applications like smart windows, metamaterial, bolometers, etc. In here, we report the synthesis of device quality VO2 thin films. Various methods like home-built Ultrasonic Nebulised Spray Pyrolysis of Aqueous Combustion Mixture (UNSPACM), Chemical Vapor Deposition (CVD), Pulsed Laser Deposition (PLD) and DC Reactive sputtering have been employed for the synthesis of phase pure VO2 thin films. The structural characterization has been carried out by XRD and Raman measurements which confirms the M1 phase of VO2 at room temperature followed by high-temperature measurements to study the phase change. Temperature-dependent resistance measurements confirm the SMT transition at T~68 °C with a three-four order of magnitude change in resistance. Temperature-dependent IR measurements show ~80% change in reflectance across the phase transition where the thin film acts as an IR reflector (T~67°C). Effect of dopant (W, Mo, Sc, Ce etc.) has been studied where the T~SM was reduced to 25 °C with 2 at % W doping. Our preliminary attempts to make metamaterials will also be presented.

**Metal-Organic Framework Cu-BTC (HKUST-1) in Poly(L-lactide) for Synergetic Effects of Nucleating Agents, Reinforcement and Toughening Resulting in Surprising Shape Memory Effects**  
Hamideh Rezvani Alanagh1,2, Babak Akbari1 and Dinamjan Pun1; 1 Department of Life Science Engineering, Faculty of New Sciences and Technologies, University of Tehran, Tehran, Iran (the Islamic Republic of); 2 Department of Bioengineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Composite films exhibiting remarkable shape memory effects are prepared via solution casting of Metal-Organic Framework, Cu-BTC (HKUST-1) in poly(L-lactide) (PLLA)
Optically Switchable Photoelectron Injection from Perovskite Nanorods for Wavelength-Distinguishable UV Photodetector

To the best of our knowledge, this work is the first one to explore the MOF induced shape memory effect in polymers. It is found that HKUST-1 is acting as a nucleating agent to trigger the crystallization of PLLA for ensuring the entropy needed for the shape memory behavior; this results in recovery ratio, and fixity ratio to be about 100 %, and 95%, respectively with 5% Mwt filler in elongation of 25%. Aspirin encapsulated in HKUST-1 reinforced PLLA is investigated to clarify the mechanism, and concluded that the supposed existing Metal–ligand coordinations are not the reason in fixing and releasing the temporary shape, instead having the transition of elastic to rubbery state in vicinity of cold crystallization temperature in semi-crystalline polymer provides HKUST-1 to act as a physical cross linking or netpoints. Moreover, the reinforcement accompanied by increased toughness resulting from HKUST-1 offering a great combination of features which demonstrates the fact that how exciting features can be obtained with simply using a piece of reticular chemistry.

CP06.04.24

Optically Switchable Photoelectron Injection from Perovskite Nanorods for Wavelength-Distinguishable UV Photodetector

Due to their hybrid inorganic–organic nature, MOFs possess attractive characteristics that are absent from purely inorganic or organic systems, the organic parts allow them to interact chemically with polymeric chains to ensure chemical nucleation. Moreover, MOFs can exhibit, for example, higher surface areas while maintaining a degree of mechanical flexibility that is largely inaccessible to inorganic materials which can lead to enhanced nucleation of small polymer crystals.

Ultrafast (UV) radiation has given rise to high-speed, wide-cover and non-line-of-site wireless optical communications due to its small susceptibility to solar background interference and flexibility of transmitter/receiver orientations such as pointing, acquisition and tracking. For a wireless UV communication, function generator produces pattern-controlled electrical signals that contain characteristic information on the intensity and on-off frequency of UV lights, which are emitted by transmitter and subsequently detected by receiver to realize the relay of information. Moreover, UV radiations with different wavelengths are employed in communication systems so as to enable bidirectional and high-capacity optical transmission, where large distinction between UV wavelengths is demanded for minimized inter-channel interference. Therefore, developing a photodetector that can accurately identify UV intensity variation, while simultaneously distinguishing UV photons in different wavelengths is highly desirable for acquiring and decoding the information embedded in UV carriers. Owing to the suitable bandgaps and superior charge transport properties, lead halide perovskites (e.g. MAPbCl\(_3\), CsPbCl\(_3\), FAPbI\(_3\)) have realized high-performance UV photodetectors. Nonetheless, such photodetectors were never able to differentiate UV photons with different energies due to indiscriminate, unidirectional transport of photogenerated charge carriers in 1) prototypical p-i-n photodiode structures, 2) lateral photoconductor structures with external voltage biases, and 3) devices utilizing metal electrodes with much discrepant work functions for guided carrier migration. In addition, photodetectors need to be sufficiently sensitive to accurately detect UV photons with temporally varying flux based on superior photoelectronic properties (e.g. large free carrier density, high mobility), since optical information can also be ciphered in the oscillating intensities. As such, it is intriguing both at scientific and technological levels to develop UV photodetector that permits multidirectional carrier transport in perovskite materials with radically improved optoelectronic properties, so as to observe perturbed photocurrent responses and to eventually elucidate the energies and intensities of UV photons. Here, with the presence of LiCl additive in formamidinium chloride (FACI) solution, as-grown LiCl:FAPbCl\(_3\) nanorods demonstrated greatly enhanced crystallinity and UV photoresponse as compared to pristine FAPbCl\(_3\) nonastructure without LiCl additive. Most importantly, LiCl:FAPbCl\(_3\) nanorod film exhibits unprecedented distinguishability to UV lights with different energies and oscillating intensities, via unpolar/bipolar and periodically oscillating photocurrents. This work could advance the fundamental understanding of photoinduced carrier processes in halide perovskites and facilitate the development of novel UV-based optical communications.
piezoelectric materials with better properties. More recently, within the context of microscale devices such as Smart MEMS, self-powered sensors, microbatteries, and energy harvesting devices, there is a growing interest in developing “thin-film” piezoelectric materials. While, advances in microfabrication technology have greatly helped the synthesis and fabrication of piezoelectric thin films and structures, there is a continuing need to develop small-scale test methods to characterize the properties of such thin film piezoelectric materials. While nano-indentation-based methods of property determination have been demonstrated to provide useful information about the mechanical properties – elastic, plastic, hard, and fracture properties, of metallic materials in the thin film form, relatively fewer efforts have focused on developing the nanoindentation (or indentation) technique for understanding the electromechanical properties of thin-film piezoelectric materials.

The objectives of the present work are: (i) to obtain a comprehensive understanding of the indentation response of several classes of anisotropic piezoelectric materials; (ii) to elucidate the role of the indenter geometry and the indenter conductivity on the effective indentation response of anisotropic piezoelectric materials; (iii) to characterize the effects of electric fields on the indentation response of piezoelectric materials; (iv) to compare the indentation response of piezoelectric thin films with that of piezoelectric islands; (v) to differentiate between materials that are piezoelectrically active or passive, that is, polarized and unpoled, and those that are piezoelectrically strong and weak; and (vi) to identify the principal poling directions in active materials.

Three-dimensional finite element models are developed to accurately capture the force–depth and charge–depth nanoindentation response of several classes of anisotropic piezoelectric materials such as relaxor ferroelectrics for which analytical models are at present unavailable. Upon validating the finite element model for transversely isotropic materials and with experimental results, it is demonstrated that the nanoindentation response of anisotropic piezoelectric materials displays a strong dependence on the nature of the indenter geometry and relatively weak dependence on the indenter conductivity. Furthermore, by recourse to “longitudinal” and “transverse” indentations, the nanoindentation method can also be used to identify the poling directions in piezoelectric materials as well. It is also demonstrated that the indentation of piezoelectric materials which are subjected to electric fields can be used to uniquely identify the piezoelectric characteristics of thin films that exhibit in-plane poling as well.

Flexible and Light Weight CNT/Silk Foam for Strain Sensor with Superior Compressibility and Sensitivity

Flexible strain sensors have attracted attention in recent years for applications in diverse field starting from soft robotics to human-machine interfaces and wearable health monitoring devices. We engineered a novel, lightweight, flexible, porous architecture composed of carbon nanotubes (CNT) and silk which act as strain sensor. Such structures were fabricated using simple salt-leaching technique where the foam densities were varied from 0.06 to 0.14 gm cm$^{-3}$ by altering CNT and salt contents which eventually tunes the
porosity of the structure up to 60%. The study showed that during compression, cell wall of the foams start moving towards each other reducing the gap between cells and form new conduction path and hence the resistance of the structure reduces along the compression direction with the increasing strain. At 50% compressive strain the normalized stress of CNT/silk-based foams structures were ranged from 30 to 60 MPa gm cm
-2. The relative change in resistance of the structures with increasing strain (up to 50% strain) follows a linear characteristic which provides an additional advantage for its application as piezoresistive strain sensor. The foam with highest porosity (60% porosity) and lowest electrical conductivity showed extremely high piezoresistive sensitivity with tuneable gauge factor ~ 250% at 50% strain. The study also revealed that with the increase in CNT content, electrical conductivity increases whereas the gauge factor decreases. For compression over multiple cycles (> 200 cycles) the foam structures exhibited excellent stability and reversibility in terms of stress and resistance. The tuneable piezoresistive sensitivity and conductivity of the structures make them suitable candidate for the application as strain sensor in the field of soft robotics, flexible and wearable electronics etc.

High Energy Density Capabilities of Relaxor-Ferroelectric Thin Films Using Interlayer Coupling
Amrit Sharma, Bo Xiao, Sangram K. Pradhan and Messaoud Bahoua; Materials Science, Norfolk State University, Norfolk, Virginia, United States.

Relaxor-ferroelectric multilayer heterostructure provides a high electric displacement or charge density, a large area to store the energy and fast discharge capacity. We have grown lead-free BaZr0.2Ti0.2O3 (BZT)/BaCa2−xTixO3 (BCT) multilayer heterostructures and studied the structural, dielectric, ferroelectric and energy density characteristics. The BZT/BCT multilayer epitaxial heterostructures were grown on La0.68Sr0.32MnO3 (LSMO) buffered SrTiO3 (STO) single crystal substrate by optimized pulsed laser deposition parameters such as substrate temperature, oxygen pressure and film thickness. The large angle x-ray scans showed only diffraction peaks from the substrate and pseudocubic reflections (00l) from the multilayer heterostructure, confirming that these films are phase pure and epitaxial in nature. The atomic force microscopy (AFM) studies indicate that the surface roughness is low and that film growth is of high quality. The low leakage current confirms the films are highly insulating in nature which is the basic requirement for the dielectric energy storage. The ferroelectric phase transitions have been proved above room temperature with relaxor behavior. The polarization versus electric field (P-E) measurement exhibits single and well-saturated hysteresis loop with large polarization. The enhancement in polarization is due to a combination of space charge effect and interlayer charge coupling between two neighboring layers. Our lead-free relaxor-ferroelectric multilayer heterostructures exhibit good energy densities with better performance at low voltage above the room temperature which will be of great interest for researchers working on the physics and materials science.

or KNN) has gained humungous popularity in the recent years due to increased environmental concerns and measures taken towards restraining the dominant use of toxic lead-based materials such as PZT in sensors and actuators for industrial applications. KNN, being eco-friendly, is considered to be a potential replacement to PZT due to its high Curie temperature (\(\sim 400^\circ\text{C}\)) providing broad temperature range for operation, and high piezoelectric and ferroelectric properties. As per the reports, a ferroelectric material exhibits the optimum electrical and piezoelectric properties at compositions especially near their morphotropic phase boundaries, where two ferroelectric phases are believed to co-exist. In K

Dual Ion Beam Sputtered RRAMs Exhibiting Quantum Conductance
Armitesh Kumar, Mangal Das, Sanjay Kumar, Vivek Garg, Md Arif Khan, Abhinav Kranti and Shabdal Mukherjee; Indian Institute of Technology Indore, Indore, India.

We report forming-free (FF) resistive random access memory (RRAM) with high endurance and retention for ZnO based thin films fabricated by dual ion beam sputtering (DIBS). We report the effect of interface anomalies such as disorder-induced interface states, Schottky barrier formation/dissolution for a resistive switch or memristor. Distribution of bulk defects with applied bias governs switching and also attributes to formation/dissolution of interfacial oxide. Further, conductance quantization is observed in the device. Device shows excellent endurance and retention with forming-free behavior. Besides, conductive quantization as exhibited by device can be used to further work upon synaptic properties of device. The present work considerably contributes to further understand the conduction mechanisms of a wide range of resistive switches.

11:30 AM CP06.05.10
Micro-Plasma Based Enhancement in Dielectric and Piezoelectric Properties of ZnO Based Multifunctional Composite Thin Films by Surface Modification—Towards Applications in Touch Based Sensors and Wearable Devices
Siddharth Mageshkumar1, Harlavpreet Brar2, Mia Bentzen2, Walker Tuft1, Saqib Ahmed2 and Sonika Baniaerjee1; 1Mechanical Engineering, California State University, Fresno, Fresno, California, United States; 2Mechanical Engineering, Buffalo State College, Buffalo, New York, United States.

Atmospheric pressure and ambient temperature based micro-plasmas have been used in polarization and alignment of dipoles in ferroelectrics. The same phenomenon can be used to enhance the surface energy and surface characteristics of composite multifunctional thin films by means of surface modification. A significant increase in non-thermal atmospheric plasma applications, such as dielectric barrier discharge (DBD) and corona discharge plasmas have been steadily increasing in industry and in the research literature. The current work involves the use of corona micro-discharge for surface modification of ZnO/ZrO nanowire-Epoxy-Graphene based multi-functional and flexible thin film devices towards enhancement in surface bonding characteristics and variation in surface wettability and surface energy characteristics. The parameters being investigated in the experiments include plasma device characteristics such as voltage, current, and frequency, as well as other significant parameters such as displacement between thin film and DBD/Corona discharge source, treatment time, and temperature of the plasma. The modified surface micro-structure is analyzed using a scanning electron microscope, profilometry, impedance spectroscopy and the bulk electrical, dielectric, and piezoelectric properties are characterized using impedance spectroscopy and piezoelectric strain coefficient measurements.
continuously being proposed and executed to reverse the trends of obesity prevalence. These efforts are often led by non-profit organizations, school administrator, university researchers, state agencies as well as federal agencies. For a long time the monitoring tool available to the population at large has been the low-cost weighing scale and only recently, as wearable electronics are becoming more widespread, new tools such as step and calorie counters are becoming available but remain expensive. This work provides insights on how novel breath-gas sensors and skin wearable sensor nanotechnology may be used for monitoring the metabolic rate patterns of individuals in relation to their diet and exercise activities. It also addresses the need for human-computer interface systems that treat social network-based support groups as learning organizations. The latter can interface with the metabolic rate monitors to effectively promote positive health behavior. The synergy of the two technologies is expected to revolutionize personalized medicine and to radically improve health and well-being practices.

Hybrid Wearable Devices for Non-Invasive Real-Time Monitoring of Blood Glucose—Optimization of Process Parameters by Analysis of Data Sets from Impedance Spectroscopy and Photoacoustic Measurements Aided with Artificial Intelligence

Chaitanya Sreenivas¹, Mohamed Muthana¹, Jodi Bishop², Soumyasanta Lahaj¹, Shaestagir Chowdhury¹, Saquib Ahmed¹ and Sankha Banerjee¹; ¹Mechanical Engineering, California State University, Fresno, Fresno, California, United States; ²Electrical and Computer Engineering, California State University, Los Angeles, Los Angeles, United States; ³Mechanical Engineering, Portland State University, Portland, Oregon, United States; 4Mechanical Engineering, Buffalo State College, Buffalo, New York, United States.

Diabetes is a chronic disease that affects a large part of the population in the United States and around the world. Real-time monitoring of blood glucose can detect early signs of diabetes by diagnosis conditions such as impaired glucose tolerance. A wide range of analytical methods and techniques are being studied for non-invasive and real-time testing/monitoring of blood glucose. These techniques include Optical Spectroscopy, Raman Spectroscopy, Photoacoustic Spectroscopy, Impedance Spectroscopy and Microwave based measurement methods among others. The following work deals with the analysis of a proof of concept hybrid monitoring system using a combination of optical and non-optical techniques such as Photoacoustic Spectroscopy and Impedance Spectroscopy. Data sets from the two methods are analyzed base on process parameters such as optical absorption, thermal expansion, acoustic velocity, specific heat, dielectric, and impedance characteristics. A system architecture based on multi-sensor and multivariable optimization is proposed. Further, to make it adaptive to different practical situations, AI or machine learning algorithms are to be investigated and implemented for reliability.

2:15 PM CP06.06.03
Development of Breathable, Self-Sealing Hazmat Suit Material for Chemically Hazardous Environments Kenneth C. Manning¹, Akshay Phadnis¹, Timothy P. Burgin² and Konrad Rykaczewski¹; ¹School for Engineering of Matter, Transport and Energy, Arizona State University, Tempe, Arizona, United States; ²School of Molecular Sciences, Arizona State University, Tempe, Arizona, United States.

The impermeability of current hazmat suits restricts the thermoregulation of the user by blocking the water vapor, which can be fatal when used over a relatively short period of time (~30 minutes) in absence of auxiliary cooling systems. Here, we develop a smart hazmat suit material based off stimuli responsive polymers that selectively swell upon action of hazardous chemical aerosols. Specifically, we develop a breathable, composite fabric that allows for perspiration cooling until they are exposed to a target range of hazardous chemicals. Once exposed, the polymer rapidly swells to close pores in the fabric turning into an impermeable membrane. Consequently, thermal stresses on the user are minimized by occurring only during actual exposure to hazardous materials. To achieve this, we develop a selectively swelling polymer, poly(N,N-butylenediamine), and integrate it with typical fabrics used in MOPP gear to create the adaptive, smart composite materials. We demonstrate the selective permeability of this smart composite fabric through a series of vapor transmission and droplet impingement experiments where we show that the fabric is permeable to water vapor but blocks droplets of target chemicals by swelling. We quantify the efficacy of this fabric in terms of response time and chemical containment. The response time largely depends upon the chemical permeation properties and polymer particle size/shape and varies inversely with it. Additionally, we develop a high-fidelity numerical model to capture the transient dynamics and optimize the polymer shape and size. Specifically, we develop a finite element model to describe aerosol droplet-polymer interactions and polymer swelling kinematics. This model is based on implementation of concurrent fluid permeation and large deformation theory combined with constitutive relation based on Flory-Rehner theory. In combination with the experimental data, we use this model to optimize the fabric design for maximum breathability while retaining the required protection levels for the user.

Bioinspirational Principles for Design of Smart Biointerfaces for Regenerative Medicine and Cancer Metastasis Models Kahtana Katti1, 2, 3, Sumanta Kar1, 2, 3, MD Shahjahman Molla1, 2, 3, and Dinesh R. Katti1, 2, 3; 1Civil and Environmental Engineering, North Dakota State University, Fargo, North Dakota, United States; 2Center for Engineered Cancer Testbeds, North Dakota State University, Fargo, North Dakota, United States; 3Materials and Nanotechnology, Biomedical Engineering, North Dakota State University, Fargo, North Dakota, United States.

Biointerfaces of biological and engineered surfaces are relevant for many applications in biomedical, energy and structural applications. Tissue engineering is a promising technology for regenerating tissues and organs. The degrading scaffold in close molecular proximity of growing tissues represents a dynamic and intelligent interface that is controlled by genetic characteristics of cells as well as the physical and chemical characteristics of degrading scaffolds. We describe the use of a biomimetic mineralization process of mineralizing hydroxyapatite inside amino acid modified nanoclay for design of biomimetic and smart scaffolds for bone tissue engineering. The nanoclay scaffold enables growth proliferation and differentiation of human mesenchymal stem cells to generate tissue engineered bone with structural hierarchy characteristic of human bone, as well as the Ca/P stoichiometry characteristic of new amelodonic bone. This type of bone is typically the niche to which prostate and breast cancer cells migrate to from their original location in a process called metastasis. At this point of bone metastasis, the prognosis is usually dismal for the patients and metastasis is the cause for most cancer deaths. We report the use of the smart scaffold to generate the first in vitro model of human prostate and breast cancer bone metastasis. The tumors at the metastasis site are investigated for gene expression that indicates that indeed the cancer is in late stage metastasis (also known as the mesenchymal to epithelial transition or MET). We report the use of FTIR and nanomechanics to capture disease progression at metastasis. The significance of the use of the scaffolds as cancer testbeds lies in the fact that human samples are unavailable and animal models fail, due to death of animal before metastasis to bone. Engineered biointerfaces of the smart scaffolds are thus the key to development of therapies advanced stages of metastasis.

4:00 PM CP06.07.02
Bioinspired Design Strategies for Nanostructured Materials Mingsheng Dua1, 2; 1Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2School of Biological Sciences, Nanyang Technological University, Singapore, Singapore.

Reducing microstructure dimensions down to the nanoscale can significantly improve the material strength. However, this is often accompanied by lower ductility, reduced fracture toughness and/or smaller fatigue crack growth resistance. There have been a number of successful strategies for achieving all-around superior mechanical properties, including the introduction of growth or deformation nanotwins, microstructure/nanostructure gradation, and various bioinspired strategies. Here a number of bioinspired nanostructure design strategies are proposed and discussed. One particular strategy is inspired by the exceptionally strong and ductile structure of byssal threads found in certain mussels. The excellent mechanical properties are shown to be
realized by structurally introducing sandwich structures at both the macro- and nano-scales. On the other hand, nanoscale heterogeneity of bone has been identified to enhance inelastic energy dissipation. Experiments and simulations have been carried out to quantify the size-dependent heterogeneity, and understand the relative importance of elastic and inelastic heterogeneity. Parameters that affect energy dissipation are investigated under typical deformation modes of bone, and possible routes to enhance this effect are discussed. Additional bioinspired microstructural design strategies are also discussed, including geometrically interlocking interface for enhanced strength as well as elastically mismatching surface layers for delayed catastrophic structure failure.

Additional safety factors for delayed catastrophic structure failure.

4:15 PM CP06.07.03
Electrochemically-Driven Transport for Room-Temperature Healing of Metallic Cellular Materials with Synthetic Vascular Systems

Numerous biological materials regenerate and self-heal in response to damage which allows them to strengthen areas under high mechanical stress and maintain their load-bearing capabilities for many decades. In bone, self-healing is enabled by the transport of nutrients and minerals through a vascular system embedded within a load-bearing cellular structure. In contrast, most human-made structural materials cannot autonomously heal or tune their mechanical strength. As a result, structures are designed with safety factors so that the strength of their constitutive materials is well above any stress they are expected to endure. Hence, not only are most human-made structures heavier and more voluminous than strictly necessary, but they also require regular monitoring and maintenance to guard against fatigue cracking, particularly in critical applications (aerospace vehicles and power plants, for example).

Self-healing materials have been developed to overcome the deficiencies of structural materials, but mostly rely on a “local healing” approach where the healing agent is available throughout the material so that cracks heal using material in the crack vicinity. Although successfully demonstrated in polymers, this method has proven impractical in metals without the external provision of heat, since metal atoms possess low diffusivities near room temperature.

Here, we overcome these limitations and report, for the first time, rapid and effective self-healing of metallic cellular materials at room temperature using electrochemistry as a method, and the structure of bones and their self-healing processes as an inspiration. In contrast to previous techniques, electrochemically-driven healing relies on the transport of metal as an ion through an electrolyte, which allows faster transport, as metal ion diffusivities in a room temperature electrolyte (~10^{-5} m^2/s) are at least three orders of magnitude greater than metal atom diffusivities in a room temperature solid. Consequently, our self-healing technique uses at least three orders of magnitude less energy to heal a crack of a given length compared to techniques which rely on heat-driven diffusion or precipitation in metallic alloys. We use tensile testing of dog-bone shaped open-cell nickel foams coated with a passivating layer, followed by electrochemical healing to understand the relationship between material structure and healing capabilities. Our nickel open-cell foams show full recovery of tensile strength and toughness using an external nickel source during healing. The use of a passivating polymer coating on the nickel foams improves the probability of achieving full recovery of tensile strength compared to uncoated nickel foams. Moreover, we show that by varying the maximum strain of the passivating coating, self-healing metals with three distinct functionalities can be achieved: materials that increase their local stiffness before failure, materials that heal microscale cracks and materials that only heal macroscale cracks above a threshold size. Finally, we design a nickel foam composite which uses an electrolyte embedded within a internal synthetic vascular system to redistribute load-bearing nickel to damaged areas and recover lost mechanical strength. Pathways for enabling a truly autonomous self-healing metallic material are discussed.

4:30 PM CP06.07.04
Catalytic Mechanism of Biomaterials in Cartilage—A Bottom-Up Computational Investigation of the Aggrecan Cleavage Site
Deng Li and Shu-Wei Chang; Department of Civil Engineering, National Taiwan University, Taipei, Taiwan.

Cartilage is an important smart material which provides crucial mechanical properties for our body. Many diseases are associated with abnormal aggrecan degradation in articular cartilage. Aggrecan degradations are mainly controlled by matrix metalloproteinase-8 (MMP9). MMP8 cleaves at the catalytic cleavage site of Glu373-374Ala in the aggrecan core protein, with another potential cleavage site at Glu419-420Ala, however, left uncut. The catalytic mechanism of how the MMP8 recognizes the catalytic cleavage site has not yet been revealed. Understanding how nature design materials to be degraded at only specific regions can enable the design of new synthetic smart materials for many engineering applications.

To investigate this, we use a bottom-up computational mechanics approach to explore this conundrum. We found that the two key residues in the vicinity of the catalytic site, arginine in P2' and glycine in P3' play an important role in forming a stable binding pose of MMP8-Actual_peptide complex. For the potential cleavage site, the arginine is replaced with Threonine and the glycine is replaced with arginine, resulting in the unstable binding pose of MMP8-Potential_peptide complex. Our results suggest that MMP8 is able to recognize the molecular structure of the catalytic cleavage site and only cleave Glu373-374Ala in the aggrecan core protein. By calculating the binding affinity between MMP8 and aggrecan core protein, we find that the binding energy of MMP8-Actual_peptide complex is higher than the binding energy of MMP8-Potential_peptide complex. We hypothesize that the stable binding structure of the catalytic cleavage site of aggrecan core protein makes MMP8 stay in an “active” state, and then hydrolyze the scissile bond of aggrecan core protein. On the contrary, unstable binding between the potential cleavage site of aggrecan core protein and MMP8 makes MMP8 stay in an “inactive” state. Our results provide fundamental insights into the catalytic mechanism of biomaterials in cartilage at the molecular and nanoscale level.

4:45 PM CP06.07.05
Contribution of Biomimetics and Simulation to the Development of 4D Printed Hydrogels
Daniela Ribeiro and Silvia L. Titotto; CECS, Universidade Federal do ABC, Santo André, Brazil.

Cartilage problems are becoming more frequent due to some factors such as population aging. Using biomimetics to understand how to minimize this problem, a biomaterial very sensitive to external stimuli has been studied as a possible substitute for worn cartilages: hydrogel, a biocompatible polymer. Thus, in order to create a basis for the feasibility of the application of this material, it is necessary to know different types of hydrogels, for instance, Poly (acrylic acid) and Polyethylene glycol, and to understand how they behave under external variations, such as pH and temperature. Accordingly, the work presented was based on recent bibliographical studies accessed mainly via Science Direct, Scientific Reports and Research Gate, for collecting fundamental information of this subject with the objective of producing visual simulation results via SolidWorks / Flow Simulation. Furthermore, the work will present objects composed of hydrogel printed in different formats by an experimental 4D printer developed at Federal University of ABC in collaboration with our research group 4DB. Moreover, it will be demonstrated how those printed objects behave in relation to external stimuli. It is hoped that the dissemination of the partial results of this ongoing research will contribute to the advancement of the subject in the interdisciplinary scientific community.

SESSION CP06.08: Smart Approaches to Modeling and Simulation

A Multiscale Modelling Strategy to Predict Precipitate Stability, Nucleation and Growth in Metallic Alloys
Hong Liu1, Ioannis Papadimitriou2, Bárbara Bellón2,1, F. X. Lin1 and Javier Llorca1; 1Technical University of Madrid, Madrid, Spain; 2IMDEA Materials Institute, Getafe, Madrid, Spain; 3KU Leuven, Leuven, Belgium; 4UC Louvain, Louvain, Belgium.

Precipitation hardening is one of the most efficient mechanisms to increase the yield strength of metallic alloys but accurate quantitative models to predict the size, shape and spatial distribution of precipitates during high temperature ageing are still lacking. In this presentation, a multiscale modelling strategy is presented to determine the precipitate stability as a function of temperature, the process of homogeneous and heterogeneous nucleation and growth of precipitates. Precipitate stability is assessed from the calculation of
the free formation energy obtained from first principles calculations of the formation enthalpy at 0K together with the vibrational entropy contribution. Homogeneous and heterogeneous (on dislocations or other precipitates) precipitate nucleation is analysed by means of classical nucleation theory in which the different contributions to the Gibbs free energy (chemical interfacial and elastic) are determined from computational thermodynamics, first principles calculations and geometric considerations of the lattice distortion, respectively. Finally, precipitate growth up to the equilibrium shape was also determined by means of mesoscopic phase-field model.

The strategy was applied to analyse precipitation in Al-Cu alloys at high temperature, a regime in which three different kinds of precipitates can be found (8º, 9º and 0º). The results of the multiscale modelling strategy were in good agreement with the experimental data and it is envisaged that the strategy presented in this investigation can be used in the future to design optimum microstructures based on the information of the different energy contributions obtained from first principles calculations.

9:00 AM CP06.08.02

The fundamental understanding of the structure – property relationships of SMART materials at the atomistic level is a critical step towards rational design for targeted applications. On the experimental side, X-ray absorption spectroscopy (XAS) is a premier element-specific technique for materials characterization. Specifically, X-ray absorption near edge structure (XANES) carries rich local structural and chemical information around X-ray absorbing species, which makes it a powerful tool to probe materials structure and dynamic processes. As such, unraveling the local chemical environment from XAS spectra is akin to solving a challenging inverse problem. Because the structure - spectrum relationship is obscure, solving the inverse problem often requires prior empirical knowledge, which is qualitative or semi-quantitative and not transferable. Here we show how data science can be combined with first-principles theory to decipher the structure-spectrum relationship from XANES, with only a small amount of experimental data typically available for training. Such an approach can be applied in multiple contexts, including prediction of the 3D structures of metal nanoparticles using machine learning, local structure refinement of amorphous materials from a XANES database, and local chemical environment classification using XANES database and machine learning methods.

9:30 AM CP06.08.03
First-Principles Study of Doping Effects on Transformation Temperatures in Ni-Mn-Ga Magnetic Shape Memory Alloys Martin Zelený 1, 2, Jozef Janovec 1, Alexei Sozinov 1, Ladislav Straka 1, Torbjørn Björkman 2, Risto M. Nieminen 2 and Oleg Heezho 1, 2; 1 Institute of Physics of Charles University, Faculty of Mathematics and Physics, Charles University, Prague, Czechia; 2 Institute of Materials Science and Engineering, Faculty of Mechanical Engineering, Brno University of Technology, Brno, Czechia; 3 Material Physics Laboratory, Lappeenranta University of Technology, Savonlinna, Finland; 4 Institute of Physics, Czech Academy of Sciences, Prague, Czechia; 5 Physics/Department of Natural Sciences, Åbo Akademi University, Turku, Finland; 6 COMP/Department of Applied Physics, Aalto University School of Science, Aalto, Finland.

The influence of Co, Cu, Zn and Cd doping on Ni-Mn-Ga Heusler alloy exhibiting magnetic shape memory behavior is investigated using the first-principles exact muffin-tin orbital method in combination with the coherent potential approximation. The control of material properties relative to structural and magnetic phase transitions, especially martensitic transformation temperature $T_M$ and Curie temperature $T_C$, is important for potential engineering applications in actuators, sensors, vibrational energy harvesters, or magnetic refrigeration systems. The energy difference between the austenite and the nonmodulated martensite phase $\Delta E_{AM}$ obtained from first-principles calculations can be used as a qualitative indicator of $T_M$ whereas the energy difference between paramagnetic and ferromagnetic state $\Delta E_{PM-FM}$ serves for prediction of $T_C$. In addition, reducing of equilibrium tetragonality of nonmodulated martensite $(c/a)_{NM}$ allows higher mobility of martensitic twins due to lower twinning stress, which further improve magnetic shape memory properties.

For Cu doping of a Ga-deficient alloy, we have found a strong increase in $\Delta E_{AM}$ but just a small change of equilibrium $(c/a)_{NM} = \Delta E_{PM-FM}$ decreases in martensite phase and remains almost unchanged in austenite phase. If, on the other hand, Cu is instead doped at Mn sites, the increase of $\Delta E_{AM}$ is much smaller and a slight decrease of $(c/a)_{NM}$ is seen. $\Delta E_{PM-FM}$ strongly decreases in both phases with increasing concentration of Cu. Co doping at Ni sites has much stronger effects, with increasing concentration of Co strongly decreasing both $\Delta E_{AM}$ and $(c/a)_{NM}$. These theoretical results are in good agreement with previous experimental findings that Cu doped in the Ga or Mn sublattice increases the martensitic transformation temperature $T_M$ and Co in the Ni sublattice decreases it. Our results for Cu and Co doping also correspond to an empirical rule that $T_M$ is correlated with the number of valence electrons per atom, $\bar{a}$, in the alloy. According to this rule Zn and Cd with more valence electron than Cu should provide stronger increase of $T_M$ as well as $\Delta E_{AM}$ if these elements are used for doping instead of Ga or Mn. However, our results show that doping Zn or Cd in Ga-sublattice will results in the increase of $T_M$ but weaker compared to Cu doping. $T_C$ seems to be affected only weakly. The substitution of Mn atoms causes the decrease of both $T_M$ and $T_C$. Thus, in contrast to Cu doping the calculation did not support the validity of the $T_M \sim \bar{a}$ rule for Zn and Cd doping.

We have also investigated alloys where both elements Cu and Co were used in simultaneous doping. Our results show that the effects of simultaneous doping can be estimated using a linear superposition of the effects of individual dopants. This can be used for effective tuning of material properties; in particular, the decreasing of $\Delta E_{AM}$ (and $T_M$) arising from Co doping can be compensated by Cu doping at Ga sites. Moreover, the reduction of $(c/a)_{NM}$ due to the Co doping is preserved because the Cu doping has just a small effect on this quantity.

9:45 AM CP06.08.04
Analysis of Conducting Filaments in HfO2 Memristors Darshan G. Pahinkar and Samuel Graham; Georgia Institute of Technology, Atlanta, Georgia, United States.

Field effect transistors (FETs) with their Boolean operation have been the fundamental building block of digital computers. While this digital framework is excellent at performing complex arithmetic and logic calculations, it lags far behind the human brain in key areas such as adaptivity, generalization, and pattern recognition. Furthermore, as the size of these transistors is reduced, energy consumption and heat removal become a critical issue. Therefore, alternative technology initiatives such as analog switching are being explored. Neuromorphic computing using nanoscale adaptive oxide devices or memristors is a very promising alternative to this framework. Oxides of transition metals such as hafnium (HfO2) are proven to be excellent candidate materials for these devices, which show non-volatile memory and analog switching, while using only two terminals, instead of three as in case of standard FETs. These devices are simple in terms of arrangement, wherein a few nanometers thick HfO2 and an Hf metal layer are deposited between two electrodes on a substrate.

The naturally occurring HfO2 has insulating properties. When it is applied with a voltage bias, Hf and O atoms dissociate, creating positively charged oxygen vacancies. While negatively charged oxygen ions migrate toward positively charged electrode and are temporarily stored in the adjacent pure Hf layer, a conducting filament of positively charged vacancies forms, which facilitates the flow of electrons through it. This is known as the on-state of the device or ‘set stage’. When the polarity reverses, oxygen ions move back into the oxide layers neutralizing the positively charged vacancies, thereby gradually creating insulating layers of HfO2. As these layers are created, current flow through the device is drastically reduced and eventually an off-state is said to have occurred. This suppression of conducting filament is known as the reset stage. The extent of set/reset through applying alternate positive/negative voltage is temperature dependent transient process and is not completely characterized. Comprehensive understanding of coupled electrical current, ion/vacancy movement and heat transfer is essential to achieve the reliable and repeatable analog switching of this material.

This work focuses on the computational and experimental investigation of local and temporal variation of voltage, current and temperature, so that the coupled nature of heat transfer and current flow through these devices could be analyzed. By simulating the coupled heat transfer, current flow and vacancy/ion movement in COMSOL Multiphysics, the effect of substrate thickness and materials, set/reset voltages on relative on-state/off-state resistances, current magnitude and filament temperature is determined. Simultaneously, temperature of these devices is measured as a function of current and voltage using Micron capable transient temperature imaging (TTI) technique. The data from these experiments are used to develop useful information about the internal states of the devices. When the model results in terms of temperature and current history match well with those from the experiments, the COMSOL models are validated. Overall, coupled electrical current and heat transfer modeling and simultaneous measurements of current, voltage and temperature are expected to provide insightful information on switching mechanisms of these adaptive oxides and warrant their scaled-up implementation for neuromorphic computing.

10:00 AM BREAK
Three-Dimensional Strain Engineering in Epitaxial Vertically Aligned Nanocomposite Thin Films with Tunable Magnetotransport Properties

Xing Sun; Purdue University, West Lafayette, Indiana, United States.

A novel concept of integrating a three dimensional (3D) strain scheme in epitaxial thin films is present in this work by combining 2-phase vertically aligned nanocomposite (VAN) with thin interlayers for an effective coupling of the vertical and the lateral interface strain. This 3D strain scheme takes advantages of both architectures and promotes various strain-driven physical properties, e.g., record high magnetoresistance values (MR%) as low field magnetoresistance properties have been demonstrated in the LSMO-CeO2 interfingered with different numbers of CeO2 interlayers. This work brings a new approach to achieve highly strained films beyond the critical thickness in epitaxial thin films and to demonstrate enhanced vertical strain coupling by the 3D strain scheme. This demonstration not only shows the power of 3D strain scheme in strain engineering, multifunctionality coupling, and flexibility in structural designs, but also fulfills the urgent demands of new material designs for future electronic devices.

Single Nanoparticle Electrochromism Reveals Heterogeneous Coloration Rates and Ion Trapping Sites in Smart Windows

Justin Sambur and Russel C. Evans; Colorado State University, Fort Collins, Colorado, United States.

Developing large area electrochromic smart windows based on nanoscale materials demands that trillions of nanoparticles modulate between transparent and colored states at the same rate. However, it is unclear how nanoparticle heterogeneity contributes to variable coloration dynamics. Here we demonstrate a single nanoparticle electrochromism approach to study optical modulation rates upon lithiation of isolated, clustered, and thin film tungsten oxide nanorod electrodes. We observe a particle-dependent waiting time for coloration (from 100 ms to 1 s) due to Li-ion insertion at optically inactive surface sites. Longer nanorods achieve higher OD modulation than shorter nanorods because they develop a Li-ion gradient that increases from the nanorod ends to the middle. Interestingly, electrochromic irreversibility increases monotonically with the number of particle-interactions due to ion trapping at nanoparticle interfaces. These findings lead us to propose a nanostructured electrode architecture that optimizes coloration magnitude, rate, and reversibility across large area electrochromic smart windows.

Giant Magnetostriction and Low Loss in FeGa/NiFe Laminates for Strain-Mediated Multiferroic Micro-Antenna Applications

Kevin Fitzell; Joseph D. Schneider; JinZhao Hu; Zhi Yao; Collin R. Rementer; Nishanth Virshubados; Michelle Jamer; Cunzheng Dong; Anthony Barra; Daniel Gopman; Nian Sun; Julie Borchers; Brian Kirby; Yuanxun Wang; Rashanda Henderson; Abdon Sepulveda; Gregory Carman and Jane Chang; Chemical and Biomolecular Engineering, University of California, Los Angeles, Los Angeles, California, United States; Mechanical and Aerospace Engineering, University of California, Los Angeles, Los Angeles, California, California, United States; Electrical and Computer Engineering, University of California, Los Angeles, Los Angeles, California, United States; Electrical and Computer Engineering, University of California, Los Angeles, Los Angeles, California, United States; Electrical and Computer Engineering, Northeastern University, Boston, Massachusetts, United States; Material Measurement Laboratory, National Institute of Standards and Technology, Gaithersburg, Maryland, United States; Electrical and Computer Engineering, Northeastern University, Boston, Massachusetts, United States; Electrical and Computer Engineering, Northeastern University, Boston, Massachusetts, United States; Electrical and Computer Engineering, Northeastern University, Boston, Massachusetts, United States.

The ability to reduce the size of antenna elements would enable a revolution in wearable and implantable devices. Multiferroic antennae, composed of individual ferromagnetic and piezoelectric phases, are posed to reduce antenna size by up to 5 orders of magnitude through the efficient coupling of magnetization and electric polarization via strain. However, this strategy requires a low-loss magnetic material with strong magnetoelastic coupling at high frequency.

Galfenol (FeGaNi or FeGa) is a promising candidate material due to its large magnetostriction (>200 ppm), large piezomagnetic coefficient (>3 ppm/Oe), and high stiffness (>50 GPa), but it is highly lossy in the GHz regime. On the other hand, permalloy (Ni$_8$Fe$_2$ or NiFe) is a soft magnetic material that has very low loss in the GHz regime (ferromagnetic resonance linewidth <20 Oe) but almost no magnetostriction. In this work, nanoscale laminates containing alternating layers of FeGa and NiFe were fabricated via DC magnetron sputtering to combine their complementary properties, yielding a small coercive field (<20 Oe), narrow FMR linewidth (<40 Oe), and high relative permeability (>700) (Rementer et al., 2017). These magnetic laminates were then grown on PMN-PT substrates and studied via polarized neutron reflectometry, demonstrating coherent rotation of the individual layers' magnetization with an applied electric field, supported by micromagnetic and finite element simulations (Jamer et al., 2018).

In addition, optical magnetostriction measurements confirmed the presence of greatly enhanced magnetostriction relative to single-phase FeGa; these laminates represent a threefold increase in magnetostriction at saturation (~700 ppm) and an enhanced sensitivity at low bias magnetic fields (25 ppm/Oe). This enhancement in magnetoelasticity relative to single-phase FeGa was correlated to the microstructure of these composites using TEM. Recent efforts have further enhanced the high-frequency properties of these composites through insertion of ultrathin Al$_2$O$_3$ layers to reduce the conductivity and mitigate eddy current losses, and subsequent integration of these laminates into a strain-multiferroic shear wave antenna successfully demonstrated the great potential of FeGa/NiFe laminates for use in microscale communications systems.

Electric Field Control of Interfacial Magnetism Through Ionic Liquid Gating

Ziyao Zhou, Zhongqiang Hu and Ming Liu; Electronic Materials Research Laboratory, Key Laboratory of the Ministry of Education & International Center for Dielectric Research, Xi’an Jiaotong University, Xi’an, China.

Interfacial magnetism in magnetic heterostructures is of great significance for the applications in magnetic memory and microwave devices. Spin-polarized electric currents or magnetic fields have been the conventional driving forces to manipulate magnetic spin dynamics. A more energy-efficient alternative has been proposed in recent reports, where electric fields are used to manipulate magnetization in multiferroic heterostructures. Also, high-density charges aggregated at the interface of the ionic liquid can be used to manipulate the magnetic anisotropy, magnetoresistance, and metal-to-insulator transition in thin films, which are promising both in physics and applications. In this talk, we report electric field tuning of interfacial magnetization through ionic liquid gating in several magnetic material systems with in-plane or perpendicular magnetization anisotropy [1-4]. The spin dynamics of the multiferroic heterostructures during the ionic liquid gating process are monitored using in situ electron paramagnetic resonance (EPR), magneto-optic Kerr effect (MOKE), and vibrating-sample magnetometer (VSM) techniques. The electric-field modulation mechanisms, including ionic migration, electrostatic doping, and electrochemical reaction, are explored to realize non-volatile, reversible tuning and large magnetoelectric coupling coefficient. Our work on electric field control of interfacial magnetism may enable ultrafast, high-density, and power efficient spintronic devices.

1:45 PM CP06.10.02
Direct Writing of Amphiphilic Graphene Ink for Stretchable Tactile Sensors with Highly Sensitive and Ultra-Broadband Frequency Response Xin Jiang and Hongwei Zhu; Tsinghua University, Beijing, China.

Tactile sensors are essential for the next generation of sophisticated electrical devices including smart robotics, robot-assisted surgery, artificial skin and biomedical devices, etc. However, research on the detection of high frequency micro-vibration is still rare, because those tactile sensors should maintain ultra-high mechanosensitivity, high signal fidelity, conformal ability and fast response at the same time. Sensors that enable accurate sensing of sound frequencies are composed of precious metal or carbon/thermoplastic polymer composites. In this work, stretchable tactile sensors with highly sensitive and ultra-broadband frequency response are fabricated rapidly by direct writing amphiphilic graphene ink on plasma treated polydimethysiloxane (PDMS) film substrate. Due to the molecular interaction among graphene sheets/polypeptide, the composite conductive film on stretchable substrate produces cut-through cracks under the stress, and sheets do not undergo significant relative sliding action. This mechanical crack-based sensor has the characteristics of fast response and high sensitivity (with a gauge factor of 928.9 in the 0-2 percent strain range), and the gauge factor raises with the decrease of the resistance. Further, microscopic morphology of cracks, namely the crack asperity height and its statistical variance, can significantly affect the sensitivity and working strain range. We also demonstrate that sensors fabricated by direct writing can accurately detect the frequencies of different musical tones, chords and portaments. Moreover, diverse musical instruments could be recognized through the principal component analysis method. A general strategy for a green, simple, portable and cost-effective approach to make stretchable tactile sensors with highly sensitive and ultra-broadband frequency response is offered here, which could be widely applied in devices for detection of high frequency micro-vibration.

2:00 PM CP06.10.03
Fabrication of High-Performance Nanocomposites by Site-Specific Nanoparticle Orientation Through Additive Manufacturing Sayli Jambhulkar, Weiheng Xu, Rushik Tank and Kenan Song; Arizona State University, Tempe, Arizona, United States.

Nanoscale particles are widely used in various applications like drug delivery, wastewater purification and thermal management areas. However, its inability to manage their alignment during processing limits its widespread applications. This technique will focus on the printing of nanoparticles-containing composites via additive manufacturing process with the promoted local alignment of nanoparticles assisted by the surface morphology and fluidic flows. Specifically, nanoparticle orientation will be controlled within a unit printing volume to obtain suitable mechanical and functional properties. Projection micro-stereo lithography (PµSLA)/fine fiber spinning based fused deposition modeling (FFS-FDM) were used for building for 3D triangular wave shape surface pattern of PVA (poly vinyl alcohol) transparent polymer. The liquid crystal 4-Cyano-4'-pentylphenyl (5CB) and halloysite nanoparticles are diffused together and this mixture is deposited over the transparent pattern to study its alignment. 5CB liquid crystal provides sufficient driving force for the unidirectional alignment of halloysite nanoparticles. The factors like fluid dynamics, colloidal inks, solidification thermodynamics and confinement systems will control the nanoparticle configurations. The orientation of nanoparticles due to the alignment of nematic liquid crystal in the groove direction were studied by polarized optical microscopy (POM), atomic force microscopy (AFM), x-ray diffraction (XRD), scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Mechanical properties like static modulus, strength and toughness were measured. The orientation management of nanoparticles will improve the efficiency of drug delivery, optical or electrical signal transfers and the robustness of automobiles etc.

2:15 PM CP06.10.04
Effective Unidirectional Wetting of Liquids on Biomimetic Patterned Surfaces via 3D Printing-Assisted Replication and Surface Modification Hau Che-Ni and Po-Yu Chen; Materials Science and Engineering, National Tsing Hua University, Hsinchu City, Taiwan.

Controlled self-propelling of liquid transport is of significant interest for extensive applications, such as DNA microarrays, fog-harvesting, self-cleaning coatings and smart microfluidic devices. It is found that many biological structures possess unique structural features that demonstrate unidirectional wetting behavior, such as cactus with conical spines, spider silk with periodic spindle-knots and joints, and Nepenthes peristome with overlapping grooves. Investigations on the structure-property-function relationships of
smart surfaces in Nature offer inspirations and insights into how to control the tendency of liquid self-transport without additional energy expenditure. In this work, we first applied the atmospheric pressure plasma (APP) treatment on inclined samples with a specific angle which resulted in gradient wettability and unidirectional wetting behavior was realized. To further improve the efficiency and durability, we further designed bio-inspired patterns consisting of arrays of asymmetric, spine-like structures and fabricated the negative molds by 3D-printing. Polydimethylsiloxane (PDMS) was utilized to replicate the bio-inspired patterns. Then, hydrophilic polyethylene glycol (PEG) was grafted onto the surface of PDMS replica in a two-step process, including APP treatment and liquid phase deposition. The chemical composition was analyzed by X-ray photoelectron spectroscopy (XPS) and profile and microstructure of PDMS replica were characterized by 3D laser scanning confocal microscopy and SEM, respectively. The static and dynamic wetting behavior of liquids on biomimetic patterned surfaces were evaluated and observed by contact angle measurement with varying tilting angles and high-speed camera. Results showed that the serial liquid droplets were unidirectionally driven by the asymmetric structure and gradient surface and were pinned in the opposite direction. The unidirectional wetting behavior of liquids was observed even when the tilting angle reached 90°. In summary, we successfully designed and synthesized biomimetic patterned surfaces by combining 3D printing-assisted replication, APP treatment and PEG grafting which possess effective unidirectional wettability and could be further applied in controlled fluid transportation, water/fog collection, microfluidic devices and smart textiles.

2:30 PM CP06.10.05
Solution Deposited Columnar Thin Films and Their Potential Application as Absorber Layers for SWIR Active Up-Conversion Devices Yuval Golan, Ben-Gurion University of the Negev, Beer Sheva, Israel.

Chemical solution deposition of lead chalcogenide thin films on GaAs substrates has been shown to result in a wide range of film microstructures, from ultra-thin nanocrystalline films, via highly oriented polycrystalline films, to single crystal films with epitaxial relation with the underlying substrate.[1-6] Of particular interest are columnar thin films, which are comprised of nanocolumn-which are vertically aligned with respect to the substrate. This talk will highlight the solution deposition route to columnar thin films, which are interestingly formed via an oriented attachment growth mechanism.[7] These films are candidate absorber layers for nanomaterials based, solution deposited up-conversion night vision devices operating in the short wave infrared (SWIR) range.[8]

Characterization and Simulation of Elastocaloric Effects of Shape Memory Poly(Cyclooctene) and Its Composites Seok Bin Hong, Yongsan An and Woong-Ryool Yu; Seoul National University, Seoul, Korea (the Republic of).

The elastocaloric cooling effect of natural rubbers has been demonstrated for cold storage, however, its programming by cold-drawing is possible only at high strain rate. We found that shape memory cross-linked poly(cyclooctene) (PCO) exhibits enhanced elastocaloric cooling effect at relatively moderate strain rate due to its strain-induced crystallization behavior during cold-drawing [1]. The elastocaloric heating and cooling effects of PCO were predicted using Green-Lagrangian strains obtained from 3D finite element analysis (FEA) with a suitable constitutive model, which was already developed for shape memory polymers in our group [2], and thermodynamic quantities, showing good agreements between simulation and experiments. In addition, carbon fiber reinforced PCO composites were also studied to investigate the effect of carbon fibers on the elastocaloric effects of PCO. For the modeling of PCO composites, anisotropic hyperelasticity theorem was used for modeling the mechanical behavior of carbon fabrics. The interaction between fiber and SMP matrix depending on temperature change was considered through thermal residual stress [3]. Finally, an application of shape memory PCO and its composite to the elastocaloric refrigerator will be studied to demonstrate that implementation of the current method into 3D FEA can facilitate the design study of a portable cooling device made of shape memory polymers.

2:30 PM CP06.10.07
Tough and Water-Insensitive Self-Healing Elastomer for Soft Electronics Jiheong Kang and Zhenan Bao; Stanford University, Stanford, California, United States.

Electronic (e-) skin has recently been widely pursued as state-of-the-art wearable electronics due to its skin-mimetic mechanical and sensing properties. Similar to human skin, which is stretchable, tough, and even self-healable with sensing capabilities, efforts to render such e-skin devices robust and durable to withstand constant mechanical damage have led to various reports of self-healing elastomers. Even though elastomers utilized in e-skin devices are stretchable, but unfortunately, they easily break along locations where damages incurred due to their low fracture energies of ~100 J/m2 or lower. Furthermore, these damages are usually not self-healable[10]. Most self-healing materials are based on weak polymer systems with low fracture energies. Towards tough, self-healable and stretchable electronics for practical e-skin devices development, we report herein a polymer film cross-linked through multi-strength hydrogen bonding engineering. We further illustrate its application through the fabrication of highly stretchable and tough self-healing e-skin devices. We found the underlying principle for our tough and self-healable film is achieved through the spontaneous formation of a mixture of both strong and weak cross-linking hydrogen bonds. The strong cross-linking bonds confer robustness and elasticity, while the weak bonds are able to dissipate energy through efficient reversible bonds breakage and reformation. Furthermore, the polymer film is autonomously self-healable and highly moldable into desired complex 3D structures. Our film is easily hybridized with conductive fillers, in which we proceed to fabricate a new generation of e-skin: highly tough and stretchable self-healing system.

3:45 PM CP06.10.08
Yb:HfO:Eu3 Nanoparticles with High Concentration Quenching Towards Red Emitting Phosphor, X-Ray Scintillator and Luminescent Thin Film Yuanbing Mao1, Santosh Gupta1, Jose Zuniga2, Maya Abdou1, Santhosh Gupta1, Jose Zuniga2. 1The University of Texas at Rio Grande Valley, Edinburg, Texas, United States; 2Bhabha Atomic Research Centre, Trombay, India.

Desirable phosphors for light emitting diodes (LED) must have good light absorption property, high concentration quenching, high quantum efficiency, and narrow color emission, etc. In this work, we first show that undoped yttrium hafnate Y3Hf2O7 (YHO) nanoparticles (NPs) display dual blue and red bands after 330 nm light excitation. Based on Density functional theory (DFT) calculations, these two emission bands are correlated with the defect states arising in the band-gap region of YHO due to the presence of neutral and charged oxygen defects. Once doped with Eu3+ ions, the YHO NPs show bright red emission, long excited state lifetime and stable color coordinates upon near-UV and X-ray excitations. Concentration quenching is active when Eu3+ doping reaches 10mol% with a critical distance of ~4.4 Å. This phenomenon indicates a high Eu3+ solubility within the YHO host and the absence of Eu3+ clusters. The optical performance of the YHOE NPs has been further improved by lithium co-doping. Also, the YHOE NPs have been dispersed into PVA polymer to make nanocomposite films, which show strong red emission under excitations at 270 and 393 nm. Overall, high emission intensity and quantum efficiency
under UV and X-ray excitations make the YHOE NPs suitable as phosphors, scintillators and luminescent probes for LED and life science applications.

4:00 PM CP06.10.09
Localized Self-Growth of Reconfigurable Architectures Induced by a Femtosecond Laser on a Shape-Memory Polymer
Yachao Zhang1, Yanlei Hu1, Dong Wu1 and Chengwei Qiu2; 1Department of Precision Machinery and Precision Instrumentation, University of Science and Technology of China, Hefei, China; 2Department of Electrical and Computer Engineering, National University of Singapore, Singapore, Singapore.

Architectures of natural organisms especially plants largely determine their response to varying external conditions. Nature inspired shape transformation of artificial materials has motivated academic research for decades due to wide applications in smart textiles, actuators, soft robotics, and drug delivery. A “self-growth” method of controlling femtosecond laser scanning on the surface of a prestretched shape-memory polymer to realize microscale localized reconfigurable architectures transformation is introduced. It is discovered that microstructures can grow out of the original surface by intentional control of localized laser heating and ablation, and resultant structures can be further tuned by adopting an asymmetric laser scanning strategy. A distinguished paradigm of reconfigurable architectures is demonstrated by combining the flexible and programmable laser technique with a smart shape-memory polymer. Proof-of-concept experiments are performed respectively in information encryption/decryption, and microtarget capturing/release. The findings reveal new capacities of architectures with smart surfaces in various interdisciplinary fields including anti-counterfeiting, microstructure printing, and ultrasensitive detection.

4:15 PM CP06.10.10
Magneto-electric Coupling in 2D Multiferroics
Menghao Wu; Huazhong University of Science & Technology, Wuhan, China.

Multiferroics material with coupled magnetism and ferroelectricity, even though scarcely exist in nature, are highly desirable for efficient “electric writing + magnetic reading”. Currently, the polarization and magnetization of traditional multiferroics with strong magneto-electric coupling are all too weak for practical applications. Here we show first-principles evidences that strong magneto-electrics can be realized in a series of 2D multiferroics: in some intercalated bilayer systems, their “mobile” magnetism can be controlled by ferroelectric switching upon external electric field, exhibiting either “on” state with spin-selective and highly p-doped channels, or “off” state insulating for both spin and electron transport, which renders efficient electrical writing and magnetic reading; vertical polarization can be maintained against depolarizing field, rendering high-density data storage possible; moreover, all those functions can be directly integrated into a 2D wafer, like n/p channels by doping in a silicon wafer. In some 2D systems, the magnetization can be switched by 90 or even180 degree upon ferroelectric switching.

4:30 PM CP06.10.11
Roll-to-Roll Manufacturing of Flexible Sensors for Environmental and Food Pollutants
Susana Diaz-Amaya1, Li-Kai Lin1, Ana M. Ullou1, Mukerrem Cakmak1-2 and Lia Stanciu1-2; 1Purdue University, West Lafayette, Indiana, United States; 2Birck Nanotechnology center, Purdue University, West Lafayette, Indiana, United States.

The rapid expansion of sensors as a research field is continuously bringing to life novel materials, detection mechanisms and practical applications. During the last few decades a vast variety of sensors have been successfully developed at the laboratory scale demonstrating an enormous potential for solving global issues such as food and environmental pollution. Unfortunately, the fact that nearly 80% of the platforms developed at lab-scale never get to meet the market is not yet a common discussion within the field.

Challenges standing in the way of bringing sensors from the laboratory to the market include difficulties in reproducibility and repeatability. We used roll-to-roll processing to design field deployable flexible electrochemical sensors for the detection of environmental pollutants. Inkjet printed gold electrodes on flexible polyimide substrates were modified with a layer of specificity for organophosphorus pesticides and for mercury, respectively. We designed both platforms to transduce the target interaction signal by impedimetric (transfer charge resistance) response. For the pesticide sensor, a mesh of zirconium oxide fibers was deposited via roll-to-roll on the electrodes, leading to a detection of methyl parathion with a limit of detection (LOD) of 0.01 µM (r²= 0.952). The specificity was demonstrated vs nitrobenzene and 4-nitrophenol. Mercury ions were captured by a roll-to-roll deposited, thiol-functionalized aptameric sequence, highly specific for the target. The LOD for the Hg²⁺ was of 0.1 ppm (r²= 0.995) and the possibility to be re-used without significant variation was demonstrated. The platform specificity was assessed vs arsenic, cadmium and lead as potential interferent ions.

The results presented by this work reveal not only the high sensitivity and specificity of both capture strategies (zirconium oxide fibers and ss-DNA aptamer) but high stability, and repeatability in sensors response. We suggest it is now possible to incorporate roll-to-roll technology in sensor design, and take the high variety of already developed lab-scale devices to large-scale manufacturing.

Electrospinning and Plasma Treatment of Polyamides for Mosquito-Repellant Fabrics
Nicholas R. Etrick1,2, Chunhui Xiang1,2 and Margaret Frey2; 1University of Florida, Gainesville, Florida, United States; 2Human Ecology and Fiber Science, Cornell University, Ithaca, New York, United States; 3Apparel, Events, and Hospitality Management, Iowa State University of Science and Technology, Ames, Iowa, United States.

The need for light-weight, high-strength, and easily machineable insect-repellant fabrics is of critical importance to the cessation of viral diseases, such as Zika, Malaria, and Dengue Fever due to climate change.

In this study, the viability of electrospinning nanofiber Nylon-6 for use in protective garments will be investigated and compared to conventional polyamide fabrics, Nylon-6 Tricot and Nylon-6,6 Knit.

Throughout this investigation, the surface coating efficiency was evaluated to determine the best method of uptake for Permethrin, as well as characterization of fabrics utilizing DSC, TGA, FTIR, FESEM, XPS, GC-MS, Porometry, Tensile Testing, Rheometry, UV degradation, and washing fastness.

Bidirectional Self-Folding with Atomic Layer Deposition Bimorphs for Autonomous Micro-Origami

We present micron sized self-folding structures that consist of nanometer-thin, atomic layer deposited SiO$_2$-Si$_3$N$_4$ bilayers, built with conventional semiconductor fabrication methods. A bending response originating from strain differentials within these bilayer stacks is used for bidirectional fold actuation. This strain differential induced bending is controlled by ion exchange reactions in our nanoscale sheets, enabling us to produce radii of curvature at the order of microns within fractions of a second. By lithographically patterning these sheets and localizing the bending using flat photoresists panels, we create microscale origami devices that can sense chemical changes in their environment and respond by changing configurations according to prescribed mountain-valley fold patterns. Finally, we show that our fabrication approach offers a range of chemical, electrical and biological functions as well as a path to sequential folding through the programming of stacks.

Foldable and Responsive Soft Metamaterials

Reconfigurable soft metamaterials that can bend, fold, or transform the shape in response to external stimuli have attracted significant interests in design of actuators, sensors, and smart materials and devices. We fabricate a variety of periodically ordered, porous membranes with different size, shape and arrangement from responsive polymers, including poly(dimethylsiloxane) (PDMS), poly(2-hydroxyethyl methacrylate) (PHEMA) based hydrogels, and shape memory polymers (SMPs). By exploiting mechanical deformation in these material systems in respond to environmental cues, such as pH, heat, light, and mechanical stretching, we investigate pattern transformation, auxetic properties, and programmed deformation for pentiletal . We further design and synthesize nematic liquid crystal elastomers (LCEs), two-way SMPs, with large and anisotropic strains, and precisely align the monomers and oligomers within the patterned microchannels. In turn, we demonstrate pre-programmed folding of 2D sheets into 3D with various curvatures.

Buckling Dominated Behavior of Elastic Hierarchical Truss Structures Matthew Begley, Geoffrey Wehmeier and Frank Zok; Materials Department and Department of Mechanical Engineering, University of California, Santa Barbara, Santa Barbara, California, United States.

The performance of porous materials with low relative density is limited by buckling of struts or cell walls, which reduces strength and energy storage during large deformations. Motivated by the expanding design space accessible via additive manufacturing, this paper examines the efficacy of combining multiple cell shapes and variable strut sizes to control buckling and improve compression response. A simple V-shaped cell between rigid platens is divided into sub-cells using smaller internal branches that run perpendicular to the loading direction (trapezoidal sub-cells) or at inclined angles (triangular sub-cells). Finite element simulations with linearly elastic beam elements that account for large rotations and self-contact are used to predict performance at fixed relative density. A broad parameter study will be illustrated showing the impact of sub-cell shape and strut size. Despite the simplicity of the structures, the simulations illustrate complex relationships between topology and post-buckling behavior that arise from highly non-linear kinematics. This complexity has important implications for the topology optimization of large deformation response of cellular solids. While performance can be highly sensitive to sub-cell geometry, the overall trends demonstrate that triangular sub-cells with small cross-sections (relative to the main V-struts) are effective in suppressing lower order buckling modes. Such structures exhibit improvements in peak stress and elastic energy storage of a factor of two or more, relative the undivided V-cell. The implications for designing low density materials are briefly discussed.

Auxetic Lattice Materials from Symmetry Breaking Pu Zhang and Quang K. Nguyen; SUNY Binghamton, Binghamton, New York, United States.

Auxetic lattice materials exhibit fascinating features like folding, expansion, and morphing due to their negative Poisson’s ratio. They play a significant role in the emerging family of mechanical metamaterials. It is well known that the negative Poisson’s ratio of auxetic lattice materials stems from specific deformation mechanisms, which have been the research focus in this area for decades. However, there is still a lack of systematic analysis of the deformation mechanisms of auxetic lattice materials. In this talk, we explore the relation between symmetry breaking and the evolution of Poisson’s ratio for lattice materials. The results offer in-depth understanding of auxetic materials from the symmetry principle and provide a promising way to discover new deformation mechanisms.

CP07.02.04
Shape Morphing Mechanical Metamaterials Michael D. Bartlett, Doh-Gyu Hwang, Sean Frey and A B M Tahidul Haque; Iowa State University, Ames, Iowa, United States.

Reconfigurable structures with tunable mechanical and functional response can enable dynamic functionality to improve performance and enhance versatility of materials and systems. One promising approach to create such structures is through the use of patterned folds or cuts in initially planar materials. Kirigami, the Japanese art of paper cutting, has demonstrated that the inclusion of cut patterns enables complex 3D structures from 2D sheets, elastic softening, and large deformations under external loading. Here we present reconfigurable and multistable mechanical metamaterials through the coupling of non-linear structural deformations with material non-linearities. First, we generate fabrication approaches to combine multiple material sets into a single material system through the combination of rapid prototyping through laser cutting and soft lithography. We then perform mechanical experiments to investigate the material and structural non-linearity upon deformation. Experimental results are supported by theoretical predications and simulations, which relate the material stiffness and deformation characteristics to the material composition and geometry. By tuning these parameters, we create 2D films which are capable of morphing into complex 3D shapes and then being electrically triggered to return to the initial 2D state. This work can enable substantial variations in stiffness and deformation of functional materials for applications in soft robotics, stretchable electronics, and human-machine interfaces.

CP07.02.05
Tailoring Materials Properties Outside Classical Bounds—Towards Mechanically Programmable Materials Peter Gumbsch, Christoph Eberl, Claudio Findeisen and Patrick Ziemke; 1Karlruhe Institute of Technology KIT, Karlsruhe, Germany; 2Fraunhofer IWM, Freiburg, Germany.

Ordinary materials neither exhibit multi-stability nor chiral mechanical response. This means that they cannot be stabilized in multiple conditions and that they do not convert stretch into twist. In contrast, metamaterials give access to such behavior. The design of such metamaterials to specific materials properties requires mechanistic materials modelling over multiple length scales to avoid tedious trial-and-error procedures and excessive experimentation.

Concerning chirality, Frenzel et al.[1] have created a chiral mechanical metamaterial and successfully mapped its behavior onto a micropolar continuum which predicts that the magnitude of the twist must decrease inversely proportionally to the ratio of the sample size to the size of one unit cell. To create chiral response for larger samples, the decay of the twist must be pushed to larger scales or eliminated. We first combine chiral unit cells with non-chiral coupling elements to form binary crystal structures exhibiting ultra-long decay-lengths compared to previous three-dimensional chiral mechanical metamaterials. We then proceed to generate structures that completely avoid this decay.

Multi-stability can be achieved with metamaterials that contain elastic buckling elements[2,3]. Gradients in the metamaterial in principle give access to a quasi-continuous regime of mechanical properties. Such graded metamaterials can be designed such that their effective materials properties can still be dramatically changed after manufacturing. I will take this as an example for an intrinsically programmable material. While the deliberate adjustment of locally different materials properties in a component may be regarded as the programming of a material to achieve component functionality, intrinsically programmable materials will allow realizing complex system functionalities including sensor and actor functions.

The Use of Negative Space Around Metamaterials to Improve the Performance of Energy Absorption Structures Dhruv Bhat, Christine Lee and Irving Ramirez Chavez; Arizona State University, Mesa, Arizona, United States.

One of the many potential applications of mechanical metamaterials is in the design of energy absorption structures used in functional components such as helmets and automotive crash structures. Traditionally, these structures have been manufactured using stochastic foams, but Additive Manufacturing (AM) process technologies have enabled the design of metamaterials with tailored and locally modified properties. The vast majority of literature on AM metamaterials for energy absporption have typically focused on the identification of a metamaterial unit cell shape that is optimal for energy absorption. In this work, we report on an alternative approach we have explored to incorporate “negative space” around metamaterials into the design of energy absorption structures.

The ideal energy absorption structure meets two objectives simultaneously - it provides high energy density, while also keeping the maximum transmitted stress to a low value. The former requirement ensures energy is absorbed with as little material as possible, which is important from a packing (in the case of a helmet) or light-weighting (in the case of an automotive crash structure). The objective of reducing the maximum transmitted stress is to keep the occupant safe and isolated from the effects of the stress.

In this work, we borrow the concept of “negative space” from the world of art, where it is typically used to describe the space around the subject. In art, negative space is often most evident when the space around a subject, and not the subject itself, forms an interesting or artistically relevant shape, and such space occasionally is used to artistic effect as the “real” subject of an image.

We used this concept to introduce negative space into a regular, periodic square honeycomb design with the intent of studying its effects on the mechanical properties of these honeycombs under compression. Our key finding in this work is that the introduction of negative space, particularly in the form of spiral patterns or as non-collinear spaces can
significantly increase the energy density for a given maximum transmitted stress. This data is collected using additively manufactured polymer honeycombs tested under compression. We leverage this empirical data to develop design principles that may be integrated into energy absorption structures more generally. While this work is limited to prismatic honeycombs, it is in principle, extendable to 3D metamaterials. On a more abstract level, we suggest that it is negative space, and not the metamaterial itself that may be functionally relevant for energy absorption and peak stress minimization, or at least play a complementary role along with the identification of an ideal metamaterial.

Programmable Mechanical Metamaterials—Material, Machine and Everything in Between Matthew Berwind and Christoph Eberl; Fraunhofer-Institut fuer Werkstoffmechanik IWM, Freiburg, Germany.

The fundamental problem of how structure scales and size-dependently impacts materials has occupied humanity for centuries. Modern manufacturing techniques now allow us to investigate this basic question with incredible freedom, and rational design approaches to the structuring of materials can result in metamaterials with unique properties. A scale-bridging understanding of how structure defines such a metamaterial independent of its base composition is necessary for this rational design process to be successful. Herein we examine metamaterials with a view spanning their internal ‘mechanisms’, the unit cell, its connectors, and finally the resultant matrix with its hierarchically subordinate components. Some recent efforts in the development of programmable mechanical metamaterials, or designed materials that respond to external stimuli in a discrete and ideally reversible fashion, will be presented that rely on a clear understanding of rational hierarchical design approaches.

Programmable Properties of Two-Photon-Polymerized Materials and Metamaterials Jens Bauer, Cameron Crook, Anna Guell and Lorenzo Valdevit; University of California, Irvine, Irvine, California, United States.

From the current perspective, there is little room for further expansion of the accessible material property space by classical material fabrication methods. Single one- and two-dimensional nanoscale objects, such as nanowires and thin films, are known to hold exceptional physical properties. Yet, their properties are intrinsically coupled to their small size and their solitary nature, and therefore can hardly be accessed in actual materials of practical volume. If nanowires and thin films are simply scaled up properties, which relate to surface to volume effects, get lost, when clustered in a composite interfaces dominate the overall performance. Nanomachined metamaterials are regular three-dimensional networks constructed from nanowires or thin films and have the potential to overcome such limitations. Two-photon polymerization (TPP) is the most versatile technology for fabricating nanomachined metamaterials and rapidly progresses towards higher throughput, resolution and a broader spectrum of printable materials. However, TPP fabrication is still largely empirical without systematic data on material properties and limited knowledge on their dependency on the process parameters. In this work, we systematically characterized the mechanical properties of two-photon polymerized resins as well as corresponding pyrolytic ceramics, from nanowires to bulk specimens. We show that the properties of the material systems can be tailored from rubbery soft to hard and strong, and explain the observed behavior by a photonics-based model allowing to predict the mechanical properties of two-photon polymerized materials depending on applied process parameters. In a second step we incorporated specifically designed material properties in different nanomachined metamaterials. We discuss the interplay of material design approaches, size-effects and different topological designs and show unique effective characteristics such as mechanical performance at the theoretical limit of both the architecture and the constituent material.

2:00 PM CP07.03.02
Meta-Crystals—A Fusion of Physical Metallurgy and Architected Materials Son Pham; Materials, Imperial College London, London, United Kingdom.

I will present a transformative idea of designing meso-structures (termed as meta-grains, meta-precipitates and meta-phases) that imitate key microstructures (namely crystal grains, precipitates and phases) in crystalline metals to generate a new type of meta-materials: meta-crystals. This mimicry enabled by additive manufacturing opens a unique opportunity to employ the key hardening mechanisms found in metallurgy to the design of architected materials. This study demonstrates that such meso-structures play the same roles on governing the properties of meta-crystals as do intrinsic microstructures in metallic alloys, opening up a new space of designing lightweight and damage-tolerant materials with desired properties.

2:15 PM CP07.03.03
Mechanical Meta-Materials Inspired by Crystal Microstructure—Size Effect and Anisotropy Chen Liu and Minh-Son Pham; Department of Materials, Imperial College London, London, United Kingdom.

Mechanical meta-materials that mimic the crystal lattices are lightweight and hold great potential for a wide range of applications, such as aerospace, automobiles and medical devices. However, previously reported lattice meta-materials consisted of lattices that are singly oriented. Such lattice meta-materials are analogous to single crystals, and normally exhibit unstable deformation behaviour due to the occurrence of single shear bands throughout the whole lattice, resulting in substantial reduction in energy absorption. In this study, we present a novel approach to mimic the polygranular structure in metallic alloys and bring the grain-size hardening effect in polycrystals to develop polycrystal-like meta-materials. We found that the boundaries separating meta-grains play an influential role in the propagation of shear bands in the same way as the grain boundaries do in slip activities in metals. Most interestingly, the strength of polycrystal-like meta-material is found to increase with decreasing the size of meta-grains, similar to the Hall-Petch relationship. Moreover, this talk will demonstrate that we can engineer the crystal-like lattice structures to tune the meta-material properties in the same way as the microstructure engineering in metallurgy. The tailoring of anisotropy of meta-materials will be presented as an example.

2:30 PM BREAK

SESSION CP07.04: Manufacturing Architectured Materials

Thursday Afternoon, April 25, 2019
PCC West, 100 Level, Room 106 A

3:00 PM *CP07.04.01
Three-Dimensional Photonic Manufacturing—From Catalytic Waste Gas Converters to Microvascular Tissue Scaffolding Nicholas Fang; Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Three-dimensional lightweight material building blocks, through the combination of molecular design of material behavior and microscale geometric patterning, show promise to revolutionize the ability to dissipate energy and manipulate wave propagation. Such materials are desirable for a broad array of applications such as structural components, catalysts supports and energy efficient materials.

In this invited talk, I will present our development of three dimensional micro/nanofabrication technique, projection microstereolithography (PuSL), to enable design and
exploration of digitally coded multifunctional and multimaterial lightweight metastructures at unprecedented dimensions. The ultra-high resolution and multi-material capabilities of the 3D printing system and the modeling tools developed can be used to design and fabricate architectured materials for combined functions, including energy absorption, actuation/morphing, and reactors with fast thermal response and efficient convection of working fluids. I will also discuss the development of engineered, three-dimensional arrays of copolymer fibers that serve as mimetics of neuronal axons, using a combination of materials engineering and high resolution 3D microfabrication, which enable study of OPC engagement and subsequent myelination in vitro.

3:30 PM CP07.04.02
Site Selective Laser Shaping of Architected Mechanical Metamaterials
Letian Wang, Zacharias Vangelatos and Costas Grigoropoulos; University of California, Berkeley, California, United States.

Multiphoton lithography is the widely used 3D micro-printing method that enable fabrication of architectured microstructures in length scales of 1 um. However, the further reduction of the feature size and the printing of curved surfaces still remain challenging. Here we report that the focused laser beam can induce localized pyrolysis on polymer-ceramic hybrid architectured materials. The minimum feature size is reduced from 400nm to 250nm, yielding a volume reduction factor of 2.56. With nanodiamond experiments, we confirmed that a top-down z-dependent deformation on the architectured metamaterial introduces an 100% enhancement in mechanical strength. Additionally, in-plane 2D xy-dependent deformation generates controllable curved surfaces from straight lattice struts. Hence, the laser induced site-selective deformation offers on-demand modification of the physical geometry and mechanical properties for architectured metamaterials.

3:45 PM CP07.04.03
3D Printing of Zinc Oxide via a Novel Photopolymer System
Darel Vee, Max L. Lifson and Julie Greer; Applied Physics and Materials Science, California Institute of Technology, Pasadena, California, United States.

In recent years, 3D printing of ceramics has become a significant area of interest as it has the potential to remove the geometrical limitations associated with the current state of the art of ceramic processing. In particular, 3D printing processes involving photolithography have emerged as some of the most promising ones due to the high resolution and small feature sizes achievable. These photolithography systems typically consist of photosensitive slurries, where fine powders of the desired ceramic of choice are dispersed in a photosensitive organic binder. By selectively exposing certain parts of the slurry to radiation of the appropriate wavelength, the binder can be cured into a desired shape, trapping the ceramic powder within as well. A subsequent high temperature treatment then burns off the organic binder and sinters together the remaining ceramic powders into a dense ceramic part. The advantages of these systems are that it’s simple and versatile – as long as the desired ceramic can be obtained in powder form and can be dispersed in a photosensitive binder, the slurry can be obtained and the part printed. However, for a part to survive the high temperature process, the slurry has to have a high loading of ceramic particles, somewhere between the ranges of 45-70 volume percent, which results in a host of other issues. At such high loadings, the viscosity of the slurry increases significantly, making it difficult to print. Homogeneous dispersion of the ceramic powder also becomes challenging at such high viscosities. Furthermore, the solid ceramic particles increase the refractive index of the resin and scatter the incident light, reducing both the cure depth and the dimensional accuracy of the print.

In this presentation, a new photopolymer system that circumvents the problems of powder loading is demonstrated. The photopolymer system is simple to make and can be easily modified to fabricate various multifunctional metal oxides. As an example of this technique, we demonstrate the printing of zinc oxide (ZnO) architectured structures. ZnO is traditionally deposited as films and can only be made 3D via a multistep process that involves depositing a thick layer of ZnO and then using an ion-mill to cut out the structure desired. Here, we show a two-step process to fabricate monolithic 3D ZnO structures out of any arbitrary design. Characterization of these structures using X-ray diffraction, energy-dispersive spectroscopy and transmission electron microscopy indicate that the structures are indeed zinc oxide. Compression of these materials also results in a voltage response, showing the piezoelectric behavior of these structures. The ability to fabricate these multifunctional 3D materials could open up the field of smart devices and change how we design them.

Atomic Layer Deposition for Membranes, Metamaterials and Machines
Tanner Pearson1, Kyle J. Dorsey1, Edward Esposito2, Baris Bircan1, Yimo Han3, Sierra Russell2, David Muller1, Itai Cohen2 and Paul L. McEuen1; 1School of Applied and Engineering Physics, Cornell University, Ithaca, New York, United States; 2Kavli Institute at Cornell for Nanoscale Science, Cornell University, Ithaca, New York, United States; 3Laboratory of Atomic and Solid State Physics, Cornell University, Ithaca, New York, United States; 4State University of New York Polytechnic Institute, Albany, New York, United States.

Ultra-thin films of inorganic materials are well-suited for fabrication of micron-scale actuators because they can sustain small radii of curvature, have large force outputs, are compatible with semiconductor processing, and are chemically robust. We leverage atomic layer deposition (ALD) on sacrificial substrates to produce micron-scale free-standing mechanical devices with sub-10 nm film thicknesses. We fabricate cantilever springs from ALD films and characterize the material’s mechanical properties. We find that ALD films are remarkably elastic and exhibit a bending stiffness on the order of femtometers. These measurements enable fabrication of cantilever springs with tailorable ultra-low spring constants suitable for micron-scale machinery. The mechanical properties of ALD are further characterized by lithographic patterning of both the ALD film and its substrate in the design of mechanical metamaterials. Substrate corrugations transferred into the ALD film enhance its bending stiffness and allow programmable bending anisotropy, while lattices imposed into the film decrease its effective Young’s modulus for stretchable and auxetic materials. We integrate these results and device concepts to produce magnetically actuated three-dimensional structures with applications in micromachining. Our results establish thin ALD films as a scalable basis for micron-scale actuators and shape-programmable microrobots.

Controlling Magnetic Properties in Fused Deposition Modeling Parts via Shape, Infill Orientation and Infill Percentage
Thomas M. Calascione, Mike V. Patton, Andrew H. Morgenstem, Nathan Fischer and Brittany Nelson-Cheeseman; University of St. Thomas, Saint Paul, Minnesota, United States.

Fused deposition modeling (FDM) is an additive manufacturing (aka 3D printing) process that extrudes viscous material in 1-dimensional lines to create 2-dimensional layers that build up to a 3-dimensional part. The creation of magnetic composite parts is just beginning to be explored with FDM. Previous work has found the out of plane direction (perpendicular to the print plane) to be a magnetically hard axis. This motivated further investigation into the influence of specific print parameters on the magnetic properties of parts, as this has not yet been fully characterized. The ability to mechanistically manipulate materials via magnetic fields (such as magnetic shape memory alloys, magnetostrictive materials, and magnetothermoelectric materials) means that tailoring the magnetic properties of such materials is intimately tied to tailoring their performance over time (i.e. 4D-structures). Here, we explore this topic with a composite magnetic filament consisting of PLA and polyacrylonitrile to print 4D-printed structures where the magnetic response is “programmable”. This filament was used in an FDM process to print magnetic samples of varying length, width, infill percentage, and infill print orientation. The length and width variables resulted in parts of two different macroscopic dimensions: 5mm by 10mm (anisotropic) and 10mm by 10mm (isotropic), both with a height of 2mm. The infill percentages printed were 60%, 70%, 80%, 90%, and 100%. The infill print orientation refers to the direction the printer extruded the 1D filament in order to create the part shape, either along or against the shape anisotropy. From these variables, and since the square samples required only one set of prints to get both print orientations due to symmetry, there were 12 unique parts. Three of each were printed, resulting in a total of 36 parts that were tested. A vibrating sample magnetometer (VSM) was used to determine the effect of these different print structures on the magnetic response to a maximum applied magnetic field of 1.4 T. Hysteresis loops for each sample were measured with the magnetic field applied along the longitudinal and transverse directions of the part, resulting in 72 total tests. This data was used to compare the magnetic susceptibilities between the different print structures. After preliminary testing, all parts were tested again for consistency of procedure and data acquisition. The results show that infill orientation has a prominent effect on the magnetic properties. At lower infill percentages, magnetic susceptibility is greater parallel to the infill orientation. However, as infill percentage increases, this effect diminishes, and the effect of the macroscopic shape then has an equal effect on magnetic susceptibility as the infill orientation. The infill orientation anisotropy effects are reduced at higher infill percentages due to the minimization of air gaps that magnetic flux lines must traverse going through the sample. Determining how shape, infill orientation, and infill percentage affect the magnetic properties of printed parts will help in understanding how an FDM process can be developed to “program” these properties in order to manipulate the mechanical performance of 4D-materials, incentivizing FDM as a method for manufacturing magnetic components.
Controllable Elastomer Shape Modulation with Solvent Droplet Sequence Akshay Phadnis and Konrad Rykaczewski; Arizona State University, Tempe, Arizona, United States.

Stimuli sensitive polymers that swell in response to interaction with various solvents offer possibilities to achieve controllable shape transformations. Temporal interaction of these materials with solvent, when controlled locally, can be translated into programmable shape modulation. These geometrical transformations occur over a time scale that depends upon the solvent and the material properties, as well as the size/shape of the material and thus can be easily controlled. Here, we use coupled experimental and theoretical methods to quantify geometry dependent shape transformations of rubbery materials that are locally subjected to a train of solvent droplets. Based on relative comparison between diffusion time scale and droplet pulse period, we identify regimes where such shape transformations can be achieved and controlled. This regime is achieved when the two timescales are comparable whereas equilibrium swelling occurs at two extremes of this scaling. To demonstrate the various regimes, we study swelling of six cylindrical geometries of PDMS with varying aspect ratio subjected to pulsating drops of n-hexane. As a result, a localized swelling feature incremental in time and space domain is observed. Furthermore, we show that the characteristic of this swelling feature depends strongly on the sample aspect ratio relative to the droplet size. We demonstrate this using two cases of cylindrical geometries and a custom finite element model. We use this validated model to predict the geometries of rest of the cases and show dependence of characteristic swelling feature on sample aspect ratio. These deformations are magnified during the droplet-train impact but dissipate during post-train polymer equilibration. Our results also show that while swelling shape is a function of lateral dimensions of the sample, with the extent of swelling increases with the elastomer sample thickness.

Block Copolymer-Templated Nanoceramics with Ductile-Like Compression Behavior Lisa Rueschhoff, Robert Wheeler, Hilmar Koerner, Matthew Dalton, Michael Cinibulk and Matthew B. Dickerson; Air Force Research Laboratory, Wpafb, Ohio, United States.

Nanoscale structured ceramics and composite compositions can exhibit extraordinary mechanical properties, including elastic deformation and high toughness. In this presentation, we will discuss a highly-scalable system that exploits polymeric self-assembly and ceramic precursors to produce inorganics with mechanical metamaterial properties. Here, block copolymers (BCPs) serve as templates for the structuring of preceramic polymers (PCPs). The heat treatment of these materials allows for the concurrent curing of the PCPs, removal of the BCP template, and finally conversion of the PCP to ceramic. Using this method we have created novel SiC-based ceramic structures with nanoscale features and porosity. Insight into the relationship between polymer chemistry and structure in thin films of this BCP/PCP system, as well as in-situ mechanical characterization of porous ceramic micropillars, will be presented.

The Implementation of Periodic Topologies and Acoustic Metamaterials to the Design of Infrastructure Systems Didem Ozevin; University of Illinois at Chicago, Chicago, Illinois, United States.

It is inevitable that structures including bridges, pipelines, and aircraft eventually develop cracks. Unfortunately, current design practice does not include the means of structural damage detection into the design process. In this paper, periodic superstructure and substructure are induced at pre-design and post-design processes in order to control dynamic response of structure and generate local resonators and redirect/control elastic waves, respectively. For the pre-design process, various truss topologies are configured with a periodic pattern for monitoring their variations with localized damage using the impulse response method independent from boundary conditions. For the post-design process, the presence of damage is monitored by Structural Health Monitoring (SHM) methods. Among many SHM methods, Acoustic Emission (AE) method has advantages of being non-intrusive, direct assessment of damage and localization. The major disadvantage of AE method is the sensitivity to background noise. Two-dimensional phononic crystal (PC) is designed to block unwanted background noise such that single AE sensor becomes sufficient to monitor the active flaws as fatigue crack and corrosion. The other application of applying acoustic metamaterials to structural systems is the isolation of building superstructure from any dynamic loading through periodic substructure design with the band gap range of dynamic signal. The integration of periodic systems and acoustic metamaterials brings unique characteristics to the long term durability and resilience of infrastructure systems.
of local defects in architectured materials play an important role in the formation of domains separated by distorted domain boundaries and analyze such phenomenon with a statistical mechanics model analogous to the Ising model. Our study provides a pathway for predicting dynamic architectured material responses according to defect density and distribution, which has not been discussed in previous works. With this understanding, we designed and implanted artificial defects in Si microlattices to deterministically control buckling directions to produce single-domain sinusoidal lattices and to program domain boundaries that form a particular pattern. This new class of architectured materials provides insights for next-generation battery electrodes with novel stress-relief mechanisms and dynamic mechanical metamaterials with tunable phononic bandgaps.

Strain Rate Dependence of Additively Manufactured Polymer, Composite and Metallic Honeycomb Structures Dhairaj Patil1, Mandar Shinde1, Thao Le1, Quoc Lam1, Derek Goss1, Alex Grisin1 and Dhruv Bhat1, 1Arizona State University, Mesa, Arizona, United States, 1Phoenix Analysis & Design Technologies, Inc., Tempe, Arizona, United States.

Metamaterials are experiencing a resurgence in engineering application on account of Additive Manufacturing (AM) since it is now increasingly possible to manufacture complex geometries that include these structures. Manufacturing parts with mechanical metamaterials have several advantages: lower material and energy utilization in the manufacturing process as well as lifetime savings due to the product’s higher performance, especially in weight sensitive domains such as transportation (ground, air, or space).

Despite the significant potential of combining metamaterials with AM, there has been limited implementation in end-use functional parts. A key challenge to realizing this goal stems from our inability to model and predict metamaterial behavior reliably. This is on account of several relatively well-understood reasons including sensitivity to geometric tolerances and microstructure variation at small scales. In this work however, we focus on an aspect of characterizing and modeling metamaterials that has not received enough attention in the additive manufacturing literature, and that is the fact that these materials are highly sensitive to strain rate. This is true at “quasi-static” strain rates, and not just at the higher strain rates associated with impact. We examine the underlying reasons for this, showing how local strain rates can significantly exceed those applied globally.

To simplify our ability to characterize and model observed behavior, we limit our study of strain rate dependence to hexagonal honeycombs across four different additive manufacturing processes: one polymer (Fused Deposition Modeling with ABS), one composite (Nylon and Continuous Carbon Fiber Extrusion) and two metallic (Laser Powder Bed Fusion of Inconel 718 and Electron Beam Melting of Ti6AI6V). We compare strain rate sensitivities of the effective elastic modulus and peak load for all four processes. We also report on strain rate sensitivities for the polymer honeycombs for five different shapes: hexagonal, square, triangular, Voronoi and for a graded structure that induced buckling failure. In all cases, significant strain rate sensitivities were observed from applied nominal strain rates ranging from 1 to 10^5 s^-1. Finally, we use beam theory and Finite Element Analysis to model this strain rate dependence for the polymeric material and show that the inclusion of strain rate dependence is essential for the accurate plastic-plastic modeling of honeycomb deformation. This study has implications for the characterization and modeling of all mechanical metamaterials and suggests that accurate representation of these structures must include strain rate effects.

High Strain Hardening, Lightweight, Three-Dimensional Mechanical Metamaterials with Microlattices Inspired by Crystal Twinning Zacharias Vangelatos, Kyriakos Komvopoulos, Costas Grigoropoulos and Letian Wang1; Mechanical Engineering, University of California, Berkeley, Berkeley, California, United States.

Mechanical metamaterials exhibit enhanced properties derived from their architecture. Advances in 3D printing techniques have enabled the fabrication of complicated designs even at the microscale, contributing to the progress of state of the art ultra light materials with superior mechanical features. Nevertheless, comprehending the mechanism of strain hardening that is an inherent characteristic to the structure and arrangement of the unit cells is rather limited and fairly empirical. In this study, we present a novel design of mechanical metamaterial structures influenced by the first stellation of rhombic dodecahedron, and juxtapose its mechanical behavior with one of the most meticulously studied metamaterial designs, the octet truss and its counterpart bulk material. The uniqueness of the present design is the adaptation of crystal twinning in a two-level design process of the unit cells, that is, the architecture of unit cells and their connection to adjacent unit cells. Our findings validate that this design strategy is highly efficient in enhancing the metamaterial’s strength and energy absorption potential, while simultaneously diminishing the volume occupied by the structure considerably. By performing simulations and nanoindentation tests for these metamaterial structures fabricated by two-photon lithography, we have proven that this new type of metamaterials surpasses both the bulk material and the octet truss structure, as indicated by the remarkably higher strain hardening and energy dissipation characteristics obtained for the same deformation, despite the significantly smaller volume of the first stellation structure. Our study introduces a novel design technique for controlled strength and strain hardening in mechanical metamaterials by the strategic placement of simple platonic solids to form more complex structures with deformation modes resembling those of microlattices that exhibit crystal twinning.

Acoustic Metasurface Yun Jing; Mechanical and Aerospace Engineering, North Carolina State University, Raleigh, North Carolina, United States.

Wave manipulation using artificial materials is a central topic in materials physics. Recent years have witnessed the emergence of a family of thin, 2D artificial materials, namely, metasurfaces. The concept of metasurfaces was introduced to the materials and physics communities for optical waves in 2011 with the generalized Snell's law, which opened up a new degree of freedom for optical wave manipulation. Inspired by this pioneering work, and because acoustic waves also follow the Snell's law, a flurry of activity has revealed acoustic metasurfaces for controlling sound and new applications in acoustics. However, mapping the success of electromagnetic metasurfaces to the acoustic domain is challenging, primarily owing to the intrinsic differences between electromagnetic and acoustic waves. In this talk, I will delineate the underlying fundamental physics of metasurfaces, describe their different concepts, the design strategy, and discuss their functionalities for controllable reflection, transmission, and extraordinary absorption. In particular, I will discuss our recent works on acoustic metasurface-based ultrathin sound diffusers and gradient-index metasurface-induced asymmetrical sound transmission.

Engineering the Shapes of Organic crystals to Generate Different Photomechanical Responses Fai Tong1, Rabih O. Al-Kaysi1 and Chris Bardeen1; 1Department of Chemistry, University of California, Riverside, Riverside, California, United States; 1College of Science and Health Professions, King Saud bin Abdulaziz University for Health Sciences, and King Abdullah International Medical Research Center, Ministry of National Guard Health Affairs, Rayadh, Saudi Arabia.

Solid-state photochemical reactions in molecular crystals can generate large-scale motions and shape changes. These photomechanical crystals have potential applications as light-controlled actuators and smart switches. Micro- and nanocrystals can exhibit motions like bending, twisting, curling, and jumping under light illumination. However, controlling the size and shape of molecular crystals remains a challenge because the weak van der Waals intermolecular forces between organic molecules undermine their ability to lock in a specific shape during crystallization. Besides the overall crystal shape, the orientation of the molecules within that shape should also play an important role in determining the photomechanical response. In general, the arrangement of molecules in a crystal are determined during the early stages of crystallization process. Recently, our group developed a surfactant-assisted seeded growth method to prepare single crystal platelets composed of 9-methylanilinacene (9MA) with two different internal molecular orientations in aqueous solution. The more stable form exhibits a photoinduced twisting motion and elongated hexagonal platelets undergo a photoinduced rolling-up and unrolling which can be used to wrap and translate magnetic nanoparticles with external magnetic field applied. What is more, we have extended our seed-growth technique to other anthracene derivatives. We had successfully grown uniform block-like microcrystals composed of cis-dimethyl-2,3-(anthracen-9-y)ylidylene)malonate (cis-DMAAM) in aqueous surfactant solutions. A brief pulse of light (< 405 nm) causes these crystals to undergo delamination (peeling). This peeling process can be repeated multiple times on the same microblock, uniformly peeling off layer after layer with a train of light pulses. Our results demonstrated how tuning crystal morphology (size and shape) can lead to novel modes of mechanical behavior. This novel crystal growth method generates new crystal shapes that illustrate the versatility of photomechanical molecular crystal materials.

11:30 AM CP07.06.06
Towards Programmable Optical Metasurfaces Isabelle Staude and Jürgen Sautter; Friedrich Schiller University Jena, Jena, Germany.

Optical metasurfaces composed of designed Mie-Resonant semiconductor nanoparticles arranged in a planar fashion offer unique opportunities for controlling the properties of light fields [1]. Such metasurfaces can impose a spatially variant phase shift onto an incident light field, thereby providing control over its wave front with high transmittance efficiency. They can also e.g. act as polarizing optical elements, exhibit tailored nonlinear optical properties, or manipulate spontaneous emission processes of nanoscale emitters integrated in the metasurface architecture. However, the optical response of most semiconductor metasurfaces realized so far was permanently encoded into the metasurface structure during...
fabrication. Recently, a growing amount of research is concentrating on obtaining dynamic control of their optical response, with the aim of creating metasurfaces with functionalities that can be programmed on demand. This talk will provide an overview of our recent advances in actively tunable Mie-resonant semiconductor metasurfaces. In particular, by integrating silicon metasurfaces into a liquid-crystal (LC) cell, we can tune their linear-optical transmittance and reflectance spectra by application of a voltage [2]. Importantly, this tuning approach is highly compatible with established LC industrial technologies. We, for the first time in our knowledge, utilize a LC photodalignment material [3] during the assembly of the LC metasurfaces, leading to a drastic improvement of the tuning performance and reproducibility. Based on this method, we demonstrate two electrically tunable LC-infiltrated dielectric metasurfaces working at near-infrared and visible wavelengths respectively. We show that these metasurfaces can be tuned into and out of the so-called Huygens’ regime of spectrally overlapping electric and magnetic dipolar resonances, which is characterized by near-unity resonant transmission, by application of an external voltage. In particular, we propose a novel route toward phase-only tuning by applying simultaneous electrical and thermal stimuli to the LC-infiltrated dielectric Huygens’ metasurfaces. However, while the integration of silicon metasurfaces into nematic LC cell represents an efficient and versatile tuning approach showing large resonance shifts and strong contrast tuning, the switching times that can be achieved based on this approach are limited. Thus, as an alternative tuning mechanism allowing for ultrafast operation, we consider the transient changes of the optical properties of semiconductor materials when optically pumped by femtosecond laser pulses. These changes can lead to pronounced changes of the resonance condition for semiconductor metasurfaces at an ultrafast time scale. This talk will review our recent progress in ultrafast switching and tuning of semiconductor metasurfaces based on different material platforms and different physical mechanisms occurring at an ultrafast time scale [4,5]. Furthermore, strategies to translate ultrafast tuning of metasurface resonances to ultrafast control of more complex metasurface functionalities such as wavefront shaping will be discussed.

Effect of Nucleating Particles on the Microstructure of 7075 Al Alloy Manufactured by Selective Laser Melting

Additive manufacturing has the potential to disrupt traditional fabrication methods for high add value applications because the flexibility of design, fast production speed for complex parts, and shorter lead times. However, there is currently a reduced range of metallic alloys that can be industrially processed using this technique. This is particularly problematic in the case of high strength Al alloys processed by additive manufacturing which present high porosity and an undesired microstructure formed by large columnar grains surrounded by longitudinal cracks (hot-cracking). It has been recently shown [1] that these problems can be overcome through the addition of ZrH2nanoparticles to the Al powders. In particular, hot cracking was significantly reduced and the microstructure was refined due to the stimulation of grain nucleation by the nanoparticles. In this investigation, a systematic study was carried out to analyze the effect of processing parameters (laser power and speed hatch distance) on the microstructure of 7075 Al alloy. Commercial powders of the 7075 Al alloy were mixed with zirconium dihydride particles by planetary milling without any grinding medium. Samples were additive manufactured by selective laser melting with and without zirconium hydride particles, using a wide range of process parameters. The microstructure of the processed samples was characterized by electron backscattered diffraction (EBSD), electron microscopy and transmission electron microscopy (TEM) in order to evaluate the influence of the addition of refining particles along the building direction.

The addition of ZrH2 led to an equiaxed grain structure (which was attributed to enhanced nucleation promoted by the Al-Zr precipitates) and to the elimination of hot cracking. A hardness increase of 30HV was observed in the Zr containing samples probably due to the hardening effect of an enhanced precipitate volume fraction. The effect of processing parameters on the microstructural features and on the hardness was analyzed.

Microstructure and Mechanical Properties of 316L Stainless Steel Fabricated Using Selective Laser Melting
Naveed Iqbal, Enrique Jimenez-Melero, Utkarsha Ankalkhope and Jonathan Lawrence; University of Coventry, Coventry, United Kingdom; University of Manchester, Manchester, United Kingdom; Manufacturing Technology Centre, Coventry, United Kingdom.

The microstructure variation and heterogeneity in mechanical properties of 316L stainless steel fabricated using selective laser melting (SLM) have been investigated. The crack free, dense samples were made using SS316L alloy powder and melt pool morphology was analysed using optical and scanning electron microscopy. Extremely fast cooling rates during laser melting/solidification process, accompanied by slow diffusion of alloying elements, produced distinct microstructure with colonies of fine-grain size as well as elongated grains grown along the direction of thermocapillary convection in the melt pool. Precipitates were mostly observed at the grain boundaries while some times also appeared inside grains. The micro hardness measurements along the build direction revealed slight but gradual increase in hardness along the sample height. The tensile tests of as build samples showed that the mechanical properties of samples produced using SLM were observed to be quite heterogeneous. The ultimate tensile strength (UTS) varied from 460MPa to 510MPa along with elongation variation from 3% to 15%. The corrosion behaviour of SLM samples were also investigated by exposing the tensile samples to 5% NaCl.

Corrosion properties and mechanisms of additive manufacturing (AM) alloys have shown to differ from traditional wrought and cast manufacturing methods relative to polarization and corrosion/fatigue. While a significant portion of published data indicates favorable yield, ultimate, and elongation mechanical properties, the practical discussion of structural and environmentally conditioned loading is a relatively unaddressed consideration in the design of AM metals. The discussion of this presentation addresses the standard polarization behavior of AM metal materials relative to as-built, heat treated, and variable controlled powder bed fusion and directed energy deposited metallic alloys, as well as initial reaction/formation of powder bed fusing processes and how they relate to various corrosion properties. Standard polarization testing of AM materials often indicates that AM metals compare favorably to wrought or cast pitting potentials in the laboratory setting, however crevice corrosion is accelerated even in the most controlled test environments. The US Naval Research Laboratory has studied the effects of AM materials in marine environments relative to their pitting, crevice and fatiguer corrosion/fatigue properties in order to more appropriately assess AM metals’ application to marine and naval designs. To that end, this presentation discusses the relationship of various AM processing parameters, powder feedstock, and post build processing relative to corrosion performance in seawater environments common to naval applications.

Materials tested to date include 316L stainless steel, titanium 6-aluminum, 4-vanadium and Inconel 625 alloys built using additive manufacturing produced by the laser powder-bed-fusion process (L-PBF) and directed energy deposit (DED) processes with the principal test in axial an transverse orientations. High cycle fatigue and corrosion fatigue properties of these metals were measured using crack opening compact tension fatigue and environmental fatigue ASTM standard practices. The fatigue and corrosion fatigue limits of these materials in high cycle fatigue were determined. The fatigue crack growth rate behavior in air was characterized and compared with information available in the literature. Furthermore, standard fatigue and fracture test protocol according to the most modern fatigue crack growth rate standardized procedures was completed with mixed results as a function of AM specific mechanisms affecting data production.

Laser Metal Additive Manufacturing onto Silicon Arad Azizi, Matthias A. Daemener and Scott N. Schifffres; Mechanical Engineering, Binghamton University, Binghamton, New York, United States.

We demonstrate how Sn3Ag4Ti alloy can robustly bond to silicon via selective laser melting (SLM). By employing this technology, thermal management devices (e.g., vapor chamber evaporators, heat pipes, micro-channels) can be directly printed onto the electronic package without using thermal interface materials. Reduction of the chip operating temperature up to 10 °C, consumed power and electronic-waste are some of the advantages of this technology which lies through the elimination of thermal interface materials in the electronic package. Bonding of common metal alloys used in additive manufacturing and silicon is relatively weak and generally possesses high contact angles (poor wetting and interfacial strength). However, reactivity and wettability of the silicon substrate increases drastically by using proper interlayer material. Furthermore, conventional dissimilar material bonding can take tens of minutes to form a strong bond, this study demonstrates how this kinetic limitation can be overcome to form a bond in microseconds via intense laser heating. Rapid bonding of Sn3Ag4Ti to silicon occurs through formation of a thin (~μm) titanium-silicide interfacial layer that makes the silicon wettable to the Sn3Ag4Ti. This rapid bonding occurs due to formation of strong intermetallic phases at low temperature, and by exposing of the sample by laser multiple times which provides sufficient diffusion time. The printed parts are mechanically robust with no visible failures after over a week of continuous thermal cycling (~40 °C and 130 °C).

Spotlight Talk—Optimization of Process Parameters for Additive Manufacturing Using Recycled Metal Powder Susana J. Castillo1, Anna K. Hayes1, Krishna Muralidharan1; Gregory Colvin1, B.G. Potter and Melissa Bushi1; University of Arizona, Tucson, Arizona, United States; ‘Honeywell, Tucson, Arizona, United States.

Powder bed fusion systems such as direct metal laser sintering (DMLS) provide unprecedented abilities to manufacture complex 3-D parts and structures; however, the process produces unused metal powder that can undergo significant change in chemistry and morphology. The ability to recycle the used powder that is typically found within the build volume and in the overflow compartments requires a thorough chemical and structural analysis in order to determine the extent of reusability. In this context, characterization of virgin powder and used powder for nickel-based and stainless steel based alloys was performed in this work in a rigorous fashion to compare and contrast properties such as composition, particle size distribution and morphology. This information was then used in conjunction with other process parameters (e.g. dose factor, spreader velocity, layer thickness, and laser energy density) to determine conditions that can enable the ready integration of used powder along with virgin powder. Experimental analysis was supported by ANSYS based process modeling in the optimization process, providing a path forward for cost effective additive manufacturing methods.

Spotlight Talk—Effect of Process Parameters on Characteristics of 316 L Stainless Steel Deposited by DED Joyce Miagava1, Raphael G. dos Santos1, Rafael Marzolla1 and Douglas de Alcantara2; Inspec, Sao Paulo, Brazil; "Industrias Romi S.A., Santa Barbara D'Oeste, Brazil.

With the objective of combining advantages of both additive and subtractive manufacturing, several manufacturers are developing hybrid machine tools. Directed energy deposition (DED) method was the additive manufacturing method adopted in these hybrid machines because of the adaptability of the equipment to the milling platform. In order to take advantage of a hybrid platform and obtain a work piece with a good final quality, it is necessary to understand the influence of the additive process parameters. In this work, laser power and scan speed were systematically varied to fabricate 316L test samples to determine the optimal parameters in a recent developed hybrid machining center (Romi DCM 620 5x Hybrid). Optical stereoscopy indicates that the optimal energy input is 50 J/mm². Lower energy inputs are not sufficient to melt the powder and higher energy inputs than 50 J/mm² (with a shield gas flow of 5 L/min) result in porous samples due to an oxidation between deposited layers. Chemical composition was evaluated by Scanning Electron Microscopy coupled to an Energy Dispersive X-ray detector (SEM-EDS) along the height of the samples. Even though an oxidation was observed, EDS results do not reveal any significant Cr and Ni content variation from one measured point to another. Findings of this study will be used as a basis to develop the process with other alloys in hybrid machine-tools.

Spotlight Talk—Corrosive Microstructurization of Nickel-Copper Gas Atomized Powders Stanislau Niauzorau, Aliaksandr Sharstniou and Bruno Azeredo; The Polytechnic School, Arizona State University, Mesa, Arizona, United States.

Microtextured and mesoporous metal alloys, due to its high surface area, have been widely used as fast-charging anodes for Li-ion batteries [1], as metal electrodes for electrolytic methane production [2], and for electocatalysis applications [3]. In recent years, there has been an increasing interest in designing 3-dimensional and hierarchical metal electrodes by integrating wet-chemical methods [4] with 3D printing techniques in order to design and scale topologically complex catalyst systems [5] with increased surface area [6]. In this
study, we examine a specific corrosion-based wet chemistry to induce the microtexturization of gas atomized metal alloy powder as a strategy to introduce surface roughness at microscales to AM feedstock intended for use in selective laser sintering. Microstructurization of NiCu powders was done by electroless chemical etching in 1M HNO3 with the formation of roughened surfaces with RMS at length scales from 20 nm to 5 μm. Additionally, post-processing of the etched microtextured powders in diluted HNO3 reduced the oxygen content from 4 % to 1 % by mass compared to the initial content present in the gas atomized metal powder. Thereby, development of the new controllable chemistry for modification and microtexturing of oxygen-free metal powders may be a promising way for fabrication of the new high surface area metal feedstock for 3D printing of high-surface area electrodes.

Fabrication of Robust and Lightweight Hollow Metal Lattice Structures Pawan K. Kanaujia1, Muhammad Azkhairy2, Yee Cheong Lam2 and Chang Quan Lai1; 1Temasek Laboratories, Nanyang, Nanyang Technical University, Singapore, Singapore; 2Mechanical and Aerospace Engineering, Nanyang Technological University, Singapore, Singapore.

In recent years, ultra-lightweight lattices with high stiffness, strength and resilience have been fabricated by coating polymeric microlattices with a thin layer of metal (e.g. Ni, Au) or ceramic (e.g. Al2O3). However, there is limited scalability in the production techniques, which typically involve time consuming processes such as 2-photon polymerization, atomic layer deposition and plasma etching. In this study, we aim to circumvent these limitations by making use of macroscopic stereolithography to 3D print lattices before applying a thin coat of metal through dip coating. The polymeric core of the lattices and binders in the coatings are then removed in a subsequent sintering step at ~1000 °C. The mechanical properties, morphology and chemical composition of the resulting hollow metal lattice are characterized with respect to different sintering duration and temperature. The low cost and easy processing of different shapes allow this technique to be commercially feasible for the mass production of lightweight hollow metallic structures.

Alloy Prototyping Techniques for Powder-Based Additive Manufacturing Eric A. Jagle and Dierk R. Raabe; Max-Planck-Institut für Eisenforschung, Düsseldorf, Germany.

In our research, we focus on designing and developing new alloys specifically for Additive Manufacturing. To avoid the long lead times and significant costs of purchasing bespoke alloy powders, we employ various strategies. In this talk, we present an overview of several of our approaches. First, we bypass powder atomization completely, instead judging alloy processability by laser re-melting coupons made by arc melting. This approach is mainly used for an initial, quick screening of alloy prototyping and allows the identification of compositions that are e.g. prone to hot cracking. Next, we produce alloys by mixing pure element powders in-situ. Using several powder feeders in the DED process, we produce graded specimens that allow quick screening of various alloy compositions in one specimen. This approach is particularly versatile when it is combined with site-specific microstructure analyses by electron microscopy and atom probe tomography. We also process powder mixtures in the L-PBF process, and show how the process needs to be controlled in order to achieve chemical homogeneity. We discuss the limitations of the powder mixing approach, which mainly lie in the limited processability of element combinations with very dissimilar densities and melting temperatures. Finally, we produce our own powders in a self-designed and built EIGA-type lab-scale atomizer. In this talk, we share our lessons learned in preparing very small powder batches for alloy development. The examples presented include steels, Ni-base superalloys and aluminum alloys.

2:15 PM *CP08.03.03
Nanofunctionalization for Additive Manufacturing of Crack-Free High Strength Aluminum Alloys John H. Martin1, Julie Miller1, Brennan Yahata2, Randall Schubert2, Mark O'Masta1, Eric C. Clough1, Jacob Hundley1 and Tobias Schaedler1; 1HRL Laboratories, Malibu, California, United States; 2Materials, University of California, Santa Barbara, Santa Barbara, California, United States.

The ability to 3D print aluminum alloys is an area of high interest due to the wide use of aluminum in the aerospace, automotive, and engineering industries. This range of applications requires an equally broad array of material properties that can be achieved through the various series of aluminum alloys. Recently, nanofunctionalization has been shown to be a viable technique for printing crack-free, high-strength aluminum 7075. Furthermore, this technique is fundamentally applicable to a variety of metal alloys and has now been successfully applied to 2xxx, 6xxx, and 7xxx series aluminum alloys. These alloy systems are historically highly crack susceptible due to their solute contents, freezing ranges, and microstructure evolution during welding, and by extension additive manufacturing. This work demonstrates the success of nanofunctionalization in printing crack-free aluminum alloys belonging to different alloy series, with a specific focus on microstructure evolution and mechanical properties. Attention is also paid to the expansion of the design space around aluminum alloy 3D printing made possible by this technology.

3:15 PM CP08.03.04
Developing Metal Matrix Composites via Selective Laser Melting to Optimize Manufacturability and Material Performance Steven Storck, Timothy Montalbano, Salahudin Nimer, Christopher Peitsch and Zachary Ulbig; Johns Hopkins Applied Physics Lab, Laurel, Maryland, United States.

Metal matrix composites (MMC) combine conventional materials to provide highly specialized and otherwise unattainable mechanical performance and material properties such as improved stiffness, strength, hardness, and thermal conductivity. These benefits have had restricted applications, however, because the traditional methods of MMC production, melt casting or powder metallurgy, are limited by high cost and the difficulty of forming desirable geometries. To overcome these limitations we integrated ceramic particles into a metal laser powder bed fusion (L-PBF) additive manufacturing process to enable production of highly complex geometries including topology optimized structures and lattice configurations. In this work, ceramic particles including SiC and TiB2 were introduced into aluminum and steel matrix materials to study the effects on processability in L-PBF
and resulting material properties. In addition, reactive techniques were also explored to form ceramic particles in-situ. Ceramic particles were found to enhance manufacturability during the L-PBF process by altering laser energy absorption and dispersion into the metal powder bed. Relationships between process parameters, microstructure and mechanical performance were elucidated using a combination of X-ray computed tomography, microscopy and hardness testing on samples processed under varying energy conditions. By leveraging the improved manufacturability of metal matrices due to ceramic addition, processing was tailored to result in a greater than 50% reduction in defects and reduced processing energy requirements by up to 56% allowing faster build speeds compared to the conventional metal AM processing. MMCs in complex geometries were demonstrated, and a method for producing metal-to-ceramic gradient materials was developed as another approach to maximize the benefits of both metal and ceramic phases.

3:30 PM CP08.03.05
Optimizing Process Parameters in Selective Laser Melting to Alter Thermal Conductivity  Jacob Simmons, Arad Azizi, Xiaobo Chen, Guangwen Zhou and Scott N. Schifferes; Binghamton University, Binghamton, New York, United States.

The variation in thermal conductivity of 316L stainless steel samples produced with selective laser melting with varying process parameters is investigated in the bulk and in the microscale. A critical scan rate was observed, while holding all other process parameters constant, above which the porosity started to rapidly increase. For the lowest-porosity sample, a local thermal conductivity map was produced using frequency-domain thermoreflectance. The local stainless steel thermal conductivity varied between 10.4 and 19.8 W/m-K. The average thermal conductivity of the thermal conductivity map agrees within measurement uncertainty with flash diffusivity measurements. The reduction in thermal conductivity with increasing scan rate is not fully explained by the porosity. The average measured values are less than conventionally produced bulk 316L due to the unique processing conditions of laser powder bed fusion, which modifies the crystallographic texture and microstructure. Similar trends are expected for all metal laser printed alloys. Complementary SEM and TEM characterizations will be presented.

Findings of this study will be used as a basis to develop the process with other alloys in hybrid machine-tools.

Spotlight Talk—Corrosive Microstructurization of Nickel-Copper Gas Atomized Powders  Stanislav Niazuoraz, Alaksandr Sharstniou and Bruno Azeredo; The Polytechnic School, Arizona State University, Mesa, Arizona, United States.

Microtextured and mesoporous metal alloys, due to its high surface area, have been widely used as fast-charging anodes for Li-ion batteries [1], as metal electrodes for electrolytic methane production [2], and for electrocatalysis applications [3]. In recent years, there has been a growing interest in designing architected and hierarchical metal electrodes by integrating wet-chemical methods [4] with 3D printing techniques in order to design and scale topologically complex catalyst systems [5] with increased surface area [6]. In this study, we examine a specific corrosion-based wet chemistry to induce the microtexturization of gas atomized metal alloy powder as a strategy to introduce surface roughness at microscales to AM feedstock intended for use in selective laser sintering. Microtexturization of NiCu powders was done by electropolishing chemical etching in 1M HNO3 with the formation of roughened surfaces with RMS at length scales from 20 nm to 5 μm. Additionally, post-processing of the etched microtextured powders in diluted HNO3 reduced the oxygen content from 4% to 1% by mass compared to the initial content present in the gas atomized metal powder. Thereby, development of the new controllable chemistry for modification and microtexturing of oxygen-free metal powders may be a promising way for fabrication of the new high surface area metal feedstock for 3D printing of high-surface area electrodes. Spotlight Talk—Optimization of Process Parameters for Additive Manufacturing Using Recycled Metal Powder  Susanna J. Castillo1, Anna K. Hayes1, Krishna Muralidharan1, Gregory Colvin2, B.G. Potter1 and Melissa Bush1; 1University of Arizona, Tucson, Arizona, United States; 2Honeywell, Tucson, Arizona, United States.

Powder bed fusion systems such as direct metal laser sintering (DMLS) provide unprecedented abilities to manufacture complex 3-D parts and structures; however, the process produces unused metal powder that can undergo significant change in chemistry and morphology. The ability to recycle the used powder that is typically found within the build volume and in the overflow compartments requires a thorough chemical and structural analysis in order to determine the extent of reusability. In this context, characterization of virgin powder and used powder for nickel-based and stainless steel based alloys was performed in this work in a rigorous fashion to compare and contrast properties such as...
composition, particle size distribution and morphology. This information was then used in conjunction with other process parameters (e.g. dose factor, spray velocity, layer thickness, and laser energy density) to determine conditions that can enable the ready integration of used powder along with virgin powder. Experimental analysis was supported by ANSYS-based process modeling in the optimization process, providing a path forward for cost-effective additive manufacturing methods.

Study on Thermal Stability of Nanocrystallized Inconel 718 Induced by Electropulsing Assisted Ultrasonic Surface Rolling Process

Zhiyuan Sun and Bo Li; Tsinghua University, Beijing, China.

The thermal stability of nanocrystallized Inconel 718 induced by ultrasonic surface rolling process (USRP) and electropulsing assisted ultrasonic surface rolling process (EP-USRP) in the range of 650-800 degrees Celsius was carefully investigated in the present work. The results indicated that EP-USRP specimens exhibited excellent thermal stability both in microhardness and microstructure below 750 degrees Celsius, which is higher than the normal service temperature (650 degrees Celsius) of Inconel 718. After a short time (1 h) heat treatment, the Vickers microhardness of USRP specimens and EP-USRP specimens still displayed gradient distributions with the surface value of EP-USRP specimens higher than USRP specimens. The microstructure of severe plastic deformation layer of EP-USRP specimen was thermally stable below 750 degrees Celsius. In addition, even after 10 h heat treatment, EP-USRP specimens still showed higher stability in microhardness and microstructure than USRP specimens below 750 degrees Celsius. For EP-USRP specimens at high temperatures, the more amounts of homogeneously dispersing nano-sized precipitates and the finer grains are likely the primary reasons for the observed phenomena. That is, the interaction between ultra-refined grains and nano-sized precipitates provides pinning forces and hence could endow the material with good thermal stability.

The Interplay of Metals with Carbon and Boron Nitride Nanotubes

Christoph Rohmann1,2 and Michael Zwolak2; 1IREAP, University of Maryland, College Park, Maryland, United States; 2PML, National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

The integration of nanofibers into the lattice of metals has been a long-standing goal, mainly due to the gained superior properties. Although intensive research has been undertaken to incorporate carbon based materials into metals, such as carbon fibers of carbon nanotubes (CNTs), the results have shown that these materials tend to dissolve and form undesired carbides, which are detrimental to the composite.

A viable alternative is presented in the form of boron nitride nanotubes (BNTNs), a structural analog to CNTs. Thus formed BNTN-metal-matrix-composite (BNTN/MMC) material is expected to be light weight with an improved elastic modulus, strength, toughness and thermal conductivity, while offering additional benefits in the form of a high oxidation temperature, corrosion-free and radiation shielding capabilities. We will present the results of quantum chemical calculations, of the binding strength and geometry of a variety of metals with carbon and boron nitride nanotubes with special focus on the integration of BNTNs into an Al, Ti and Cu metal matrix.

An Electrochemical 3D Printer for Room-Temperature Direct Additive Manufacturing of Multiple Metals

Matteo Chiesia1, Marco Stefancich2, Thor Sverre Minnesjord1 and Harry Apostolides1; 1Khalifa University of Science and Technology, Abu Dhabi, United Arab Emirates; 2Dubai Electricity and Water Authority, Dubai, United Arab Emirates; 1Fluid Metal 3D, Skien, Norway.

The current paradigm of metal 3D printing, based on laser sintering of metal powder, has revolutionized industrial prototyping and even manufacturing of custom parts. However, this approach, relying on high-temperature processes and expensive equipment, is poorly suited to smaller-scale applications such as the development of electronic components. We present an electrochemical 3D printer that uses localized electrodeposition of metal to directly print 3D structures at room temperature. The presented instrument consists of a 100µm-scale nozzle mounted on a 3-axis movement system similar to a conventional 3D printer, with an electrical potential applied between the nozzle and the build plate. An electroplating solution is circulated through the system so that emerges from the nozzle as a high-speed jet before impinging on the build plate, where metal ions are reduced onto the surface by electrodeposition. The jet allows the system to achieve deposition speeds many times higher than conventional electrodeposition methods by disrupting the diffusion-limited boundary layer at the deposition surface. We describe the physics of the jet-assisted electrodeposition process and derive the relationships between various parameters including current, jet speed, composition of the print solution, and print speed. Particular attention is given to the current-voltage characteristic and its relationship to jet speed; the limiting current for the deposition process and how it can be enhanced; and the impact of high current densities on deposition quality. Consideration is given to the fluid dynamics of the system, and importance of the nozzle geometry in determining the properties of the jet. We present detailed results for the printing of copper from a Cu/H2SO4 solution, preliminary results for printing nickel, and the potential for the use of other metals with different deposition solutions. We offer a detailed characterization of printed Cu, proving that the deposited metal is of high purity and density, with the expected thermal, mechanical and electrical properties. We demonstrate the printing of geometries, including freestanding 3D structures without supports, that are beyond the capabilities of conventional 3D printers; multi-material 3D printing capability; and the ability to print on non-conductive substrates, overcoming a key limitation of standard electrodeposition methods. We furthermore explore the printer’s capability as a reversible deposition/etching system, allowing for additive and subtractive processes to be combined in a single run. A promising area of application is in the prototyping of electronic circuit boards. We demonstrate how the electrochemical printer can rapidly print circuit boards, either in subtractive mode by locally etching the Cu coating from a conventional PCB, or in additive mode by directly printing conductive electrical connections onto a non-conductive substrate.

Reactive 3D Printing of Semiconductor GaN

Jarod C. Gannon, Michael Presley, Timothy Montalbano and Steven Storck; Johns Hopkins University Applied Physics Lab, Laurel, Maryland, United States.

We have demonstrated a reactive additive manufacturing process that results in the formation of single-crystal semiconductor GaN. Printed GaN regions have been fabricated through the presented method with a single GaN(002) peak present in θ/2θa-omega XRD scans, indicating a single orientation crystal film. X-ray diffraction and energy dispersive spectroscopy have been used to confirm full conversion of reactive precursors to form GaN with no remaining precursors present in the crystal structure. Through this method, single-crystal GaN films up to 1µm in thickness have been fabricated with crystal growth rates that are orders of magnitude higher than standard semiconductor synthesis methods. We will outline the semiconductor printing method as well as the challenges associated with this process including print resolution, crystal orientation and impurity control.

Texture in Electron Beam Melted Tungsten for Fusion Power

Elizabeth A. Ellis1, Michael M. Kirk1, Chase B. Joslin1, Lauren M. Garrison2, Yutai Katoh2 and Ryan R. Dehoff1; 1Manufacturing Demonstration Facility, Oak Ridge National Laboratory, Knoxville, Tennessee, United States; 2Nuclear Materials Science and Technology, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

The application of additive manufacturing (AM) techniques to problems in fusion power provides an exciting opportunity to advance both technologies. Small plasma-facing components such as divertors and armor tiles for tokamak power plants are required to withstand extremely high heat and neutron fluxes, and must therefore be manufactured from difficult-to-machine materials such as tungsten. Additive manufacturing allows fabrication of components in new geometries out of new materials, with a high degree of control over component microstructure. Microstructure is particularly important for small plasma-facing tungsten components, where intergranular fracture is a common failure mode and grain boundary placement must therefore be carefully considered. To be discussed is AM of tungsten components for fusion applications via electron beam melting (EBM). EBM offers a high degree of control over heat input, including the possibility of site-specific microstructure control by means of a point melt scan strategy. Spot melting strategies were...
Printability of CrMnFeCoNi High Entropy Alloy envisioned. Vibro-finishing was found to be an efficient post-processing method for fatigue life improvement. X-ray tomography (voxel size of 0.75 µm) also involving ex-situ fatigue crack propagation. When excessive roughness is the cause of fatigue failure, other post-treatments may be implemented. This post-treatment could be applied locally in regions of stress concentration more prone to fatigue failure. A significant improvement in fatigue life was inadmissibly low level. In this sense, friction stir processing (FSP), a post-treatment method derived from friction stir welding that has been proven useful in Al cast material, was sometimes be unavoidable to improve the fatigue life. Hot isostatic pressing (HIP) yields very satisfactory results for Ti based AM alloys and is routinely applied in this industry. The optimisation of process parameters has already been extensively studied for bulk AlSi10Mg and is provided by the machine manufacturers. Now, post-treatments may sometimes be unavoidable to improve the fatigue life. Hot isostatic pressing (HP) yields very satisfactory results for Ti based AM alloys and is routinely applied in this industry, but the typical 500°C/100MPa/2h cycle used for AlSi10Mg cast parts increases ductility, but also ruins the SLM fine microstructure, depleting mechanical strength to an inadmissibly low level. In this sense, friction stir processing (FSP), a post-treatment method derived from friction stir welding that has been proven useful in Al cast material, was implemented. This post-treatment could be applied locally in regions of stress concentration more prone to fatigue failure. A significant improvement in fatigue life was demonstrated on polished bulk samples. This is attributed to the positive impact of FSP allowing to eliminate large porosities. These porosities were studied by 3D synchrotron X-ray tomography (voxel size of 0.75 µm) also involving ex-situ fatigue crack propagation. When excessive roughness is the cause of fatigue failure, other post-treatments may be envisioned. Viro-finishing was found to be an efficient post-processing method for fatigue life improvement. Contrarily to the bulk structures mentioned above, for thin structures (typically a couple of 100µm of µm) the contouring strategy plays a dominant role on the roughness and sub-surface porosities. The surface roughness of a large variety of processed parts was compared and their origin discussed. The sub-surface porosities were studied by laboratory X-ray tomography. The post-treatments mentioned previously may cause excessive deformation of very thin samples. Thus, a contour strategy optimisation is a first step towards their fatigue resistance improvement.

Printability of CrMnFeCoNi High Entropy Alloy Son Pham; Materials, Imperial College London, London, United Kingdom.

The printability of CoCrFeMnNi high-entropy alloy in laser powder bed fusion is evaluated in this study. A single-track of the alloy was examined to study the solidification microstructure in rapid cooling. Subsequently, multi-layer builds were fabricated with different scanning strategies to study the consolidation and how the microstructure evolves in the subsequently repeated deposition. The present study shows that CoCrFeMnNi has excellent printability with high consolidation and excellent strength. Both monotonic tension and cyclic loading were carried out to study the plasticity and fatigue performance of the alloy additively manufactured with varying scanning strategies.

Transients in Plastic Instabilities During Thermo-Mechanical Reversals in Metal Additive Manufacturing Sabina C. Kumar1,2, Peyyush Nandwana2 and Sudarsanam S. Babu1,2; 1University of Tennessee, Knoxville, Tennessee, United States; 2Oak Ridge National Laboratory, Knoxville, Tennessee, United States.

Additive Manufacturing (AM) literature has shown that the final properties of AM fabricated components are influenced by the complex interactions between geometry, process parameters and alloy chemistry. These interactions can be traced back to spatial and temporal variations of thermal and mechanical signatures (i.e., T \{x, y, z, time\}). These variations affect all phenomena starting from defect formation, solidification grain structure, solid state transformation and accumulated plastic deformations. Although the above changes are similar to welding, we do observe large reversals of these signatures in AM because of the spatial and temporal transients brought about by the rapid changes in energy delivery modes. The evolution of residual stress distribution due to the non-uniform accumulation of plastic strains within the build is a common concern among all different methods of AM of metallic parts. This plastic strain evolution during repeated thermal cycling is brought about by macro scale changes in the thermal gradients, changes in thermal expansion-coefficient and crystallographic changes between phases and constitutive stress-strain properties. The fundamental response of metals and alloys that undergo solid state phase transformations while being subjected to alternating temperature (above and below the instability temperature) and stress (elastic and plastic) have not been measured before and forms the basis for the current research. The model alloy chosen to understand this complex behavior is Ti – 6Al – 4V. Thermomechanical processing of α/β titanium alloys are largely based on the β → α + β transformation on cooling. It is well known in titanium literature that α plates usually maintain a specific orientation relationship with the β matrix, referred to as the Burgers orientation relationship which is (101)β // (0001)α, and [-111]β // [2110]α. There are 12 crystallographically equivalent orientation variants of the α phase within a single β grain. Each of the variants has a different transformation strain, different degrees of elastic self-accommodation when in contact with each other and different interfacial energies when in contact with grain boundaries. Phase field simulations have shown that this leads to variant selection (i.e., some variants appear more frequently than the other) accompanying a precipitation which then led to the formation of a transformation texture or microtexture. Since the α phase has highly anisotropic in its physical and mechanical properties, this evolving microtexture will determine to a large extent the response of the alloy towards thermo-mechanical cycling. Thus, it would be detrimental if only a single or few variants of alpha percolate the whole matrix. For our research, three different scan strategies (a line scan and 2 types of spot scan) were incorporated to build 15 x 15 x 25 mm cubes, in order to get a variation of thermal gradients across the build. Initial characterization of the as fabricated Ti – 6Al – 4V cube of the line scan sample, using back scattered electrons with SEM, has shown that different α morphology has precipitated along either side of the prior β grain boundary. On one side we see a basket-weave type α while on the other side we see a fine lath type α. Further EBSD analysis has shown that the texture of α is different at the top of the cube and the bottom of the cube. Our work here illustrates the response of this α/β Ti-alloy to thermo-mechanical cycling with proper registration of boundary conditions to simulate typical thermal
cycling conditions during AM of metals. Based on the literature, we hypothesize that the response will be dictated by redistribution of global stress/strain in between the rapidly changing phase fractions (i.e., HCP - α and BCC - β). A semi-analytical heat conduction model was used to predict the transient heat transfer behavior during powder bed metal AM. Using this model we can register proper boundary conditions.

Laser Beam Melting of Large-Scale Ti-6Al-4V Parts—Increasing Productivity and Reducing Residual Stresses Dirk Herzog1,2, Katharina Bartsch1,2, Kai-Fabian Schenk1 and Claus Emmelmann1,2; 1Institute of Laser and System Technologies, Hamburg University of Technology, Hamburg, Germany; 2Fraunhofer Research Institute for Additive Manufacturing Technologies IAPT, Hamburg, Germany.

Parts made of the titanium alloy Ti-6Al-4V make up for about 50% of the titanium market. The material is today widely used for lightweight applications, e.g. in the aerospace industry. Additive Manufacturing can significantly contribute to lightweight design due to its high design freedom and only very few manufacturing restrictions. Therefore, lightweight Ti-6Al-4V parts represent some of the most promising industrial business cases for Additive Manufacturing these days, such as the brake caliper of Bugatti Chiron and brackets holding the flight crew rest compartment in the Airbus A350 produced by laser beam melting. Part integration, where larger assemblies of parts are integrated to one additively manufactured part, has shown to save additional costs in industrial applications. This leads to the desire to print ever larger parts through Additive Manufacturing technologies such as laser beam melting.

Large scale parts, with dimensions exceeding 0.3 m in at least one orientation, however feature increasing problems from residual stresses during the process. As a result, a high amount of support structures is needed to handle the stresses, which in turn causes high amount of post processing. Depending on the exact geometry, a first-time right production cannot be guaranteed or the parts are simply not manufacturable. Taking into account the comparatively low productivity of today’s laser beam melting machines it is also less economical to produce large scale parts.

In this context, a new approach for laser beam melting is proposed. Instead of optimising process parameters with regard to the highest possible density, the process parameters are optimised to yield the highest possible speed and the lowest possible residual stresses while maintaining a density above 95%. It can be shown that parts fulfilling these criteria may be fully densified through hot-isostatic pressing in a following step. The presentation will look at the differences in residual stresses in test specimens as well as in a large scale part, on the resulting microstructures, as well as on the economics of the process, which profits from a ~60% speed gain and thus reduced machine time.

SESSION CP08.07: Characterization—Microstructure Analysis and Mechanical Behavior II

Qualification of Additive Manufactured Components—Integration of Modeling, Measurement and Manufacturing Processes Sudarsanam S. Babu1,2; 1University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 2Manufacturing Demonstration Facility, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Additive manufacturing (AM) enables design and production of structural metallic components with complex geometries. Recent work has shown that, in addition to complex geometries, site-specific microstructures can be achieved through careful control of processing condition at every layer. These advances are made by leveraging the similarity of physics between welding and AM processes. The interactions between boundary conditions imposed by component geometry, wide variations of thermal signatures brought about by mode of energy delivery, and composition of the alloys can be used for qualification of AM components. This overview presentation will discuss pragmatic integration of recent innovations related to modeling, measurements and manufacturing methodologies with case studies from titanium and nickel alloys.

The first part of the paper will focus on the modeling tools for topology optimization of component geometry, process modeling of heat and mass transfer, solidification and solid-state transformations, plastic deformations, residual stress, distortion and performance of the components. The process flow involved in linking all these discrete modeling tools, challenges and future directions will be outlined with published examples from both welding and additive manufacturing. The second part of the paper will focus on the in-situ characterization of process and also correlation of the same to evolution of defects and microstructure in titanium and nickel alloys. The third part of the paper will focus on case studies involving both computational modeling and in-situ characterization to arrive at strategies for qualification of the AM components. Finally, this paper will also focus on some of the unresolved questions related to stability of interfaces between liquid and solid, solid and solid, as well as, deformation conditions within the solid during additive manufacturing and approaches to address the same.

2:00 PM *CP08.07.02
Rapid Development of Mechanical Models for Additively Manufactured Materials Michael Presley, Phillip Koshute, John Skotwinski and Christopher Peitsch; JHU/APL, Laurel, Maryland, United States.

Material property variance in powder bed fusion processes is heavily influenced by both pore like defects and microstructure, complicating extension of traditional microstructural models to optimization and qualification of AM materials. In addition while traditional A/B basis testing approaches capture variability in an ideal process, they do not allow prediction of properties for local variations in laser power, melt pool size, or powder layer thickness. As in-situ monitoring becomes more wide spread the ability to predict the impacts of these common deviations will be vital to process certification. In this work we demonstrate how simple nonlinear regression techniques including neural networks and random forests can be used to quickly model the influence of lack of fusion defects on mechanical properties of Ti64. These models can then be leveraged to predict experimental regions of interest to minimize the number of high cost experiments needed for more in depth analysis. 128 vertical Ti64 ASTM ES tensile bars were produced using different laser processing parameters on a Renishaw AM400. Four parameters were varied using a Latin hyperecube sampling approach: laser power, hatch distance, point distance, and exposure time. Test outputs were modulus, ductile vs. brittle fracture, yield strength, and ultimate tensile strength. Given a set of processing conditions, predictive models were developed that could successfully predict ductile vs. brittle fracture at 84% accuracy, and yield strength within 90%. Five samples selected to span the entire mechanical output range were further analyzed using X-Ray computed tomography to evaluate the degree of lack of fusion cracking and explain underlying microstructural basis for varying mechanical behavior. Going forward, these models can be used both to estimate process variability and selectively tailor AM parts for desired mechanical performance.

Microstructural Analysis and Mechanical Behavior of a High Entropy Alloy Produced with Selective Laser Melting (SLM) Nikole Kucza1, Michelle A. Othon1, Mallikarjun Karadge1, Daniel Ruscito1, Cole Crawford1, Keith Lauria1, Richard J. Blair1, Raul Rebak1, Martin Morra1 and Kosuke Kuwabara1; GE Global Research, Niskayuna, New York, United States; 2Global Research & Innovation Technology Center GRIT, Hitachi Metals Ltd., Kumagaya, Japan.

A CoCrFeNiTiMo-based high entropy alloy (HEA) powder was used to successfully print near-net-shape hardware and test-blocks for examination of selective laser melting (SLM) materials properties. Additive manufacturing (AM) has enabled the manufacture of this difficult-to-process material. By simultaneously exploiting the fast cooling rate of industry. Additive Manufacturing can significantly contribute to lightweight design due to its high design freedom and only very few manufacturing restrictions. Therefore, lightweight Ti-6Al-4V parts represent some of the most promising industrial business cases for Additive Manufacturing these days, such as the brake caliper of Bugatti Chiron and brackets holding the flight crew rest compartment in the Airbus A350 produced by laser beam melting. Part integration, where larger assemblies of parts are integrated to one additively manufactured part, has shown to save additional costs in industrial applications. This leads to the desire to print ever larger parts through Additive Manufacturing technologies such as laser beam melting.

Large scale parts, with dimensions exceeding 0.3 m in at least one orientation, however feature increasing problems from residual stresses during the process. As a result, a high amount of support structures is needed to handle the stresses, which in turn causes high amount of post processing. Depending on the exact geometry, a first-time right production cannot be guaranteed or the parts are simply not manufacturable. Taking into account the comparatively low productivity of today’s laser beam melting machines it is also less economical to produce large scale parts.

In this context, a new approach for laser beam melting is proposed. Instead of optimising process parameters with regard to the highest possible density, the process parameters are optimised to yield the highest possible speed and the lowest possible residual stresses while maintaining a density above 95%. It can be shown that parts fulfilling these criteria may be fully densified through hot-isostatic pressing in a following step. The presentation will look at the differences in residual stresses in test specimens as well as in a large scale part, on the resulting microstructures, as well as on the economics of the process, which profits from a ~60% speed gain and thus reduced machine time.
Additively manufactured metallic materials are known to exhibit high levels of micro-structural inhomogeneity, defects and residual stress. These undesirable features originate from the non-equilibrium manufacturing process involving very high spatial and temporal gradients in temperature. As a result, these materials have defects spanning multiple length-scales and suffers from drastic loss in ductility and toughness. The conventional approach to mitigate this issue is to perform thermal treatment, such as annealing or hot isostatic pressing.

In this study, we explore an alternate route that is non-thermal in nature. The selected material was Ti-6Al-4V alloy manufacture using laser-based, directed energy- deposition system. Thin section (50-150 microns) specimens were prepared to be used in an experimental setup that allows us to study the synergy of electrical current and tensile strain instead of temperature. Our approach involves passing electrical current in the specimens at much lower current density than the electro-migration damage limit. This directly causes Joule heating, which is eliminated by both passive and active heat removal techniques to keep the specimen temperature at or near ambient conditions. We then study the role of mechanical strain on the grain growth at room temperature. The experiments were performed inside a SEM with Electron back scattered diffraction (EBSD) for in-situ characterization. For electrical tuning below 150 °C, the fraction of kernels with misorientation less than 2° increased to ~70% and 99%, respectively; whereas the kernels with misorientation greater than 4° dropped to ~9% and 0%, respectively. These changes are with respect to the as-deposited specimen materials, which is a clear evidence of the reduction/elimination of residual strain via electric field annealing.

4:00 PM CP08.07.05
Evaluation of a Learning Tool for In Situ Monitoring of Metal Additive Manufacturing Brent Valle1, Karel Lietaert1, Fatania Antler2, John Newman2, Erik Xiao2, Sam Crock3 and Jonas Van Vaerenbergh1; 13D Systems, Leuven, Belgium; 2KLA Tencor, Milpitas, California, United States.

This study describes a multi-channel in-situ monitoring system developed to better understand defect formation signatures in metal additive manufacturing. Three high-speed imaging modes coupled with an image computer capable of processing and storing these data streams allowed an examination of defect formations signatures and mechanisms. It was found that defects later detected in x-ray computed tomography (CT) scans were related to regions with anomalous heat signatures and powder bed morphology. Automated defect detection algorithms based on these defect signatures captured 80% of defects greater than 300µm.

4:15 PM CP08.07.06
Nanoindentation Based Investigation of Additively Manufactured Inconel 718 at High Temperature Tyler Palma1, Ali Beheshti2 and Keivan Davami2; 1Lamar University, Beaumont, Texas, United States; 2George Mason University, Fairfax, Virginia, United States.

Advanced alloy materials are frequently utilized in applications comprising extreme conditions such as high temperatures or corrosive materials. Nickel chromium based alloys are one such group which is commonly used in industries including jet engine manufacturing, thermal and nuclear power generation, and petroleum engineering, and thus it is crucial to learn how reliably they operate at various scales and in different conditions. There is broad interest in further understanding the mechanical behaviors and reliability of these advanced alloys in settings which more closely mimic those in which they are applied, particularly pertaining to how they are affected at the nano and microscales. This work focuses on the experimental investigation of one such alloy, Inconel 718, which has been fabricated by means of additive manufacturing, and the dependence of its mechanical properties on temperatures ranging from –200 °C up to 800 °C. Advanced nanoindentation methods are used to characterize mechanical and tribological properties, including tribological responses, creep behaviors, and the variation of cracking thresholds for the determination of fracture toughness. Previous work has shown that mechanical properties in such alloys can be altered by variation of their environment, and it is reported that for large changes in temperature there are noticeable effects in the basic mechanical properties such as hardness and elastic modulus, which was seen to decrease by nearly 30 % at increased temperature, as well as more vital qualities like fracture behavior. It was concluded that the fracture toughness of additively manufactured Inconel 718 at room temperature is approximately 70 MPa-m²/2, and the cracking threshold load is variable and is dependent on the material temperature.

10:30 AM CP09.01.01
Electrically Driven Three-Dimensional Solitary Waves as Director Bullets in Nematic Liquid Crystals Oleg D. Lavrentovich1, Bing-Xiang Li2, Rui-Lin Xiao2 and Sergij Shyanovskii; 1Advanced Materials and Liquid Crystal Institute, Department of Physics, Kent State University, Kent, Ohio, United States; 2Advanced Materials and Liquid
Electric field induced collective reorientation of nematic liquid crystal molecules is of importance for fundamental science and practical applications. This reorientation is either homogeneous over the area of electrodes, as in displays, or periodically modulated, as in electroconvection. The question is whether spatially localized three-dimensional solitary waves of molecular reorientation could be created. Here we demonstrate that the electric field can produce particle-like propagating solitary waves representing self-trapped “bullets” of oscillating molecular director. The oscillations are of the same frequency as the frequency of the driving electric field. These director bullets lack fore-aft symmetry and move with a very high speed perpendicularly to the electric field. They can move either parallel or perpendicularly to the initial alignment direction. The solitons moving perpendicularly to the director have been described in recent publication by our research team, see B.-X. Li et al, Nature Communications, volume 9, 2912 (2018). The bullets are true solitons that preserve spatially-confined shapes and survive collisions. The solitons are topologically equivalent to the uniform state and have no static analogs, thus exhibiting a particle-wave duality. Their shape, speed, and interactions depend strongly on the material parameters, which opens a door for a broad range of future studies. The work is supported by NSF DMREF grant DMS-1729509.

11:00 AM *CP09.01.02 Spherical Particle in Nematic Liquid Crystal Under an External Field—The Saturn Ring Regime Stan Alama1; Lin Brennard1 and Xavier Lamy2; 1Math and Stats, McMaster University, Hamilton, Ontario, Canada; 2Institut de Mathématique, Univ de Toulouse Paul Sabatier, Toulouse, France.

We consider a nematic liquid crystal occupying the exterior region in $\mathbb{R}^3$ outside of a spherical particle, with radial strong anchoring. Within the context of the Landau-de Gennes theory, we study minimizers subject to an external field, modelled by an additional term which favors nematic alignment parallel to the field. When the external field is high enough we obtain a scaling law for the energy. The energy scale corresponds to minimizers concentrating their energy in a boundary layer around the particle, with quadrupolar symmetry. This suggests the presence of a Saturn ring defect around the particle, rather than a dipolar director field typical of a point defect. This is joint work with Stan Alama (McMaster) and Xavier Lamy (Institut de Mathématique, Université de Toulouse Paul Sabatier.)

11:30 AM *CP09.01.03 Chromonic Liquid Crystals and Bacteriophage Viruses Maria-Carme Calderer; University of Minnesota, Minneapolis, Minnesota, United States.

Lyotropic Chromonic Liquid Crystals (LCLCs) consist of disk, plank-like molecules with rigid cores and ionic groups in the periphery, that undergo phase transitions from isotropic to hexagonal columnar phases as the concentration increases. The chromonic liquid crystal family embraces a very broad range of materials ranging from nucleotides, DNA and RNA to dyes and food additives (e.g. Sunset Yellow), proteins and pharmaceutical products. With the addition of condensing agents, such as pEG and spermine, the columns are found to aggregate into faceted, elongated toroidal clusters, with a typical size of 200 microns, with pressures of the order of 0.1 atmospheres. Double-stranded DNA in free solution also forms toroidal aggregates in the presence of condensing agents, but with cluster sizes about 100,000 times smaller than those formed by DSCG. An important class of chromonic aggregates are those formed by bacteriophage viruses as their dsDNA spoils into an ordered structure inside the capsid. Typical viral capsids measure about 50 nm and sustain pressures of the order of 30-60 atmospheres. These large pressure values result from the competition of the high bending resistance of the DNA filament with the repulsive electrostatic force between neighboring strands.

The increased awareness of the relevant role that bacteriophage viruses may have in controlling bacterial infection processes motivates our study of such systems. In this presentation, I will discuss two models of chromonic cluster formation, one purely mechanical and a more comprehensive second model that accounts for the permeability of the capsid and changes in its polyelectrolyte environment.

SESSION CP09.02: Mathematical Methods in Design of New Materials and Applications
Session Chairs: Patricia Bauman and Dmitry Golovaty
Tuesday Afternoon, April 23, 2019
PCC West, 100 Level, Room 106 B

1:30 PM *CP09.02.01 The Direct Conversion of Heat to Electricity Using Ferroelectric Oxides Richard D. James; University of Minnesota, Minneapolis, Minnesota, United States.

We describe recent progress on materials and devices for the direct conversion of heat to electricity applicable to the small temperature difference regime, 10-200 C. We are pursuing an idea based on the use of first order phase transformations in epitaxial ferroelectric oxide films. It is a “direct” method in the sense that there is no separate electrical generator. We develop a mathematical theory of this method and apply it to the design of the materials and devices and the analysis of cycles. We compare theoretical predictions and the behavior of a prototype under cyclic heating/cooling. These devices provide interesting possible ways to recover the vast amounts of energy stored on earth at small temperature difference. They move heat produced by natural and man-made sources from higher to lower temperature and therefore contribute negatively to global warming.

2:00 PM *CP09.02.02 Design of Nematics Through Colloidal Homogenisation Arabir D. Zarnescu1,2; 1,2Basque Center for Applied Mathematics, Bilbao, Spain; 1“Simion Stoilow” Institute of Mathematics, Bucharest, Romania.

We work within the framework of Landau-de Gennes variational theory of nematics and show how one can obtain from a given nematic material, say A, a desired a posteriori prescribed nematic material, say B, through a suitable homogenisation procedure of suitably chosen (depending on A and B) colloidal inclusions. This is joint work with Giacomo Canevari (Basque Center for Applied Mathematics).

2:30 PM *CP09.02.03 Hidden Variables and Internal Scales in Composite Materials Elena Cherkaeve; University of Utah, Salt Lake City, Utah, United States.

Formulations of problems governing the behavior of the fields in composite materials and heterogeneous media with microstructure often contain internal or hidden variables that model the influence of the processes on the microstructural level. The talk discusses a set of internal variables that are naturally related to the structure of a composite. These hidden variables determine the characteristic internal scales in the composite corresponding to the microlevel processes of different characteristic wavelengths. The parameters of composite’s microgeometry are incorporated into the internal variables through the spectral measure in the Stieltjes analytic representation of the effective properties of the composite; this spectral measure determines the equations for the evolution of the internal variables. The spectral measure contains all information about the geometry of the media on the microscale and links it through the hidden variables to the behavior of the material on the macroscale.

3:00 PM BREAK

3:30 PM CP09.02.04 Flow Effects in High-Frequency Homogenization of Porous Media in Electromagnetic Heat Exchangers Hrut Tilley; Vadim V. Yakovlev and Joseph M. Gaone; Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

Electromagnetic (EM) heat exchangers are devices which absorb EM radiation converting it into thermal energy to do mechanical work. Applications involving both solar and microwave energy have garnered increasing attention but have yet to utilize the potential benefits of short-wave interactions with the local geometry when the wavelength is comparable to a material’s microstructure. It has been shown for a three-layer laminate that Bragg resonance occurs in this case, and this resonance can be used to control steady
state temperature and thermal runaway effects. We investigate these effects in a mathematical model approximating a porous medium for use in a heat exchanger. Classical homogenization methods average over the microscale to obtain a macroscopic description of the material, however, they are incapable of describing short-wave behavior. High-frequency homogenization methods have been developed, but they are restricted to cases incompatible with modeling heat exchangers, such as assuming a lossless medium, spatially uniform dielectric constants, and reducing Maxwell’s equations to the Helmholtz equation. Here we develop a high-frequency homogenization technique that relax these assumptions, considering a laminate geometry composed of alternating layers of lossy dielectric material and lossless fluid channels in the homogenization limit. The presence of flow in the three-layer laminate is shown to induce sharp, but controlled, increases in the spanwise average temperature. The effects of slow flow along with thermal transport throughout the effective medium are also discussed.

3:45 PM CP09.02.01
Predicting Dynamic Properties of Computer Designed Metal-Organic Frameworks by Deep Learning Weiwei Zhang1, Chengxi Yang2, Matthew Campbell2 and Alex Greenay1, 2 Materials Science and Engineering, University of California, University of California, Riverside, Riverside, California, United States; 3 School of Mechanical, Industrial, & Manufacturing Engineering, Oregon State University, Corvallis, Oregon, United States.

Metal-Organic Frameworks (MOFs) are found to be one of the best materials for gas storage because of their large surface area and high flexibility. MOFs are compound with metallic nodes and organic linkers. We have developed an automated system to design the linkers for MOF by computer. This approach formally encompasses a design space of molecules that is astronomically large and beyond the brute force exploration by computer. In order to accelerate the search of this space, we have tested machine learning methods for forecasting several different forms of linker molecules' mechanical behavior from the structure. Two systems representing the structures, high order geometric moments and blurred voxelization, were taken as well-performed features for deep learning artificial neural networks to be trained for dynamic, physics and chemical properties with high accuracy. The capability of predicting the evaluation results rather than experiment or simulating calculation will accelerate the search of new materials in a vast design space. The result shows that with the system size grows, the prediction will be more accurate.

4:00 PM CP09.02.02

Dislocations are fundamental defects that mediate plastic deformation in metals. Studies of dislocation core structures have relied on a variety of coupling techniques to manage the far-field strain fields; one very successful approach for pure materials has been the flexible boundary condition method based on the lattice Green function. However, the treatment of dislocations in random alloys with atomic-level detail is significantly more challenging due to the range of environments: both local relaxation of atoms as well as the long-range field must be considered, and there is lack of efficient and accurate approaches to treat both. Here, we describe a method to calculate the dislocation core of non-dilute BCC binary random alloy efficiently by combining the first-principle calculation with an optimized multicomponent Gaussian Approximation Potential (GAP) specially designed for use with flexible boundary conditions. We use density functional theory to compute the energies, forces, elastic constants and force constants of BCC-based Ti-Mo ordered and disordered structures at zero and finite temperatures. This provides the database for our optimized Ti-Mo GAP model that accurately reproduces first and second derivatives of energies for a range of structures relevant to a dislocation. The GAP model relaxes a large dislocation geometry with random chemical species, and then the force constants for the full dislocation are computed and the lattice Green function constructed. This initial step is crucial, as flexible boundary condition methods leave far-field forces unchanged through the relaxation process. Finally, boundary conditions can be used with density-functional theory to compute the core structure of a random alloy.

4:15 PM CP09.02.07
Flow Instability Mechanism for Formation of Self-Ordered Porous Anodic Oxide Films Pratyush Mishra and Kurt R. Hebert; Department of Chemical and Biological Engineering, Iowa State University, Ames, Iowa, United States.

Electrochemical oxidation of aluminum in electrolytes that dissolve the oxide produces porous anodic oxides (PAO). For specific ranges of anodic voltages and electrolytes, highly ordered hexagonally arranged pores are formed with a well-defined scaling relationship between the spacing of nanoscale pores and the anodizing voltage. Nano PAO has been used for a wide range of applications, including dye-sensitized solar cells, biosensors, and templates for secondary nanomaterials such as carbon, polymers and semiconductor materials. Despite the diverse applications, the mechanism for self-ordering is not yet clearly understood. Recent studies have demonstrated the importance of oxide flow and mechanical stress generation during PAO formation. Here a mathematical model is developed that includes oxide flow as an essential mechanism that drives porous growth, combined with ionic migration and electrochemical reactions in the oxide. The oxide flow is driven by mechanical stresses at oxide film interfaces, volume expansion associated with electrochemical reactions and transport of species, and divergence of ionic migration flux in the oxide. A morphological stability analysis is performed at the inception of instability that leads to the formation of steady-state porous film. Shape evolution at both metal and solution interfaces is included, in contrast to our prior model in which the metal interface was fixed. Instability at the solution interface is determined by the competitive effects of destabilizing surface stress driven oxide flow and stabilizing oxygen ionic migration flux. Metal interface evolution results in a new instability mode due to pressure-driven flow driven by the surface stress at the solution interface. As a result, the present model predicts voltage-dependent pore spacing in good agreement with experimentally observed value. The model determines the sensitivity of pattern formation to critical process parameters and predicts their range of values required for the self-organization of PAO.

4:30 PM CP09.02.08
A Fully Coupled Diffusion-Mechanical Finite Element Modeling for Tin Dioxide-Coated Copper Anode System in Lithium-Ion Batteries Kyung Jae Jeong1, Hoon-Hwee Cho2 and Haeung Nam Han1; 1 Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of); 2 Materials Science and Engineering, Hanyang National University, Daejon, Korea (the Republic of).

As the demand for lithium-ion batteries (LIBs) with high energy density, faster charging times and longer lifetimes has been increasing explosively, it has become very important to understand the huge volume change phenomenon during lithium-ion insertion and extraction in electrodes since those can affect mechanical stability in LIBs. Several finite element (FE) simulation models have been developed to investigate the diffusion of lithium-ion and the corresponding mechanical behavior in anode materials. However, all of the models share a common drawback in that they did not take the effect of hydrostatic stress into account caused by lithium-ion insertion. When a relatively high charging rate is required, it could be essential to consider the effect of hydrostatic pressure inside anodes in order to precisely describing the diffusion behavior of lithium-ion because the surface-locking problem occurs. In this study, we propose a fully coupled diffusion-stress FE model that simultaneously solves the diffusion process and stress equilibrium equations by taking into consideration the mechanical contact between the tin dioxide active layer and the copper foam, and the hydrostatic stress gradient inside the active layer as well as the complex geometric structures. The numerically calculated strain values are compared with the experimental strain data collected in operando using X-ray diffraction. The computed strain histories are in good agreement with the measured data, enabling the possibility of precisely predicting the mechanical behavior and performance of anode materials in LIBs by only using numerical FE modeling.

SESSIO10 CP09.03: Evolution of Interfaces and Grain Growth

Session Chair: Patricia Bauman and Dmitry Golovaty

Wednesday Morning, April 24, 2019
PCC West, 100 Level, Room 106 B

8:30 AM CP09.03.01

Phase field modeling is a powerful and versatile method used for the study of microstructure evolution, as it allows the prediction of arbitrarily complex microstructures of multi-
phase systems using continuous variables such as the solute concentration, and the order parameters, which act as phase identifiers. In order to compare the phase field predictions to experimental observations, recent work has focused on developing quantitative models that accurately describe the chemical and elastic properties of the systems of interest. However, quantitatively describing the kinetic properties of a system in a phase field model is not straightforward. Although the diffusion coefficient D of the solute might be known experimentally, the mobility L of the order parameters cannot be directly measured. As a result, L is often arbitrarily fixed to describe either a diffusion-controlled process or a reaction-controlled process. In this study, a method is developed to determine the value of the kinetic parameter L based on a comparison between experimental observations and simulation results. This method is applied to the study of zirconium hydride precipitation.

8:45 AM CP09.03.02 Multi-Phase Field Model of Localized Corrosion Kinetics with Corrosion Products Formation Talha Q. Ansari and San-Qiang Shi; The Hong Kong Polytechnic University, Hong Kong, Hong Kong.

Localized corrosion is one of the complex forms of corrosion which makes it difficult to detect and design-against. During metal corrosion in the corrosive environment, corrosion products are also formed as a result of electrochemical reactions inside the electrolyte. These products can precipitate on the corroding surface and stop/ slowdown the overall corrosion process. In order to understand this complex phenomenon, a multi-phase field model is proposed to simulate metal corrosion with corrosion products formation. Both anodic (metal oxidation) and cathodic (oxygen reduction) reactions along with other electrochemical reactions in the electrolyte are considered. The free energy of the system is described in terms of its metal ion concentration and the order parameters. Rather than considering linear kinetics (Allen-Cahn equation), inspired from classical rate theory, non-linear kinetics (Butler-Volmer) is considered to describe the temporal evolution of order parameters. The time dependent evolution of ionic species is governed by Nernst-Plank equations while electrostatic potential is governed by Poisson equation. The model results are compared with experimental findings and several examples are presented to show the practical applications of this model. One interesting example, which can be studied in detail with this methodology, is the formation of metal oxide nanowires (zinc/ aluminum oxide).

9:00 AM CP09.03.03 Precipitation and Strengthening Modeling for Disk-Shaped Particles in Aluminum Alloys—Size Distribution Considered Yue Li1,2,3, Hongxiang Li2 and Qiang Du2; 1University of Science and Technology Beijing, Beijing, China; 2SINTEF, Oslo, Norway; 3Norwegian University of Science and Technology, Trondheim, Norway.

For an ICME (Integrated Computational Material Engineering) modeling framework to be used for the age-hardening aluminum alloy design and heat treatment parameters optimization, it is critical to take into account the geometric shape of precipitates, as it is tightly related to the precipitation kinetics and particles’ hardening effect. The aim of this study is to present such an ICME modeling approach to describe the precipitation of disk-shaped hardening particles during aging treatment and predict the final yield strength. The classical Kampmann-Wagner Numerical (KWN) model is extended to consider the influence of disk-shaped particle morphology on growth kinetics. The extension consists of two correction factors to the growth rate equation and to the Gibbs-Thomson effect. The extended model, coupled with a metastable thermodynamic database, is applied to simulate precipitation kinetics of Al-Cu and Al-Mg-Zn alloys during aging treatment. The predicted microstructural features are in reasonable agreement with the reported experimental observations. Furthermore, a strengthening model for disk-shaped particles, which considers the size distributions of precipitates, is developed. The predicted yield strengths are compared with reported tensile test results and with predictions from other strength models. Unlike other models, the proposed strength model can reveal the strength contribution from disk-shaped precipitates without an additional tuning parameter for accounting for the impact of the mean particle spacing in the slip plane.

9:15 AM CP09.03.04 Refraction with Phase Discontinuities on Nonflat Metasurfaces Eric Stachura1, Cristian Gutierrez2 and Luca Pallucchini2; 1Kennesaw State University, Marietta, Georgia, United States; 2Mathematics, Temple University, Philadelphia, Pennsylvania, United States.

We provide a mathematical approach to study metasurfaces in nonflat geometries. Analytical conditions between the curvature of the surface and the set of refracted directions are introduced to guarantee the existence of phase discontinuities. Both the far field and near field cases are considered. The starting point is a vector form of Snell’s law in the presence of discontinuities on interfaces.

Our results are new since metasurfaces considered in the literature are normally flat, and the incoming radiation is directly normal to the surface. Our analysis allows for the possibility of designing non-flat metasurfaces for optical applications. In particular, we allow for a variable set of directions in which we want to refract radiation. There is a compatibility condition between the variable field and the surface that must be satisfied; in the case that the field is constant, this condition is trivially satisfied.

Our general analysis includes planar and spherical lenses as special cases, and we recover previous work of F. Capasso et. al. when the surface is a plane or a sphere, as one would expect.

This is joint work with C. E. Gutierrez and L. Pallucchini (Temple University).

9:30 AM *CP09.03.05 On the Voronoi Implicit Interface Method Alexander Zaitzeff, Selim Esedoglu and Krishna Garikipati; University of Michigan, Ann Arbor, Michigan, United States.

We present careful numerical convergence studies, using parameterized curves to reach very high resolutions in two dimensions, of a level set method for multiphase curvature motion known as the Voronoi implicit interface method. Our tests demonstrate that in the unequal, additive surface tension case, the Voronoi implicit interface method does not converge to the desired limit. We then present a variant that maintains the spirit of the original algorithm, and appears to fix the non-convergence.

10:00 AM BREAK

10:30 AM *CP09.03.06 Theory and Modeling of Abnormal Grain Growth Elizabeth A. Holm1 and Carl E. Krill2; 1Carnegie Mellon University, Pittsburgh, Pennsylvania, United States; 2Ulm University, Ulm, Germany.

Abnormal grain growth (AGG) occurs when an individual grain grows faster than the mean growth rate, and so achieves a size advantage that increases with time. AGG occurs in a wide variety of polycrystalline systems, including superalloys, nanocrystalline metals, and functional ceramics, and it can be desirable or detrimental. Despite its technological importance, the mechanisms and outcomes of AGG are not fully understood. In this presentation, we review AGG phenomenology and discuss the universal characteristics of AGG, namely the growth advantage and the persistence mechanism. Two approaches to modeling AGG are developed: A statistical model predicts the frequency of abnormal growth events as a function of microstructural characteristics and grain boundary properties, but does not capture the growth trajectories or morphologies of individual grains. In contrast, a local model based on grain boundary breakaway provides insight into the effects of grain characteristics and environment on the likelihood that a given grain will grow abnormally and on its outcome morphology. We will conclude by outlining the remaining knowledge gaps that may provide fruitful areas for further research.

11:00 AM *CP09.03.07 Shape and Composition Control in 2D-TMD Alloy Sheets—Benjamin "MoSe2" Franklin David J. Srolovitz1,2, Joel Berry1, Simeon Ristic2 and Songsong Zhou2; 1Materials Science and Engineering, City University of Hong Kong, Kowloon, Hong Kong; 2Materials Science and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 3Hong Kong Institute for Advanced Study, City University of Hong Kong, Kowloon, Hong Kong.
Many transition metal (TM) dichalcogenide (TMD) trilayer sheets may be alloyed in the upper or lower chalcogen layers or within the TM layer. Since alloying elements typically are of different size than the atoms for which they substitute, alloying leads to localized strain which may cause bending in a free standing TMD sheet. On the other hand, bending the sheet creates spatially-localized site preference for the different alloying elements. This effect can be used to impart 3D sheet shapes through composition patterning or composition patterning through sheet bending. In this presentation we focus on shape and composition programming in MoSe$_2$S$_{0.5}$Te$_{0.5}$, i.e., MoSeS. We develop a compositional strategy to do this through a quantitative, first principles-informed continuum model for the coupled mechanics and alloy thermodynamics. We apply this method to optimizing the MoSeS composition profile to reproduce the topography of a Benjamin Franklin half-dollar coin. Non-uniform spatial composition distributions give rise to electric dipoles that may lie in-plane or perpendicular to the plane of the sheet (Janus structures). The shape of such compositionally-modulated Janus sheets may be dynamically actuated through application of an electric field.

11:30 AM CP09.03.08

Gamma-Convergence of Threshold Dynamics Algorithms

Tiago Salvador and Selim Esedoglu; University of Michigan, Ann Arbor, Michigan, United States.

I will report on recent developments in a class of algorithms, known as threshold dynamics, for computing the motion of interfaces by mean curvature. These algorithms try to generate the desired interfacial motion by alternating two very simple operations: convolution, and thresholding. I will present a simplified version of the threshold dynamics algorithm given in the work of Esedoglu and Otto (2015) for the isotropic multiphase case that does not require the use of retardation functions. I will discuss the stability and convergence of the proposed algorithm, and threshold dynamics in general, which rely heavily on the positivity of the convolution kernel and its Fourier transform. Some counterexamples in which Γ-convergence fails in the very simple isotropic, multiphase case will also be presented. Finally, I will discuss recent results on Γ-convergence of the two phase, anisotropic case for sign changing kernels. Our contribution, which will also be discussed, is enlarging the class of admissible sign changing kernels since it is possible to construct interesting anisotropies not covered by the previous work. Joint work with Selim Esedoglu.

11:45 AM CP09.03.09

Mathematical Modelling Beyond Computation—An Example on Epitaxial Growth of Magnetic Films for Tailoring of Magnetic Anisotropy

Artur Braun; Empa, Duesseldorf, Switzerland.

Epitaxial growth of metal films is an established and mature technology. The management of epitaxial strain is not a technical burden and difficulty, but opens new opportunities and functionalities in heterostructure materials. I am presenting here a case where epitaxial strain is exploited for the manipulation of the magnetic anisotropy, for example for applications in magnetic data storage. The materials engineer has only a limited set of materials and process parameters available, all of which shall be entered in an analytical mathematical model. In particular are these the elasticity of substrate including its lattice constant, and the magnetic parameters of the evaporation material including its lattice constant, plus the final film thickness. From these choices the elastic constants of the film material are immediately derived by standard materials databases. Now, an energy balance approach is used to enter the mathematical modelling. The result is a closed mathematical expression for the thickness (critical reorientation thickness) for the epitaxial film beyond which the magnetization axis switches into the film plane. The approach requires virtually no computing power. The model is tested for three different materials systems and delivers good match.

hydrodynamics interactions enhance MIPS. The transition to a phase-separated state strongly depends on the nature of the swimmer’s flow field, with an increased tendency toward MIPS for pullers, a reduced tendency for pushers. Thus, hydrodynamic interactions show opposing effects on MIPS for spherical and elongated microswimmers, and details of the propulsion mechanism of biological microswimmers may be very important to determine their collective behavior.

Hydrodynamic interactions play a particular role in systems with a large number of internal degrees of freedom like in filamentous, polymer-like structures. As simulation and analytical studies show, activity leads to swelling of flexible polymers, shrinkage and reswelling of semiflexible polymers, and an enhanced dynamics [3]. In such systems, hydrodynamics enhances shrinkage, modifies swelling significantly, and changes the intramolecular dynamics. The shrinkage, even in the presence of excluded-volume interactions, results in an enhanced packing, which might be important for polymer organization in confinement.

4:30 PM CP09.04.06
First-Principles Calculation of Third-Order Elastic Constants via Numerical Differentiation of the Second Piola-Kirchhoff Stress Tensor
Angelo Bongiorno; College of Staten Island - CUNY, Staten Island, New York, United States.

Third-order elastic constants allow to quantify and characterize the nonlinear elastic properties of a material, e.g. thermal expansion, Gruneman parameters, specific heats, sound wave mixing and attenuation, and elastic phase transitions. Measuring these physical parameters is difficult and prone to large errors, whereas current methods based on fitting energy-density curves, strain curves work well only for high symmetry crystals.

In this paper, we present and illustrate a novel method to calculate from first principles the full set of third-order elastic constants of a material of arbitrary symmetry. The method relies on a periodic first-principles scheme to calculate the Cauchy stress tensor of a material and numerical differentiation of the second Piola-Kirchhoff stress tensor to evaluate the elastic constants. Here we discuss an implementation of this method based on the use of a plane-wave density functional theory scheme to calculate the Cauchy stress tensor. In particular, we show that finite difference formulas lead to a cancellation of the finite basis set errors, whereas we propose simple solutions to eliminate the numerical errors arising from the use of Fourier interpolation techniques. Then, we show applications of our method to diamond, silicon, aluminium, magnesium, graphene, and a graphite conformer. In all cases, our method is shown to give results in excellent agreement with both the experiments and previous calculations based on fitting energy-density curves, thereby demonstrating both accuracy, validity, and generality of our new computational approach to investigate nonlinear elastic behaviors of materials.
Despite rapid penetration of computer technologies practically in any area of data analysis, manual peak labeling still remains the main technique for mass spectrum peaks identification procedure is crucial for accurate interpretation of the measured data [2, 3]. Of mass-spectrometry data [1] and requires preliminary establishing of correct correspondence between the peaks in the spectrum and the particular atomic species. This peak identification procedure is crucial for accurate interpretation of the measured data [2, 3].

Despite rapid penetration of computer technologies practically in any area of data analysis, manual peak labeling still remains the main technique for mass spectrum peaks identification. The procedure is time-consuming and vulnerable to errors [3]. Also, it is extremely difficult to take into account all the available information about the sample, the measured data and the possible correlations between detection of different ion species simultaneously during manual analysis.

Computer-assisted peak labeling has recently been shown to provide noticeable advantages over manual procedure [2]. However, large amount of work is still to be done in this area. First, it is desirable to have reliable physical and mathematical background, which the analysis algorithm could be based to at least its universality and the absence of adaptation to different measurement conditions. Also, the algorithm should be able to take into account all the information, known about the investigated sample a priori, which can be extremely useful for making the analysis result even better.

In this contribution, we propose a solution of the tasks listed above on the base of the Bayesian approach, which proved to be a powerful and useful tool for solving a very similar peak identification problem in powder X-ray diffraction [4]. The key idea of the proposed approach is to rank ions according to their probabilities, calculated from Bayes’ formula and conditioned by the measured data. More specifically, the initial information about the investigated specimen (e.g. presence or absence of some elements, correlations between certain ions’ detection, etc.) is encoded in prior probabilities of ions and their combinations. The expected inaccuracies of the measurement and peak search are quantified by the likelihood function. Based on the measured data, posterior probabilities are calculated for the specimen models (combinations of ions, possibly describing the actual measured data). The posterior probability for an ion is defined as the total probability of all the models, containing such ion, and can be estimated even without actual construction of all those models. If several ions have already been accepted as appropriate by the user, only the models containing those selected ions are taken into consideration. For each combination of ions, the corresponding optimal peak labeling is chosen by maximization of the measured mass spectrum likelihood.

The designed approach has been applied to a number of time-of-flight mass-spectrometry datasets, measured for inorganic samples (alloys and semiconductors). Each mass spectrum was iteratively analyzed by accepting one of the top-ranked ions at each step. A simple approach, when each ion is ranked according to the measured data and the already accepted ions only, was compared with “smart” peak labeling, when the higher probabilities of observing correlated ions groups (e.g. Te⁺ together with Te²⁺, Te³⁺ and TeO⁻) were taken into account. As one would expect, including the additional information into the analysis increased the quality of the obtained results and enabled reliable construction of sample models, consistent with the results of manual analysis.

In recent years, due to the energy crisis and environmental pollution, the researches on the issues of energy and environmental sustainability had attracted more and more attention. The clean renewable energy source, such as the solar power, provides the most promising way to face these challenges. In order to improve the efficiency of energy transfer, surface modification by wet chemical etching has become one of the most widely used approaches in this field. To control the surface and interface structures, the facets for forming the surface and interface are the key parameters that should be rationally selected. The facets exposed on the etched surface would affect the photovoltaic or photocatalytic performance through various working mechanisms. To understand and give insights into the growth mechanism of faceted morphologies by wet chemical etching, in this study a phase-field model was established to simulate the process of anisotropic chemical etching in a crystalline material. Different crystallographic materials, e.g. the cubic and hexagonal systems, were investigated. By altering the numerical parameters in the simulations, such as the etching rate, temperature, and the preferential etch orientation, the influences of the relevant experimental parameters on the formation and evolution of faceted morphologies were revealed. In addition, various featured surface morphologies, including the nano-pyramids and square columns, controlled by the anisotropy of the crystalline structures and etching rate were numerically reconstructed. These simulation results were consistent well with the observations of chemical etching experiments. This study was expected to offer fundamental knowledge and detailed information of surface modification by wet chemical etching for the advanced applications in solar energy technology.
The Peculiarities of Mathematical Modeling of Electromagnetic Stirring of Silicon Melt—A Crystallographic Model with the Emphasis on the Role of Partial Stacking Faults in HCP Metals

Lucy Johana Jiménez González

The research results are as follows:
- The requirements to the geometry and local specification of the triangulation computing mesh are determined.
- The approach based on the use of the Lorentz force averaging is justified for several periods.
- The possibility of calculating electromagnetic stirring under the conditions of nonsinusoidal current waveforms in inductors is provided.
- The possibility of calculating electromagnetic stirring within the conditions of inductors supply by voltage source is provided.
- The described approaches are illustrated by calculations of electromagnetic stirring for large volumes of silicon (65 crucible).

Recent studies have shown that graphene is one of the two-dimensional nanomaterials with vast applications due to its excellent structural, thermal, electrical, mechanical and magnetic properties, mainly in the field of biomedicine. Graphene doped with other materials and modified in its structure has achieved wide recognition among the academic and industrial sectors to create next-generation medical systems and therapies. In this work, we present novel stable molecular structures of modified graphene with doping or by changing the length of some of its bonds and obtaining physicochemical properties through multiscale methods including ab initio, quantum chemistry, force fields, mesoscopic methods, and statistical and thermodynamic methods. The results obtained in this work show that the, designed theoretically, modified graphene structures are suitable for the development of new devices for diagnostic, generation of bioimages in deep parts of the human organism, devices for targeted delivery of drugs and detection of macromolecules.

Computational Techniques for Calculating Material Properties from Coarse-Grained Epoxy Curing Simulations

Mike Henry, Stephen Thomas, Monat Alberts, Carla E. Estridge, Eric Jankowski, Micron School of Materials Science and Engineering, Boise State University, Boise, Idaho, United States; The University of Tennessee at Knoxville, Knoxville, Tennessee, United States; Next Generation Composite Materials, The Boeing Company, St. Louis, Missouri, United States.

The atomic displacement vectors associated with the zonal-twinning mechanism are derived analytically and expressed in a mathematical form generalized for the whole twinned domain of any HCP crystal with κ=c/a ratio within a practical range of 1.5<κ=c/a<1.9. This displacement field demonstrates that the atoms must move in a cooperative and coordinated manner during twinning.

For the special case of κ=3, a pure shuffling mechanism is predicted by the current model in which the shear type atomic displacement vectors are zero, and shear-shuffle type atomic displacement vectors become net shuffle type atomic displacement vectors without varying magnitudes with respect to the height of the twinned domain.

In contrast to the classical twinning mechanism, the new twinning mechanism suggests a simple and traceable pattern of atomic motions such that the associated absolute and relative magnitudes of the atomic displacement vectors are considerably smaller. Moreover, in the new mechanism, the resulted twinned lattice has a correct HCP structure, and the invariance of plain strain condition for (10-12) plane is preserved during twinning.

The new model describes a structural property of HCP metals, a new crystallographic model is developed for (10-12)<1011> twinning system.

Recent studies have shown that graphene is one of the two-dimensional nanomaterials with vast applications due to its excellent structural, thermal, electrical, mechanical and magnetic properties, mainly in the field of biomedicine. Graphene doped with other materials and modified in its structure has achieved wide recognition among the academic and industrial sectors to create next-generation medical systems and therapies. In this work, we present novel stable molecular structures of modified graphene with doping or by changing the length of some of its bonds and obtaining physicochemical properties through multiscale methods including ab initio, quantum chemistry, force fields, mesoscopic methods, and statistical and thermodynamic methods. The results obtained in this work show that the, designed theoretically, modified graphene structures are suitable for the development of new devices for diagnostic, generation of bioimages in deep parts of the human organism, devices for targeted delivery of drugs and detection of macromolecules.
Block copolyelectrolytes are one of the leading candidate materials for use as solid-state single-ion electrolytes (for ion transport) and ion-conductive membranes (for ion exchanging) in electrochemical energy storage systems, such as Li-ion batteries and fuel cells. They self-assemble into nanostructures that enable both ionic transport and maintain structural integrity. Ion transport in these charged block copolymers strongly depends on the alignment of specific anisotropic nanostructures. In this work, a modified dissipative particle dynamics (DDP) simulation framework has been developed to systematically study ion diffusion dynamics considering various experimentally controllable factors, such as block volume fraction, Flory-Huggins parameter, block charge fraction (or ion concentration), and dielectric constant. Using a novel “diffusivity tensor” approach, we predict the phase-dependent ion diffusivity along the principal micromdomain orientations, and find that the degree of anisotropy in ion diffusivity strongly correlates with that of the polymer microdomains. Ion conductivity in block copolyelectrolytes strongly depends on ion concentrations and temperatures, but weakly on other experimentally controllable parameters. Surprisingly, we discover that the inverse topology gyroid and cylindrical phases are the optimal candidates for single-ion conductors with high-flux ion conductivity, well-percolated isotropic diffusion pathways, and mechanical robustness. Finally, we find that higher ion diffusivity can be achieved by increasing the dielectric constant, which facilitates ion diffusion across block micromdomain interfaces. This work significantly motivates future efforts in exploring inverse phases without removing grain boundaries in order to enhance ion transport.

CP09.05.10 Computational Modeling of Surface Sputtering and Redeposition from Micro-Architected Surfaces Andrew Alvarado1, Hsing-Yin Chang1 and Jaime Marian1,2 1Materials Science and Engineering, University of California, Los Angeles, Los Angeles, California, United States; 2Mechanical & Aerospace Engineering, University of California, Los Angeles, Los Angeles, California, United States.

As electronic propulsion continues to be a lucrative approach for space travel, the uncertainty of thruster and spacecraft component lifetimes solicit a need for a reduction in harmful effects. The recent developments of micro-architected surfaces show that these surfaces can partially negate the effects of plasma-induced sputtering and erosion. Due to the recent developments, the sparse collection of sputter yield data on micro-architected surfaces and materials remain an inhibiting obstacle. Therefore, we develop a 3D computational model to simulate the surface morphology evolution of micro-architected tungsten (W) samples and its instantaneous sputtering (erosion) rate under xenon (Xe) plasma exposure. We quantify the dynamic evolution of micro features of surfaces with built-in architecture and the corresponding variation in the sputtering yield through a Monte Carlo based ray-tracing method and adaptive meshing techniques. From our simulation, the surface profiles show the deposition of sputtered atoms as a result of geometric re-trapping and re-growth of surface layers. We find that micro-architected W samples exposed to 300 eV Xe plasma result in sputtering yield reductions of over 50% of the corresponding value for flat samples, indicating a self-healing mechanism of micro-architected surfaces under plasma exposure. Our model provides a framework allowing rapid expansion of its capabilities, such that the problem of sputtering redeposition from complex surfaces can be easily separated into a “physics” part (in idealized scenarios) and a “geometry” part (discretized to take advantage of the physical calculations).

CP09.05.11 Computational Modeling of Secondary Electron Emission from Micro-Architected Surfaces Hsing-Yin Chang1, Andrew Alvarado1 and Jaime Marian1,2 1Materials Science and Engineering, University of California, Los Angeles, Los Angeles, California, United States; 2Mechanical and Aerospace Engineering, University of California, Los Angeles, Los Angeles, California, United States.

Surface erosion and secondary electron emission (SEE) of the channel walls of Hall-effect thrusters for space propulsion have been identified as the most critical life-limiting factors. Recently, new wall concepts based on micro-architected surfaces have been proposed to mitigate surface erosion and SEE. The idea behind these designs is to take advantage of very-high surface-volume-to-radius ratios to reduce SEE and ion erosion by internal trapping and redeposition. This has resulted in renewed interest to study electron-electron processes in relevant thruster wall materials. In this work, we present calculations of SEE yields in micro-porous W and BN surfaces using discrete event simulations. First, we study SEE as a function of primary electron energies between 100 eV and 1 keV and incidence angles between 0 and 90 degrees. For this, we use Monte Carlo simulations of electron multi-scattering processes, tracking the trajectories of primary electrons as they move through the materials and accounting for elastic and inelastic energy losses, as well as plasmonic/polaronic interactions. The results are then used to present the source term in ray-tracing Monte Carlo simulations of arbitrary geometry surfaces. We find that SEE yields in the energy range expected in Hall thruster conditions, are reduced several fold when using the new surface designs compared to ideal flat surfaces. This points to the suitability of these micro-architected surface concepts to mitigate SEE-related issues in compact electric propulsion devices.

CP09.05.12 The Sensitivity of the Electron Transport Response within Zinc Oxide to Variations in the Crystal Temperature, the Doping Concentration, and the Non-Parabolicity Associated with the Lowest Energy Conduction Band Valley Poppy Siddiqua1, Walid A. Hadi1, Michael Shur1 and Stephen K. O'Leary1 1School of Engineering, University of British Columbia, Kelowna, British Columbia, Canada; 2Department of Electrical, Computer, and Systems Engineering, Rensselaer Polytechnic Institute, Troy, New York, United States; 3Florida State University, Panama City, Florida, United States.

We examine how the character of the electron transport that occurs within zinc oxide is shaped by the crystal temperature, the doping concentration, and the non-parabolicity associated with the lowest energy conduction band valley. The aim of this analysis is to provide the emerging community of zinc oxide based device engineers with a detailed understanding of how the electron transport varies in response to changes in these parameters. While variations in the crystal temperature and doping concentration naturally arise from the range of device applications expected for zinc oxide based devices, the non-parabolicity coefficient associated with the lowest energy valley of the conduction band may be adjusted through the application of stress. An analysis of this effect will be presented. Both steady-state and transient electron transport responses will be considered within the scope of this analysis. The device implications of these results will be probed.

CP09.05.13 Simple Models for Testing Self-Assembly Robustness Rachel Singleton, Alex Chaney, Mike Henry and Eric Jankowski; Boise State University, Boise, Idaho, United States.

The robust self-assembly of proteins into virus capsids provides inspiration for designing synthetic building blocks that could aggregate into arbitrary structures, but the timescales of capsid assembly make atomistic modeling of such processes difficult. In this work we develop a simple simulation testbed for evaluating the assembly robustness of simple protein analogues and work towards modeling the conformational state changes that occur in real capsid proteins. We demonstrate how simple building blocks are difficult to design for robust assembly, and strategies for encoding desired structures into the design of individual particles. Finally, we discuss how such modeling techniques provide an accessible on-ramp for learning molecular simulations and intuitions for thermodynamic self-assembly.

CP09.05.14 Dislocation Dynamics of Deformation and Creep in Alloys Apay Annamareddy and Jacob Eapen; North Carolina State University, Raleigh, North Carolina, United States.

Alloy 709, which is an austenitic stainless steel strengthened with niobium, portrays excellent high temperature thermo-mechanical properties; it is currently being considered as a candidate material for the fast nuclear reactor program. Alloy 709 derives its high temperature strength from different precipitates such as M23C6 and M6C that are mostly formed at the grain boundaries, and nano-sized Z phase precipitates. These precipitates provide resistance to dislocation and grain boundary movements, and also improve resistance to creep. In this work, we use mesoscale discrete dislocation dynamics (DDD) simulations to investigate the mechanical deformation and creep behavior of model high temperature alloys under accelerated test conditions. In particular, we probe the dynamic interactions between the dislocations and the precipitates. At lower precipitate strengths, we show that the dislocations shear across the precipitates, but for higher strengths, the dislocations bypass by looping around the precipitates. As expected, the yield stress increases with increasing concentration of the precipitates. Further, the material also hardens with increasing strength of the precipitates, with the maximum hardening exhibited for Orowan strengthening. We also delineate the fundamental deformation mechanisms during creep and elucidate the correlations associated with the evolution of dislocations and interactions with the precipitates, at different stresses and temperatures.

CP09.05.15
Study of the Critical Probability of Percolation in a 3D Simulation System with Random Radius in Its Pores for Grids of Variable Size 

Gustavo M. Ángel, Yessica Yazmin C. Calderon-Segura and Genndady Burlak, Institute of Research in Basic and Applied Sciences, Cuernavaca, Mexico.

We study the filtration simulation in 3D porous materials, assigning pores with sizes in a solid medium represented by a 3D grid of variable size. We identify the clusters for each grid as well as the infinite cluster that determines its critical probability through the neighbor hybrid structure method, and we determine the depth of each cluster in the material as well as the volume of the infinite cluster that allows the filtration step in the materials. In this work several tests were performed varying the size of the grid that allows us to determine the importance of the size and how it affects the filtration in the simulated grids.

Predicting Assemblies of Complex Macromolecules for Organic Photovoltaics 

Mia Klopfenstein, Mike Henry, Evan Miller, Matthew L. Jones and Eric Jankowski; Materials Science and Engineering, Boise State University, Boise, Idaho, United States.

Understanding the packing of the molecules used in organic photovoltaics (OPVs) is necessary for predicting charge transport and understanding structure-property relationships of these devices. In this work, we perform molecular dynamics simulations to understand how complex macromolecules ranging from representative asphaltenes, to new electron acceptors like ITIC aggregate. We develop computational tools for initializing simulations of these molecules in isolation, as mixtures, and with polydispersity in molecular weight when appropriate. We find that pi-stacking drives the aggregation of molecules, including the formation of symmetrical stacks for planar molecules with few side-chains. Such structures are beneficial for charge mobility, a good thing for efficient organic solar cells. This work demonstrates the potential to use the oil refining waste (asphaltenes) as an ingredient for solar energy production and has potential for identifying molecular features that correlate with robust assembly for charge mobility.

CP09.05.17

Coupled Ray Tracing and Lattice Boltzmann Model of TiO\textsubscript{2} Micropillars Array for Water Purification 

Pegah Mir Abedini\textsuperscript{1}, Agnieszka Truskowska\textsuperscript{2}, Duncan Z. Ashby\textsuperscript{3}, Masaru Rao\textsuperscript{1} and Alex Greeney\textsuperscript{1, 2}; \textsuperscript{1}Material Science and Engineering program, University of California, Riverside, Riverside, California, United States; \textsuperscript{2}School of Mechanical, Industrial and Manufacturing Engineering, Oregon State University, Corvallis, Oregon, United States; \textsuperscript{3}Department of Mechanical Engineering, University of California, Riverside, Riverside, California, United States.

TiO\textsubscript{2} has been widely studied as a photocatalytic material due to its non-toxicity, chemical inertness, and high photocatalytic activity. Here, we explore the operational behavior of a novel TiO\textsubscript{2} micropillar array for treating recycled wastewater in space. A ray tracing model is used to model light adsorption, and the lattice Boltzmann method is used to simulate the water flow through the pillars and the evolution of hydroxyl radicals in the vicinity of the pillars.

CP09.05.18

Is Atomic Size-Mismatch a Sufficient Condition to Yield Fragility in Bulk Metallic Glass Forming Liquids? 

Tina Mirzaei; University of California, Riverside, Riverside, California, United States.

The fragility of glass forming alloys in their molten state is found to correlate with the alloys’ ductility as a glass. Fragility is the deviation of the temperature dependence of a liquid’s viscosity from Arrhenius behavior. It was recently shown that there are qualitative differences in the way the medium range order changes with temperature in strong vs fragile glass forming liquids. The relatively long range differences in atomic order hint at differences in cooperative packing of atoms in strong vs fragile alloys, and lead us to ask the question: is atomic size mismatch sufficient to cause fragility? The answer to this question made classical molecular dynamics models to be created for alloys of size mismatched, but chemically identical atoms. Simulations of these systems were performed across a range of temperatures and the viscosity and medium range order computed as a function of temperature.

A Neural Networks Approach to Predicting the Orientations of Images 

Vincent Davis\textsuperscript{1}; \textsuperscript{1}Mathematics, North Carolina Central University, Durham, North Carolina, United States; \textsuperscript{2}North Carolina State University, Raleigh, North Carolina, United States.

Electron backscatter diffraction (EBSD) is a technique that describes the orientation of crystals in a sample. A series of deep convolutional neural networks was built to determine the orientation of a polycrystalline sample based on its electron diffraction patterns. By establishing a fixed coordinate system, a mathematical model will take .jpg files of a series of rotations as training data at a rate of approximately 250 seconds on each epoch. The networks determine the orientation of a sample image at substantially higher orders than traditional physics-based forward models. Statistical techniques are applied within the model to attain a loss in accuracy of only 5-8 degrees for rotations between 0 and 360 degrees. This simple and robust python software tool can be utilized in further offline analysis to index electron diffraction patterns much more efficiently while maintaining an average level of accuracy greater than or equal to 80%.

CP09.05.20

Surface Coupling Suppression by Nanostructure Manipulation in a SiO\textsubscript{2} Thin Film 

Sunny Sinu\textsuperscript{1}, Kartik Venkatraman\textsuperscript{1}, Peter Rez\textsuperscript{2} and Peter Crozier\textsuperscript{3}; \textsuperscript{1}School for Engineering of Matter, Transport and Energy, Arizona State University, Tempe, Arizona, United States; \textsuperscript{2}Department of Physics, Arizona State University, Tempe, Arizona, United States.

Electron energy loss spectroscopy (EELS) is an experimental technique providing structural and chemical information about a material. Recent advances in transmission electron microscopy (TEM) technology have improved the energy resolution of the electron beam which has realized the investigation of vibrational modes within a material [1]. When coupled with the exceptional spatial resolution of approximately 1 angstrom achievable with current aberration-corrected transmission electron microscopes, high resolution EELS mapping of the atomic structure, chemical and electronic properties, and now vibrational modes is possible. In the vibrational regime of EELS, electrons can excite vibrational coupled with the exceptional spatial resolution of approximately 1 angstrom achievable with current aberration-corrected transmission electron microscopes, high resolution EELS mapping of the atomic structure, chemical and electronic properties, and now vibrational modes is possible. In the vibrational regime of EELS, electrons can excite vibrational modes within the sample through short-range “impact” scattering and “long-range” dipole scattering. We focus on vibrational modes dominantly excited by dipole scattering. In polar dielectric materials like SiO\textsubscript{2}, as the electron beam is incident on the material, surface phonon polariton (SPhP) signals couple strongly at thicknesses employed in typical TEM sample geometries [2]. These surface coupling effects manifest as a peak signal in the “reststrahlen” band with thickness-dependent energy losses in the EELS spectra. In a SiO\textsubscript{2} truncated slab geometry, as the electron beam is incident on the SiO\textsubscript{2}/vacuum interface, there is a suppression in the intensity of the SPhP that is accompanied by an increase in the intensity of the SiO\textsubscript{2}/vacuum interface phonon polariton [3]. Our work aims to suppress the SPhP signal through manipulation of material nanostructure. Utilizing classical dielectric theory, we can simulate dipole scattering in TEM samples of SiO\textsubscript{2} [2]. Commercial software COMSOL Multiphysics can accurately simulate dipole scattering through finite element method while also considering phonon-polariton interactions. Through finite element method, we can calculate the electron energy loss probability when an electron beam transmits the material, which is corroborated with experimental spectra. We can now vary the nanostructure and compute the corresponding electron energy-loss probability for a given model geometry with ease. Current calculations show significant surface coupling suppression using a 2x2 array of nanoholes surrounding the electron beam. We believe this phenomenon is the result of increased SiO\textsubscript{2}/vacuum interface vibrational signal coupling, which will invariably reduce surface coupling intensity via surface peak reduction from competing vibrational modes. In practice, such nanoscale holes would be easily fabricated with conventional focused ion beam (FIB) lithography.

Proton-conducting ceramic fuel cells (PCFCs) have been actively studied as a next generation alternative power source, thanks to their low operation temperatures (~800 K) [1]. BaZr1-xY2O3 (BZYO) and BaCe1-xY2O3 (BCYO) perovskites have been the two mostly studied electrolyte materials. Recently, BaZr1-xCe1-yO2 was introduced by mixing the two materials to overcome the weak points of the two materials; high sintering temperature and low grain-boundary conductivity in BZYO, and poor chemical stability in BCYO [2]. In this study, we used lattice statics and genetic algorithm [3] to find energetically stable lattice structures among many possible structures in BaZr1-xCe1-yO2 (y=0.15) bulk as a function of Ce content. The lattice volume increases with the Ce content, because Ce atom is bigger than Zr atom. Despite the increase in volume, the distance among Y atoms diminishes, indicating that the Y atoms are agglomerated with the Ce content. This behavior could be further explained by the interaction between Y atoms and oxygen vacancies. We also applied this procedure to study grain-boundary structures (sigma 3 and 5) [4].

The dynamic fracture of brittle solids is a particularly interesting collective interaction connecting both large and small length scales. Apply enough stress or strain to a sample of brittle material and one eventually snaps bonds at the atomic scale leading to fracture of the macroscopic specimen. We discuss a nonlocal model for calculating dynamic fracture. The force interaction is derived from a double well strain energy density function, resulting in a non-monotonic material model. The material properties change in response to evolving internal forces eliminating the need for a separate phase field to model the fracture set. The model can be viewed as a regularized fracture model. In the limit of zero nonlocal interaction, the model recovers a sharp interface evolution characterized by the classic Griffith free energy of brittle fracture with elastic deformation satisfying the linear elastic wave equation off the crack set. We conclude with a numerical analysis of the model which is joint work with Prashant Jha.

Debonding of a Gel from a Rigid Substrate
devan hemao1, maria-carme calderer2, carlos garavito-garzon2 and suping lyu3; 1facultad de matematicas, pontificia universidad catolica de chile, santiago, chile; 2school of mathematics, university of minnesota, minneapolis, minnesota, united states; 3medtronic inc., plymouth, massachusetts, united states.

A variational model for the delamination of polymer gel thin films from rigid substrates is presented. A formal asymptotic analysis of a simplified 2D version of the underlying governing equations show that, as the film grows thinner, the absorption of the moisture of its surroundings tends to produce a homogeneous vertical stretch in the part of the film that remains bonded to the substrate and a state of free swelling in the debonded part. A transition layer, with a width comparable to the film thickness, is developed in order to connect the two swelling modes. This work is joint with carme calderer (u. minnesota), carlos garavito-garzon (u. minnesota) and suping lyu (medtronic inc.).

A Geometric Theory of Wrinkling for Confined Elastic Shells
ian tobacco; mathematics, university of michigan, ann arbor, michigan, united states.

Thin elastic membranes readily take on shapes wildly different from their own. Motivated by recent experiments on wrinkling patterns observed in thin floating shells, we obtain a fully rigorous asymptotic expansion of the energy (elastic and otherwise) valid in the highly-wrinkled limit. After renormalizing by the typical energy of wrinkling, we derive a coarse-grained model in which an elastically compatible pattern is assigned energy proportional to the difference between its intrinsic undeformed area and its projected area in the plane. Energetically optimal patterns therefore maximize their projected area. Surprisingly, this limiting model turns out to be explicitly solvable in a large variety of cases, including for shells whose (possibly non-constant) curvature is of a known sign. We demonstrate our methods with concrete examples and offer comparisons with experiments. What results is an ansatz-free explanation for the geometry of wrinkle patterns seen in confined thin elastic shells.

Asymptotic Analysis of the Helical Twisting Power of Chirally Doped Nematics
jamie m. taylor;bcam, bilbao, spain.

Elongated molecules with mirror symmetry have a tendency to form nematic phases, where the ground state is constant in space and molecules roughly point in the same direction. However, the introduction of a small quantity of chiral molecules can be enough to cause a helically twisted ground state, with periodicity comparable to the wavelength visible light, making them ideal for many applications related to optics. The Helical Twisting Power (HTP) is the constant of proportionality between the concentration of dopant and the frequency of the ground state in dilute systems, and quantifies the ability of the dopant to twist the host ground state. Typically HTP depends highly on both the dopant and host, and may increase or decrease with temperature. In this work we attempt to understand the HTP by considering a mean-field model, which is essentially a non-local Landau-de Gennes type model describing coupling between the dopant and host species, accounting for the symmetries of their long-range attractive pairwise interactions. The model contains many terms and is illusive, but by taking a simultaneous large domain and dilute dopant limit in a periodic domain, we can obtain the Oseen-Frank free energy for cholesteric liquid crystals, and can relate the macroscopic HTP with certain scalar quantities derived from the pairwise molecular interactions. In particular, we see that in essence the HTP is heavily related to the ratio of quantities relating to the strength of achiral Host-Host interaction and chiral Host-Dopant interaction, and the qualitative temperature dependence of HTP changes depending on their relative strength.

SESSION CP09.07: Mathematics of Nanoscale Structures and 2D Materials

Plasmonics on 2D Materials—A Flavor of Dispersion and Homogenization
Dionisios Margetis; Mathematics and IPST and CSCAMM, University of Maryland, College Park, Maryland, United States.

In the last decade, tremendous advances have been made in the design and fabrication of 2D materials with novel electronic structures. Celebrated examples of such materials include graphene, black phosphorus and van der Waals heterostructure. The surface conductivity in the infrared regime in some of these systems may allow for the propagation of fine-scale electromagnetic waves, called surface plasmon-polaritons (SPPs), which can defy the usual diffraction limit. In this talk, I will discuss macroscopic consequences of the optical conductivity of 2D materials via solutions of classical Maxwell's equations. In particular, I will formally discuss how geometry, i.e., the presence of material edges and curvature, can influence SPP dispersion. In addition, I will show how slowly varying waves with nearly no phase delay may possibly propagate through suitably designed plasmonic crystals.

Multiscale Modeling of van der Waals 2D Stacked Materials
john lowengrub1; zhenglu guo1 and vivek b. shenoy2; 1mathematics and chemical engineering & materials science, university of california, irvine, irvine, california, united states; 2materials science, university of pennsylvania, philadelphia, pennsylvania, united states.

Vertical stacking of monolayers via van der Waals (vdW) interaction opens promising routes toward engineering physical properties of two-dimensional (2D) materials and designing atomically thin devices. However, due to the lack of mechanistic understanding, challenges remain in the controlled fabrication of these structures via scalable methods such as chemical vapor deposition (CVD) onto substrates. In this talk, we develop a general multiscale model to describe the size evolution of 2D layers and predict the necessary growth conditions for vertical (initial + subsequent layers) versus in-plane lateral (monolayer) growth. An analytic thermodynamic criterion is established for subsequent layer growth that depends on the sizes of both layers, the vdW interaction energies, and the edge energy of 2D layers. We then explore the effect of nonlinearity using a new, 2nd order accurate diffuse domain formulation of the governing equations that places no constraints on the morphologies of the islands. We find that the analytic criterion accurately captures the conditions for which the 2nd layer grows even when the morphologies are complex (e.g., highly anistropic, have negative curvature, etc.). Our model agrees with experimental observations of monolayer and bilayer growth of graphene and other 2D materials by CVD.

Multiscale Modeling of Weakly Interacting Incommensurate 2D Lattices
j.p. wilber, dmitry golovaty and malena espanol; university of akron, akron, ohio, united states.

We derive a continuum variational model for a two-dimensional deformable lattice of atoms interacting with a two-dimensional rigid lattice. The starting point is a discrete atomistic model for the two lattices, which are assumed to have slightly different lattice parameters and, possibly, a small relative rotation. This is a prototypical example of a three-dimensional system consisting of a graphene sheet suspended over a substrate. A discrete-to-continuum procedure is used to obtain a continuum model that recovers both qualitatively and quantitatively the behavior observed in the corresponding discrete model. The continuum model predicts that the deformable lattice develops a network of domain walls characterized by large shearing, stretching, and bending deformation that accommodates the misalignment and/or mismatch between the deformable and rigid lattices. Two
integer-valued parameters, which can be identified with the components of a Burgers vector, describe the mismatch between the lattices and determine the geometry and the details of the deformation associated with the domain walls.

Hamiltonians and Order Parameters for Crystals Containing Orientable Molecules John C. Thomas, Jonathon Bechtel and Anton Van Der Ven; University of California, Santa Barbara, Santa Barbara, California, United States.

Crystalline materials containing easily reorientable molecular species are an increasingly important category in the search for modern functional materials. Such materials include hybrid organic–inorganic halide perovskites, a record-breaking class of photovoltaic materials. Despite current interest in these materials, orientational fluctuations of arbitrary molecules are challenging to describe mathematically and do not fall within the conventional lattice models of solid state physics. The presence of orientable molecular species thus constitute a significant hurdle to truly predictive simulation of thermodynamic and kinetic phenomena in these promising materials.

In this talk, we present a mathematical framework for constructing accurate anharmonic model Hamiltonians that express the crystal potential energy in terms of collective orientations of interacting molecular ions, which we abstract as rigid rotors. The approach is motivated by the cluster expansion framework from alloy theory and is appropriate for describing both chiral and achiral molecules. By utilizing a quaternion parameterization of molecular orientation, along with a hyperspherical harmonic basis set, we are able to construct Hamiltonian expressions that reflect all symmetries of both the host crystal and the molecular species. The resulting Hamiltonian is compact, systematically improvable, and suitable for Monte Carlo or molecular dynamics simulation. Moreover, the basis functions employed in constructing the Hamiltonian are useful as order parameters for characterizing orientational order and phase transitions. We describe results obtained via this method for the CH₃NH₃PbX₃ lead-halide hybrid perovskites, including symmetry-adapted order parameters and Hamiltonian basis functions.

A Practical Approach to Bypassing Kohn-Sham DFT Using Machine Learning Techniques Amit Samanta and John Klepley; Lawrence Livermore National Laboratory, Livermore, California, United States.

The Kohn–Sham scheme of density functional theory (KS-DFT) is popularly used to solve electronic structure problems in materials for applications, like catalysis, hydrogen storage, electronic and optical applications, mechanical strength and phase stability. In this talk, I will present a machine learned DFT (ML-DFT) framework that can be used to predict the energy and forces for a given atomic structure at significantly reduced computational cost. This ML-DFT framework relies on two different machine learning models, one that allows us to predict the ground state charge density of a structure and another that allows us to predict the total energy and forces acting on each atom from the ground state charge density. We believe such a framework can be used to handle multi-component systems, systems that involve charge transfer during evolution and in principle can also be trained using a database derived from hybrid functional calculations. This ML-DFT framework requires fewer computing resources than direct KS-DFT calculations, meaning that a system can be evolved for longer durations using molecular dynamics with ML-DFT. In addition, the memory requirements in ML-DFT are limited to storing the charge densities of structures in the database. This fact suggests that system sizes (up to 4000 atoms) can be studied that are not easily accessible in KS-DFT.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

3:45 PM CP09.07.06

Thermal/Electrostatic Green’s Function for 2D Phosphorene/Metal Composite and Possibility of Its Measurement by Using SPM Vinod K. Tewary and Edward J. Garboczi; National Institute of Standards and Technology, Boulder, Colorado, United States.

Mathematically modeling of materials is emerging as an independent branch of materials science. A mathematical model of a material plays a major role in the characterization and production of real materials as it provides a prototype for virtual experimentation. In this talk, I will present a machine learned DFT (ML-DFT) framework that can be used to predict the energy and forces for a given atomic structure at significantly reduced computational cost. This ML-DFT framework relies on two different machine learning models, one that allows us to predict the ground state charge density of a structure and another that allows us to predict the total energy and forces acting on each atom from the ground state charge density. We believe such a framework can be used to handle multi-component systems, systems that involve charge transfer during evolution and in principle can also be trained using a database derived from hybrid functional calculations. This ML-DFT framework requires fewer computing resources than direct KS-DFT calculations, meaning that a system can be evolved for longer durations using molecular dynamics with ML-DFT. In addition, the memory requirements in ML-DFT are limited to storing the charge densities of structures in the database. This fact suggests that system sizes (up to 4000 atoms) can be studied that are not easily accessible in KS-DFT.

The connection between the GF and the process of measurement arises from the fact that the GF corresponding to an operator is the inverse of that operator. In Physics, the process of measurement of a quantity for a system is represented by an operator equation, which gives the response of the system to an applied probe. The GF is independent of the probe. For example, if we have a system whose GF is known, we can calculate the response of the system to any probe.

On the experimental side, in a typical scanning probe microscopy (SPM) experiment, one measures the response of a sample to a point probe or a distribution of point probes. Interestingly, that is exactly the mathematical definition of the Green’s function – response of a material to a point probe. With the recent developments in the science and technology of SPM, it should be possible, at least in principle, to measure the GF of a material system for the SPM measurement. It would prove to be an especially useful technique for the new 2D semiconductors. In these systems, it is still a challenge to understand the relationship between their structure and their physical properties. Understanding such relationships is vital for their engineering industrial applications.

In this talk, I will describe a new and computationally powerful technique for calculating GFs for the Laplace/Poisson equation for the thermal/electrostatic response of a system of 2D composite materials. The technique is based on a partial Fourier representation of the GF. In this representation, integration over one variable can be obtained analytically, which results in a substantial economy of computational time and effort. We have used this technique for calculating the response map of anisotropic 2D phosphorene containing a metallic inclusion. Phosphorene and its composites are materials of strong topical interest because of their potential applications in electronic and other devices. We have also used our formulation to calculate an effective value of the conductivity of the composite, which can be a useful single parameter for preliminary design of devices. Numerical results will be presented and discussed.

Role of Mesoscopic Friction and Network Morphology in Carbon Nanotube Yarn Formation—A Distinct Element Method Study Yuezhou Wang, Hao Xu, John C. Thomas, Jonathon Bechtel and Anton Van Der Ven; University of California, Santa Barbara, Santa Barbara, California, United States.

Carbon nanotube (CNT) yarns are promising synthetic nanomaterials for a variety of applications. To better understand the mechanism for yarn formation process, we performed mesoscopic scale distinct element method (mDEM) simulations for the stretching of CNT networks. With parameters input from full atomistic simulations, mDEM bridges across the atomistic and mesoscopic length scales. Our model predicts accurately the mechanical response of the network over a large deformation range. At small and moderate deformations, the model predicts accurately the mechanical response of the network over a large deformation range. At small and moderate deformations, the model predicts accurately the mechanical response of the network over a large deformation range.
Assessing the Size Effect on Frank-Read Source Operation in f.c.c Metallic Materials Through Concurrent Atomicstic-Continuum Simulations

Cobalt-based superalloys with γ′ microstructures offer great promise as candidates for next-generation high-temperature alloys for applications in, e.g. turbine blades. It is essential to understand the thermodynamic and kinetic factors that influence the microstructural evolution of these alloys in order to optimize the alloy compositions and processing steps with a goal to improve their coarsening, creep and rafting behavior. We are developing a phase field approach to study the diffusion process and to predict the equilibrium shapes of Co-AEW γ′ precipitates. In order to obtain quantitatively predictive capabilities we use a combination of molecular dynamics simulations, 3D atom probe tomography, and thermodynamic data to obtain bulk and interfacial energies, misfit strain, elastic constants and mobilities. A particular focus of our study is to understand how different energy balances, misfit strain and kinetics affect the rafting behavior and necking of γ′ precipitates, building on a previous model [1]. Apart from the shape bifurcation behavior reported in the previous work, we observe other characteristic microstructures as a result of the competition between the bulk free energy, interfacial energy, and elastic energy. The results indicate that the form of the bulk free energy may also have an influence on the equilibrium shape of the γ′ precipitates. Bulk free energy properties such as the separation between free energy minima and the height of the barrier between them may indirectly affect the morphology of the precipitates, as the total interfacial free energy also depends on this barrier. We are examining how the form of the bulk free energy affects the coarsening and rafting behavior of superalloy models, especially when the composition changes across interfaces.

8:30 AM CP09.08.01 Acousto-Plasmonic Coupling—The Raman Energy Density (RED) Nicolas Largé, Joe Luís Montalvo-Prieto, Lucien Saviot and Adnen Mlayah; Department of Physics & Astronomy, The University of Texas at San Antonio, San Antonio, Texas, United States; Laboratoire Interdisciplinaire Carnot de Bourgogne CNRS, Université de Bourgogne, Dijon, France; Centre d’Elaboration de Matériaux et d’Etudes Structurales CNRS, Université de Toulouse, Toulouse, France.

Most of the studies done around the plasmonic properties of metallic nano-objects are based on static measurements. Nevertheless, nano-objects are continuously changing in size and shape driven by the vibrations of their lattice. Therefore, the plasmon properties of the nano-objects are being modulated by the lattice vibrations, and vice versa. We present the study of the interaction between the acoustic plasmonic properties of metallic nano-objects and the localized surface plasmon resonance (LSPR) which give rise to a low-frequency Raman scattering response. The resonant Raman scattering process is described using a new approach on a single acousto-plasmonic interaction step described by a Fermi golden rule. In this effort, we introduce the concept of Raman energy density (RED) which represents the electromagnetic energy density excited by the Raman probe and modulated by the acoustical vibrations of the nano-object. To illustrate this new concept, RED spatial distributions and the Raman spectra are calculated for a gold nanoparticle with 5 nm in radius excited at its LSPR which give a clear picture of the coupling between the plasmon and the first isotropic and anisotropic acoustic vibrations (breathing and quadrupolar modes) and these are in good agreement with the experimental reports.

8:45 AM CP09.08.02 Assessing the Size Effect on Frank-Read Source Operation in f.c.c Metallic Materials Through Concurrent Atomicistic-Continuum Simulations Thanh Phan, Rigelesaiyin Ji and Liming Xiong; Iowa State University, Ames, Iowa, United States.

The Frank-Read (FR) source is one of the main dislocation multiplication mechanisms in crystalline materials. A FR source can produce multiple dislocations which may pile up against a grain boundary or other material interfaces. In a typical polycrystalline engineering material, the diameter of a dislocation loop generated from a FR source may be hundreds of nanometers and even above, which is beyond the reach of traditional optical microscopy. Moreover, the artificial force from free surface or periodic image on FR source in an atomistic model is often significant due to its length-scale limit. In this work, we use a freely developed concurrent atomistic-continuum (CAC) computational tool, which is based on a theoretical framework that unifies the atomistic and continuum description of materials, we simulate growth of a micron-sized dislocation loop through a FR source from the bottom up. At a fraction of the cost of full MD, CAC overcomes the length-scale limitation of MD and scale up the model up to several microns and even above, in which the image force effect becomes negligible. It enables us to systematically calibrate the relationship between FR source length and the critical shear stress for dislocation bowing out from the atomistic to the micrometer level. This work demonstrates the applicability of CAC in predicting the dynamics of dislocations at the mesoscopic level. It also opens up the possibilities of understanding a variety of dislocation-interface reactions which require a fully atomistic resolution near an interface and a coarse-grained material description of the long-range interactions between dislocations away from the interfaces in materials.
Due to its outstanding electromechanical properties, lead titanate (PbTiO₃) and its solid solutions, such as Pb(Zr, Ti)O₃ (PZT) and Pb(Mg₁/₃, Nb₂/₃)O₃-PbTiO₃ (PMNPT), have been widely applied in technological devices like non-volatile random access memories (FeRAMs), micro-actuator and sensors. For such materials, a slight atomic displacement strongly affects both mechanical and ferroelectric (FE) properties. Thus, a proper understanding of the atomic behavior of ferroelectrics is required. Computational simulation is a promising tool for analysis of the properties above. In this study, we have successfully reparameterized the core-shell model to model PbTiO₃. The new parameters considered the crystal structures, elastic properties and phonon frequencies which calculated by ab-initio density functional theory calculations. In addition to material mechanical properties, it can reproduce the thermodynamic properties like isometric heat capacity, adiabatic compressibility. Moreover, the new parameters were also tested by molecular dynamics simulations to examine the predictive ability at finite temperature. The phase transition temperature of 490 °C from the tetragonal to the cubic phase was obtained, which is consistent with experimental results. Furthermore, the new model was then used to study the interfacial effect on ferroelectricity at the nanoscale. The observed morphology changes of the ferroelectric domains at various temperatures, with or without an electric field in bulk, thin film and nano-rods match with the experiments. From the simulated models, a deeper understanding of the domain motion in atomic scale was achieved.

**Quantifying the Length-Dependent Mobility of Dislocations in Metallic Materials from the Atomsitic to the Microscale**

Riipelaavin Il, Thanh Phan and Liming Xiong; Iowa State University, Ames, Iowa, United States.

In this work, the mobility of dislocations in f.c.c. and b.c.c. metals under deformation is quantified using a recently developed coarse-grained (CG) atomistic model. Fundamental to the CG method is an atomistic field formulation that unifies the atomic and continuum description of materials through an Irving-Kirkwood procedure in statistical mechanics. At a fraction of the cost of full molecular dynamics (MD), the CG model is shown to be applicable for calibrating the dislocation mobility law from the bottom up. In particular, using a modest computational resource, the mobility of extremely long dislocation lines (a length up to one micron and even above) in billion-atom material samples under deformation is predicted from the atomistic to the microscale. Results show that the dislocation mobility law in f.c.c. materials is insensitive to its length. In contrast, in b.c.c. materials, when the length of a dislocation is at micron level and above, its mobility is found to be proportional to the line length, i.e., the longer the dislocation line, the faster it moves. With the atomistic information being retained, the CG simulations also provide an explanation for the observed different line length-dependent dislocation mobility in f.c.c. and that in b.c.c. materials: both short and long dislocation lines in f.c.c. materials migrate through gliding, while dislocation motion is mainly controlled by kink pair nucleation and diffusion in b.c.c. materials, and the length will be the limiting factor for kink pair density. In parallel, in order to validate the CG model, a limited set of full MD simulations has been also performed. The one-to-one comparison between CG and MD demonstrates that the CG simulation does retain the atomic nature of dislocation dynamics, such as (i) the dislocation velocity-dependent line energy and core structure; and (ii) the phonon wave emission from a moving dislocation. In addition, the limitation, the future development, and the potential applications of CG will be also discussed in this presentation.

**Determining the Optimal Phase-Change Material via High-Throughput Calculations**

Nicholas Pike¹ and Ole Martin Lovvik²-³; (University of Oslo, Oslo, Norway; SINTEF Industry, Oslo, Norway).

The discovery and optimization of phase-change materials is often a long and expensive process. Here we propose a simple computational method to determine the ideal phase change material for a given chemical composition. Using first-principles calculations, within a high-throughput computational framework, we are able to determine the ideal composition of a phase-change material between any two assumed phases. This ideal composition is determined by a calculation of the co-factor conditions which, when equal to 1, ensure the lowest possible interface energy during the phase change. This ideal composition can then be targeted to produced materials with low mechanical failure rates due to the low interface energy. Here we will provide evidence of the effectiveness of our calculations for two well-known phase change materials in which we predict the ideal composition and compare it to experimental results.

**10:30 AM CP09.08.07**

**Coarse-Grained Modeling for Polymer Solutions via the Mori-Zwanzig Formalism**

Shu Wang and Wenxiao Pan; Mechanical Engineering, University of Wisconsin–Madison, Madison, Wisconsin, United States.

In this talk, we present a new method to establish implicit-solvent coarse-grained (CG) modeling for polymer solutions to conserve the dynamical properties of polymers. In the CG modeling, tens to hundreds of atoms were grouped as one CG particle; and the CG dynamic equations were rigorously derived from the atomistic data. The solvent-mediated dynamics of polymers was accurately captured via the generalized Langevin equation (GLE) with a non-Markovian memory kernel based on the Mori-Zwanzig formalism. The computational cost for direct evaluation of the non-Markovian memory kernel and generation of colored noise was significantly reduced by exploiting the equivalence between the non-Markovian dynamics and Markovian dynamics in an expanded space. A higher-order time-integration scheme was developed to further accelerate the CG simulations. To assess, validate, and demonstrate the established CG modeling, we have applied it to simulate four different types of polymer solution systems. We find that the proposed CG modeling effectively conserves the velocity autocorrelation function and diffusivity of polymers and enables two orders of speedup in computer time, compared with the reference molecular dynamics simulations.

**Real-Space Formulation for Simulating Defects in Crystalline Materials from First Principles**

Swarnava Ghosh, Kaushik Bhattacharya and Michael Ortiz; California Institute of Technology (Caltech), Pasadena, California, United States.

Density Functional Theory (DFT) has the highest accuracy to cost ratio among all electronic structure methods and provides valuable insight in understanding and predicting a wide range of materials properties. Defects in crystalline solids, play crucial role in determining macroscopic properties of materials. The profound significance of defects underlies from the coupling between the discrete effects of the lattice; chemical effects of the core and the long-range effects of the elastic field. While DFT is capable of accurately describing the chemistry of the defect core, but are too complicated and expensive for defects with long range fields, methods capable for describing long-range fields rely on empiricism and lack fidelity. This poses an outstanding dual challenge to simulate defects from first principles. To overcome this, we develop a novel coarse-grained formulation of DFT. We employ Linear Scaling Spectral Quadrature method to solve for the electronic fields and develop a coarse-graining strategy based on updated Lagrangian method to describe the long-range elastic fields. We discuss a real space formulation based on high-order finite differences, local reformulation of electrostatics, reformulation of the atomic forces and a parallelization strategy based on domain decomposition method. The developed formulation is sublinear scaling with respect to the system size and can efficiently simulate defects in crystalline materials from first principles calculations.

To demonstrate our framework, we use magnesium, the lightest among all commonly used structural metals, and has a high strength to weight ratio, and therefore has the potential to be significantly integrated into a wide range of applications. Existing magnesium alloys show low spall strength, which inhibits their applicability in dynamic environments. Magnesium alloys achieve their desirable mechanical properties via age hardening, and controlling the size of precipitates is necessary for spall strength. We use first principles calculations to understand the energetics of precipitation in magnesium-aluminum binary alloys and report the influence of deformations (which arise during processing) on the energetics of the precipitation process. We show strong dependence of concentration and volumetric strains on the cohesive energies of binary solid solutions and report a power law for these mixtures. We also show that the formation enthalpies of the solid solutions are dependent on the concentration and hydrostatic stress. The free energies of the solid solutions reported in this study are used to draw insight into the precipitation process. Since vacancies serve as nucleation sites for voids, which lead to spall, we also discuss the interaction of point defects (vacancy-solute, solute-solute and vacancy-vacancy) in magnesium-aluminum alloys using first principles calculations.
In organic electronics, it is critically important to understand how chemical structure influences molecular packing, carrier transport, and ultimately device performance. The self-assembly properties of liquid crystalline semiconductors offer many interesting advantages for fabricating highly ordered molecular films with interesting properties, including high carrier mobilities and good thermal stability.

This tutorial will provide a comprehensive overview of molecular self-assembly and liquid crystallinity in organic electronics. We aim to highlight the great potential for exploiting these effects in large-scale applications. We will begin by introducing the basics of liquid crystalline small molecules and polymers, liquid crystalline mesophases, film processing and characterization, and device physics. Relevant experimental and theoretical tools for studying this class of materials will be introduced. Finally, we will survey state-of-the-art results on the application of liquid crystalline semiconductors in high performance organic electronics.

This tutorial is aimed at experimentalists and theorists in physics, chemistry, and material science.

Concepts of carrier transport in organic semiconductors with focus on how molecular ordering determines transport phenomena.
The molecular structure of the backbone of semiconductor polymers determines the electronic levels that are relevant for organic electronic devices. Sidechains are added to the backbone to enable solution-processing by improving solubility. While the sidechains are relatively isolated from the electronic structure of the backbone, they play a significant role in the final morphology and molecular packing in thin films of semiconducting polymers. We have examined how sidechains control the resulting microstructure in thin films of a series of high performance co-polymers. Using a combination of high resolution transmission electron microscopy (HR-TEM) and grazing incidence wide angle X-ray scattering (GIWAXS) we have determined connections between sidechain structures and the domain boundaries in ordered donor-acceptor polymers. HR-TEM reveals that the aspect ratio of the crystallographic repeat unit of the backbone and sidechain length helps to determine the possible structure of domain boundaries. We have also studied conjugated polymers with unique macrocyclic sidechains that reveal the photophysical behavior of conjugated backbones without the interference of aggregation. These investigations reveal that sidechains should be considered from the outset of the design of new semiconducting polymers.

The presence of unknown polymorphs within thin films is a frequently observed phenomena for organic electronic molecules. These polymorphs can have considerably different optical and electronic properties which influences the device performance in organic electronics and optoelectronics considerably. A first step of understanding the origin of substrate induced phases is the determination of the molecular packing. A combination of grazing incidence x-ray diffraction with molecular dynamics simulation is used for crystal structure solution. Recently, also single crystal diffraction is used for crystal structure solution of substrate induced phases. We selected a number of different molecules and demonstrate fundamental properties of the crystalline structure in relation to the bulk crystal structure. It is shown that confirmation of the molecular packing with the substrate surface is an important parameter, additionally the different polymorphs can show fundamental different packing motifs like herringbone packing and stacking of aromatic rings. In a subsequent step the importance of the crystal growth kinetics is presented which causes the substrate induced polymorph and finally the thermodynamic stability of these phases. The selected examples are molecules which forms van der Waals crystals like pentacene [1], benzo[b]thiophene-benzothiophene based molecules [2] and oligothiophenes [3] but also examples from molecules with hydrogen bonds are discussed like dibromo-indigo [4] and dicyano-distyrylbenzene [5].

The molecular structure of the backbone of semiconducting polymers determines the electronic levels that are relevant for organic electronic devices. Solution-processed organic thin-film transistors (OTFTs) have received enormous interest due to their great potential for realizing low-cost, lightweight and flexible electronics applications such as displays, wearable sensors and electronic skins. Although several novel solution-processing techniques for achieving highly-crystalline organic semiconductor (OSC) films have been introduced to OTFTs, there still remains a challenging work to control thin-film properties, such as crystallinity, morphology and uniformity accompanying the rapid coating speed demanded for industrial-scale production. Here, I will present a new solution coating method that is compatible with a fast-moving roll-to-roll system by using a gap-controlled wire-bar and a bar-motion programming strategy. The developed method is highly practical and industry-friendly as well as feasible to fabricate high-quality OSC thin films in a large area at a high rate. In this method, we found that blending of high-crystalline semiconductor small molecules and an amorphous semiconducting polymer additive in an active ink could significantly improve the crystallinity of the small molecular semiconductor layer with the aid of efficient vertical phase separation during the process. Using the motion programmed bar-coated blend OSC thin films, we demonstrated large-area flexible single-crystal OTFT arrays with a superior charge carrier mobility, high uniformity, and high reproducibility. A crystallization and growth mechanism of the bar-coated films and structure-charge-transport properties will be discussed.

UNDERSTANDING THE IMPACT OF BOTH THE ORGANIC SEMICONDUCTOR DESIGN AND PROCESSING CONDITIONS, ON BOTH MOLECULAR CONFORMATION AND THIN FILM MICROSTRUCTURE IS ESSENTIAL IN ACHIEVING THE REQUIRED OPTICAL AND ELECTRICAL PROPERTIES OF ORGANIC ELECTRONIC DEVICES. FOR EXAMPLE, THE CHARGE CARRIER MOBILITY IN AN ORGANIC FIELD EFFECT TRANSISTOR CAN BE SIGNIFICANTLY INCREASED THROUGH APPROPRIATE OPTIMIZATION OF THE SEMICONDUCTOR MOLECULAR CONFIGURATION AND SELF-ASSEMBLY. THESE ASPECTS WILL BE EXPLORED WITH AN INDACEO-NITRILEPHENOL AS A CASE STUDY. IT IS BELIEVED THAT CONFORMATIONAL DISORDER REDUCES CHARGE CARRIER MOBILITY IN ORGANIC ELECTRONIC DEVICES. UNDERSTANDING THE RELATIONSHIP BETWEEN THE MOLECULAR CONFIGURATION AND THE ELECTRICAL PROPERTIES IS CRUCIAL FOR THE DEVELOPMENT OF HIGH-MOBILITY ORGANIC ELECTRONIC DEVICES.
In order to solve these problems, we proposed the utilization of the liquid crystallinity in the soluble crystalline OTFT materials on the basis of our previous research for liquid crystals as a crystalline organic semiconductor [1]. Liquid crystalline materials exhibit crystal phase up to 100 °C, i.e., liquid crystal phase shows over 100 °C. We propose a new fabrication technique for uniform and molecularly flat polycrystalline thin films by utilizing liquid crystalline thin films as a precursor for polycrystalline thin films [2]. In order to improve the thermal durability of the films, we propose to utilize new liquid crystalline materials exhibiting highly ordered liquid crystal phases such as smectic E (SmE) phase, which gives high thermal stability in the thermal process thanks to solid-like nature of the highly ordered liquid crystals [3]. In this presentation, we will show the good processability, high thermal durability of the film up to 200 °C, and high mobility over 10 cm²/Vs in polycrystalline thin films of 2-phenyl-7-octyl-bezotheniobenzothiophene (Ph-BTBT-10) as representative liquid crystalline materials [4]. Ph-BTBT-10 has highly and low ordered smectic phases of SmE and SmA, respectively. The polycrystalline thin films of Ph-BTBT-10 fabricated by spin-coating at 110 °C for SmE phase were very uniform without any crystal flakes and cracks and the surface of polycrystalline thin films existed terrace structure with molecular step of ca. 3 nm that corresponds to a molecular length of Ph-BTBT-10. The polycrystalline thin film of thermal stability is much improved. The thin films unchanged after the thermal stress at 200 °C, thanks to the solid-like nature of SmE phase up to 210 °C. The FET devices after thermal stress at 200 °C, thanks to the solid-like nature of SmE phase were improved with the conductivities of up to 7.5 S/cm. These results show how effective the SmE phase is to improve thermal durability of OTFT in BTBT derivatives. Polycrystalline thin films of Ph-BTBT-10 show high mobility over 10 cm²/Vs after short thermal annealing at 120 °C at cryo phase. The polycrystalline thin films changed from monolayer to bilayer crystal structures after the thermal annealing and the utilization of bilayer crystal films via monolayer crystal films is good idea to realize for fabrication of uniform thin film by solution process and high mobility of bilayer crystal structure.

Device Performance of Polycrystalline Ph-BTBT-10 OFETs Solution-Processed Under a Low Voltage and Bias-Stress Conditions

Improved Molecular Order and Conductivity in Fulleren Derivatives by Tailoring the Side Chain

Jian Liu, Bas Zee, Jingjin Dong, Li Qiu, Giuseppe Portale, Jan C. Hummelen and Lambert Jan Anton Koster; University of Groningen, Groningen, Netherlands.

Organic semiconductors have attracted increasing attention as low-temperature thermoelectric materials, offering the possibility of fabricating low-cost, large-scale and mechanically flexible thermoelectric modules. The thermal conductivity of organic semiconductors is intrinsically low, leaving the power factor as the most important parameter for optimization. The widely used strategy to optimize power factor, molecular doping, enables an increase in electrical conductivity, but usually at the cost of reducing the Seebeck coefficient. Molecular ordering, which is typically low in a doped organic semiconductor, can improve the electrical conductivity and, hence, the power factor. However, there is no universal strategy to induce a disorder-to-order transition in a doped organic film.

In this contribution, we demonstrate that the molecular order of pristine and doped fulleren derivatives can be greatly improved by a suitable choice of the side chain. We use a fullerene derivative with two oligo ethylene glycol side chains, PTEG-2. Annealing induces a significant ordering in thin films of this material. After cooling back to the room temperature, the ordered form of PTEG-2 remains. GIWAXS data show that the molecular order is significantly enhanced after thermal annealing, leading to very promising results that may lead to the use of PTEG-2 as a new material for optoelectronic applications, with increasing resulting in conductivities of up to 7.5 S/cm. Additionally, this structural transition does not greatly influence the Seebeck coefficient, and leads to a power factor of up to 25 μWm⁻²K⁻². Finally, doped PTEG-2 films are very stable during annealing at 150 degree Celsius, which is of importance in thermoelectric applications. Our work introduces an effective strategy for improving molecular order and thus n-type organic thermoelectric performance.

2:45 PM EP01.02.04
Device Performance of Polycrystalline Ph-BTBT-10 OFETs Solution-Processed Under a Low Voltage and Bias-Stress Conditions

Masaumi Kunii, Hiroaki Ito and Jun-Ichi Hanna; Tokyo Institute of Technology, Yokohama, Japan.

Organic field effect transistors (OFETs) have attracted high attention in the past decades for its potential in industrial applications such as flexible displays, organic bio-medical sensors, and flexible radio frequency identification (RFID) tags. In fact, among various OFET materials so far proposed, some of which exhibited high OFET mobility over a few cm²/Vs. However, FET performance have hardly been investigated in detail where practical device performance are concerned such as OFET characteristics under low voltage driving and high bias-stress stability. In this study, we evaluated OFET performance fabricated with solution-processed polycrystalline thin films of liquid crystalline organic semiconductor of 2-phenyl-7-decyl-[1]benzothenio[3,2-b][1]benzotheniophene (Ph-BTBT-10) under the low voltage and high bias-stress conditions described above.

Ph-BTBT-10 OFETs (bottom-gate and bottom-contact FET with W/L of 350 μm/70μm) were fabricated with low-k polyamide/SiO₂ hybrid gate dielectric using highly ordered smectic E (SmE) liquid crystalline phase, which helps organic molecules form a well-aligned crystaline thin film during spin-coating process and gives it high thermal stability.
The transfer characteristics were measured at drain voltage ($V_D = -0.1$ V for linear regime and at $V_D = -2$ V for saturation regime) under ambient air at room temperature. Despite the polycrystalline nature of Ph-BTBT-10 and low-$\kappa$ gate dielectric, the solution-processed, bottom-gate, bottom-contact Ph-BTBT-10 OFET exhibits saturation mobility up to 4.9 cm$^2$/Vs with the subthreshold swing of 79 mV/decade, which is very close to the theoretical limit of 60 mV/decade at room temperature [1].

On the other hand, we evaluated OFET bias-stress stability that depends on gate voltages as a function of operation time up to 10$^3$ s. The negative gate bias-stress caused negative threshold voltage shift ($\Delta V_T$) for Ph-BTBT-10 FET in ambient air, but $\Delta V_T$ rapidly decreases as the gate bias decreases and approaches to near zero when the gate bias went down to 0V in amplitude. In contrast, positive gate bias-stress causes negligible $\Delta V_T$ even with a relatively high bias voltage [2]. All these results conclude that Ph-BTBT-10 FET has excellent FET performance at a low voltage operation as well as excellent bias-stress stability in ambient air in the range of low to moderate operating voltages.

Energetics and Transport in Ordered Mesophases of Organic Semiconductors—Implications for the Solar Cells Performance

Denis Andrienko$^{1,2}$, Max Planck Institute for Polymer Research, Mainz, Germany; King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

We discuss the role of mesoscale order, electrostatic effects, defects, and roughness for charge splitting and detrapping at organic–organic interfaces. We show how inclusion of mesoscale order resolves the controversy between experimental and theoretical results for the energy-level profile and alignment in a variety of photovoltaic systems, with direct experimental validation [1,2]. We also show how one can predict open circuit voltages of planar heterojunction solar cells, in excellent agreement with experimental data, based only on crystal structures and interfacial orientation. We explain how long-range molecular order and interfacial mixing generate homogeneous electrostatic forces that can drive charge separation and prevent minority carrier trapping across a donor-acceptor interface [2]. Comparing several of small-molecule donor-fullerene combinations, we illustrate how tuning of molecular orientation and interfacial mixing leads to a trade-off between photovoltaic gap and charge-splitting and detrapping forces, with consequences for the design of efficient photovoltaic devices. By accounting for long-range mesoscale fields, we obtain the ionization energies in both crystalline [3] and mesoscopically amorphous systems with high accuracy [4,5,6,7].

Charge Transport in Diareno-Fused Antiaromatic Molecules

Andrew Zeidell$^1$, Laura Jennings$^2$, Coned K. Frederickson$^1$, Qianxiang Ai$^1$, Chad Risko$^2$, Michael M. Haley$^2$ and Oana Jurchescu$^1$; $^1$Department of Chemistry & Biochemistry and the Materials Science Center, University of Oregon, Eugene, Oregon, United States; $^2$Department of Chemistry, University of Kentucky, Lexington, Kentucky, United States; $^3$Max-Planck Institute for Polymer Research, Mainz, Germany; $^4$King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

Charge transport in organic semiconductors is strongly related to the molecular structure and the solid-state packing within the crystal. Reducing molecule aromaticity, while preserving conjugation length, can be effective in enhancing carrier mobility. One example of such a system is the diareno-antiaromatic compounds. In this study, we synthesized a series of dinaphtho-fused x-indacenes and evaluated their electronic and electrical properties using a combined computational and experimental approach. Three different substitutions of the linear fused dinaphthindacene (DNI) backbone were investigated, namely (n-octylidiosopropylisilyl)ethyl nODIPS, (tris(isobutylisilyl)ethynyl)TIBS, and (tris(isopropylisilyl)ethynyl)TIPS. Computational studies find high effective masses in the nODIPS and TIBS derivatives, suggesting that the charge transport is not effective in these materials. On the contrary, the TIPS substituted molecule yielded low effective masses for both holes and electrons, indicating that charge carrier mobility can be high in this compound. To test the electrical properties of these semiconductors, thin films of each derivative were electrically characterized in a top-gate bottom contact field effect transistor architecture. Gold and silver, in combination with several chemical treatments, served as source and drain electrodes, while spin-coated Cytop fluoropolymer was the dielectric. To improve thin film morphology and crystallinity, a solvent vapor annealing post-processing step was employed. The TIPS and nODIPS derivatives did not yield working devices, in agreement with the theoretical predictions. In the TIPS-substituted DNI, we measured hole mobilities as high as 2.25 cm$^2$/Vs, in agreement with the low effective mass of 0.52 m, and over three times larger than the mobility measured in the linear isomer. We were not able to detect unipolar electron transport, in spite of the low electron effective mass of this compound (0.43 m), most likely because of inefficient injection from the high work function electrodes and trapping at the semiconductor/dielectric interface. Our results underline the importance of fine-tuning the molecular structure in order to obtain high mobility organic semiconductors.

Effect of Static Disorder Comparable to Dynamic Disorder on Charge Transport in Liquid Crystals

Akira Ohno, Jun-Ichi Hanna and Hiroaki Iino; Tokyo Institute of Technology, Yokohama, Japan.

During the past decade, many new candidates of organic semiconductors exhibiting not only performance (high mobility exceeding over 10 cm$^2$/Vs) but also stability (thermal stability or lifetime etc.) or processability (printable or low-cost process) have been fabricated and developed significantly in response to various demands of device performance. However, there is no general solution to satisfy both performance and structural stability. Our approach to using liquid crystallinity is one of the candidates for the general solution. Introducing partial disorder of liquid crystallinity for the device fabrication is to accept the fluidity of the material and to provide the large- and uniform- thin film without structural defects or grain boundaries, which extrinsically cause serious problems for charge transport. On the other hand these partial disorder and fluidity provide static disorder ubiquitously distributed. For example, the degree of freedom in alkyl chain or flip-flop motion of p-conjugated core, which are typical behavior of “high-ordered” liquid crystal. In our research, we focus on these static disorders which are inherent in liquid crystals. We discuss these static disorders using the theoretical estimation and the simulation compared with experimental results for phenyl naphthalene, biphenyl, the thiophene and BTBT derivatives exhibiting smectic E phase which is typical phase using for device process we are proposing. We found that these disorders are controlled by order parameters of liquid crystallinity because they are not extrinsic origin but intrinsic disorder caused by the degree of freedom originated by liquid crystallinity. These typical values of disorder (typically ~50meV in energetic disorder) in liquid crystal are small compared with those in amorphous (~100meV). However, they are not ignored and their activation energy is comparable with polaron binding energy. Thus their transport behavior is the superposition of small polaron and Gaussian disorder effects.
In introducing side chains into the phthalocyanine (Pc) molecule to induce liquid crystalline (LC) phases, there are two types of molecular structures, namely, a peripheral type and non-peripheral type. We have investigated the molecular packing and electronic transport characteristics of mesogenic Pc having alkyl side chains at non-peripheral sites, 1,4,8,11,15,18,22,25-octaalkylphthalocyanine (CnPc), and their families. These compounds exhibit very high long-range drift mobility up to 1.4 cm²/Vs evaluated by time of flight measurement and must be a candidate of organic semiconductor for printable electronics [1,2]. However, this fact is contrary to expectation. Namely, it can be easily predicted that the planarity of the Pc molecular plane might be reduced due to large steric hindrance between non-peripherally substituted chains and disordered molecular stacking undesirable for carrier transport is formed.

We have also demonstrated a high-efficient bulk-heterojunction (BJH) solar cell based on C6PcH and their family, which shows a high power conversion efficiency of 5.3% [3-5]. For the formation of the optimally phase-separated nano-structure for efficient carrier generation and transportation, the mesogenic properties should play an important role. Using self-organizing characteristics of LC phase, we can fabricate a large area monodomain thin film of CnPc for electronic devices. A well-aligned uniaxial single crystal growth in large area of printed thin film was obtained by means of conversion process from LC phase in a supercooled state to crystal phase. CnPc shows a crystal polymorphism and forms two different crystal structures (α-phase or β-phase) depending on the growth condition of the crystal. The high mobility of C6Pc reported so far is evaluated in the crystal structure of the β-phase. However, according to the theoretical prediction, higher mobility is expected in the α-phase [6]. We have demonstrated a large area single crystaline film of α-phase converted from spin-coated β-phase Pc film, which is based on the crystal polymorphism conversion triggered by the solvent vapor treatment [7,8].

Benzothiophen[3,2-b]-[1]benzothieno[3,2-b]thiophene (BTBT) derivatives are very promising candidates in the field of solution processable organic semiconductors. In this work the surface crystallization behaviour of Ph-BTBT-T-10 is investigated. Thin films starting from the monolayer regime up to thick films were prepared by spin coating and physical vapour deposition. The films were investigated in terms of crystalline properties and thin film morphology by X-ray diffraction, X-ray reflectivity and Grazing Incidence X-ray diffraction, atomic force microscopy and optical microscopy. It is shown that by spin coating at low concentrations of 0.3 g/l an incomplete monolayer of standing molecules with the aromatic core pointing towards the substrate is formed. At higher concentrations between 0.5 g/l and 3 g/l strong island growth starts which leads to the formation of macroscopic islands with dendritic monolayers in-between them. Physical vapour deposition demonstrates a more homogenous distribution of the material forming terraces of multiple molecules. In thin films whether in solution (5 g/l) or PVD (300 Å) crystalline structures are observed in XRD. As well as the known bulk phase with a head to head arrangement of two molecules in an orthorhombic unit cell possessing a herringbone structure, also other polymorphic phases are present.

Recent advances in organic solar cell ingredients and processing have enabled fabrication of single devices with power conversion efficiencies in excess of 15%. However, such high efficiencies are not realized in commercial products because of the difficulty scaling up robust self-assembly of the active layer components. For mass-produced devices to be commercially viable, the factors governing self-assembly of structure, and how that structure determines charge transport must be understood. Investigating these factors is challenging due to the multiplex combinations of chemistries and processing protocols that are feasible. However, searching these combinations can be accelerated through the use of computational tools such as molecular dynamics and kinetic Monte Carlo. In this work, we develop an united-atom model for the benchmark donor polymer poly-(3-hexylthiophene), resulting in the most experimentally accurate structures to date. We then predict the self-assembly and charge transport under hundreds of processing variable combinations. We find that ordered structures obtained using good solvents allow for the highest charge transport rates. Furthermore, we find that polymer ‘tie-chains’, which span between crystallites, are critical in preventing charges from becoming trapped within local structural features. We discuss modeling successes with more complex molecules and demonstrate promise for these tools in developing design rules for mass producing organic solar cells.

High-Performance Ternary Organic Solar Cell Enabled by a Thick Active Layer Containing a Liquid Crystalline Small Molecule Donor Fei Huang; South China Univ of Technology, Guangzhou, China.

Inverted thermal activation of charge mobility in polymer field effect transistors (FETs) has been recently observed in a few cases for holes and in a single case only for electrons. Such exciting observations lead us to foresee a future of polymer FETs beyond hopping transport limitations. Yet, there is a clear lack of understanding of the fundamental reasons leading to such transport regime and, as a consequence, of synthetic and processing guidelines. Here we make use of uniaxial molecular alignment and specific thermal treatments within the melting endotherm of a diketopyrrolopyrrole-tetrafluorobenzene-based electron transporting copolymer films to induce a favorable microstructure for electron transport. Thanks to such strategy we can achieve a single-crystal like, voltage independent mobility, with vanishing activation energy close to room temperature. We make use of extensive microstructural, electrical, electro-optical and theoretical investigations to rationalize the transition from a hopping to a band-like transport regime, and link it to the microstructure. Thermal barriers present in the disordered phase can be effectively suppressed in the direction of molecular alignment by a more efficient interconnection of the ordered phase following the increased crystals extension occurring during the thermal process.

Polaron Delocalization and Mesoscale Effects in Charge Transport in Semicrystalline Conjugated Polymers Alberto Salleso; Stanford University, Stanford, California, United States.

Typically semicrystalline conjugated polymers exhibit much higher mobility than their amorphous counterpart. The archetypical example is regio-random P3HT, with mobilities on the order of 10−6 cm2/V.s as compared to regio-regular P3HT with mobilities on the order of 0.1 cm2/V.s. The oft-cited reason for these differences is the fact that in polymer crystallites charges delocalize and take a partial 2D character, enabling higher mobility. The amount of delocalization and how it depends on structure and processing is however difficult to measure. We will show that charge modulation spectroscopy in the IR with model materials allows to determine the delocalization of the polaron in P3HT when aided by theory. In order to extract systematic trends we will use 100% regio-regular P3HT of well-defined molecular weights (PDF−1.1). These model materials allow to clearly discern different limiting factors in charge transport and how they depend on molecular weight. On one hand, short polymer segments crystallize well but have torsional disorder, which localizes the charges in 1D. As the molecular weight increases, backbone torsion decreases and charges delocalize in 2D. Eventually delocalization saturates and mobility increases are attributed to connectivity between crystallites. We extend this framework beyond model materials and study charge delocalization in high-performance donor-acceptor polymers and aligned polymers for stretchable electronics. In aligned films we are able to directly measure delocalization along the backbone and across molecules.

Nematic Interactions, Ordering and Effects on Charge Mobility in Semiconducting Copolymers Scott T. Milner; The Pennsylvania State University, State College, Pennsylvania, United States.

Organic semiconducting polymers are typically rather stiff compared to traditional polymers, because the monomers are aromatic rings, and the deflection angle between successive rings is small. This leads to the possibility of significant nematic interactions between chains in an isotropic melt just from steric considerations. Working against this tendency are the solubilizing sidechains, which dilute the stiff backbones with flexible “grease”. In recent work, we have used atomistic simulations to predict the nematic coupling constant alpha for semiconducting polymers such as P3HT, and predicted the isotropic-nematic (IN) transition temperature. Our method does not rely on observing the nematic ordering transition with its attendant slow kinetics, but instead infers alpha from its amplifying effect on the elongation of chains in an isotropic melt in response to an applied
external tension. Even when alpha is not large enough to result in a stable nematic phase, nematic interactions can amplify the aligning effect of an impenetrable surface, at which semiflexible chains tend to lie parallel. We have investigated this effect with coarse-grained MD simulations of melts near a wall, in which we observe how far nematic order extends from the wall into the bulk, as a function of chain stiffness. These results compare well to our predictions from self-consistent field calculations adapted to semiflexible chains. We have exploited this surface alignment effect to locate the IN transition, by observing how surface alignment propagates into a slab of polymer chains confined between walls, as the chain stiffness increases. Below the IN transition, surface-induced alignment grows into the bulk with a velocity proportional to the undercooling. By observing how the front propagates as we cool (or increase chain stiffness), we can accurately locate the transition.

Nematic order is important in semiflexible polymers because electronic transport in semiflexible polymers is inherently anisotropic. Conformers move readily along straight chains, which can hop with relative ease between parallel chains in a crystal, and hop only with difficulty between obliquely oriented chains in an isotropic melt. Crystallization from a nematic phase may give better-organized crystalline domains with fewer amorphous regions, and may induce chain alignment even in the amorphous regions. In a separate thrust of our research, we have developed coarse-grained electronic models capable of describing carrier states and motion in crystalline and amorphous semiflexible polymers such as P3HT. Our approach uses tight-binding models, in which each ring moiety is a site, with hopping between adjacent sites. Parameters are tuned to agreement with state-of-the-art DFT calculations for small systems in well-defined geometries. Hopping matrix elements along chains are large for trans dihedrals, but fall off and vanish as dihedrals rotate to 90 degrees, breaking conjugation. Conformers in P3HT form polars, in which the surrounding material reorganizes (“polarizes”) in response to the presence of the charge. The polaron size is set by a competition between electronic kinetic energy (which seeks to delocalize the charge) and the reorganization energy (which stabilizes a localized charge more effectively). The most important contribution to reorganization energy in these materials is dielectric polarization of nearby material, leading to polarons a few rings long. These polarons can move between chains a crystal, by hops described by Marcus theory. In the hopping barrier state, the polaron is midway between two degenerate locations, in a symmetric superposition of states. We use our tight-binding model to compute barriers for hopping between chains, in a crystal and an amorphous melt. The melt barrier is larger, because obligiously oriented chains do not share very effectively the same polarization field, which increases the reorganization energy.

Quantitative Analysis of the Density of Trap States in Organic Semiconductors by Current-Voltage Measurements on Low-Voltage Thin-Film Transistors

Michael Geiger1, Lukas Schwarz2, Ute Zichesichang2, Dirk Manske1, Jens Pflaum1, Jürgen Weis2, Hagen Klauck2 and Thomas Weitz2,3,4

1Max Planck Institute for Solid State Research, Stuttgart, Germany; 2Faculty of Physics, Ludwig-Maximilians-Universität München, München, Germany; 3Center for NanoScience (CeNS), Ludwig-Maximilians-Universität München, München, Germany; 4Nanosystems Initiative Munich (NIM) and Center for NanoScience (CeNS), Ludwig-Maximilians-Universität München, München, Germany.

The electrical characteristics of thin-film transistors (TFTs) based on disordered semiconductors, such as hydrogenated amorphous silicon, metal oxides and conjugated organic semiconductors, are greatly influenced by the density and energetic distribution of localized electronic states in the energy gap of the semiconductor arising from chemical or structural defects. In the 1980s, Grünewald et al. developed a method to convert a measured transfer curve of a field-effect transistor to the underlying density-of-trap-states (trap DOS) function [1]. Solvent vapor annealing [2] involving swelling and recrystallization of as-cast films allows to control nucleation densities and to grow sphere-like superstructures. Interestingly, the sphere-like superstructures result from radial growth of fibers with the fiber growth direction being the polymer chain direction. Simple blade coating from concentrated solutions even yields square centimeter large oriented films – again made of fibers - with dichroic ratios of 18 and charge transport anisotropies up to 14. Nucleation and growth mechanisms can be understood in terms of a reorientation of pre-formed aggregates in solution, suggesting nematic-like preorientations. These findings show completely different growth behavior than previously developed for the well-studied p-type polymer poly(3-hexylthiophene) [3].

The influence of regioregularity on aggregation behavior [4] and on chemical and electrochemical doping performance will be also discussed during the presentation [5].

Grazing incidence X-ray diffraction (GIXD) is an experimental method frequently applied to characterize a wide variety of thin films and surfaces. Depending on the texture of the surface's crystallites, special care is required during the experimental measurements and successive data evaluation. For example, samples with large individual crystallites on a surface resulting in poor statistics or epitaxially grown samples with defined in-plane alignment of the crystallites require both a full sample rotation around the surface normal during data collection. This is necessary to obtain all information for phase, texture and epitaxy analysis. Moreover, this experimental approach opens new possibilities for advanced characterisation methods which in simple static experiments are inaccessible, e.g. the determination of the in-plane mosaicity. GIDVis is a software package developed in MATLAB for visualization and analysis of GIXD data in general but mostly used for thin films. It is specialized on data obtained during a sample rotation around the surface normal, i.e. a rotating GIXD experiment. Due to the geometrical independent character of the underlying algorithms implemented, most features can be used independently from the input data type. GIDVis allows the user to perform detector calibration, data stitching, intensity corrections, standard data evaluation (e.g. cuts and integrations along specific reciprocal space directions), crystal phase analysis, etc. Further, these features are not limited to a single experimental setup, data from mostly all diffraction setups can be processed. To fully take advantage of the measured data in the case of sample rotation, pole figures can be calculated from the experimental data for any q value covered. As an example, GIDVis is used here to investigate the epitaxial alignment of pentacenequinone (P2O) crystallites on a Au(111) surface, illustrating the importance of the sample rotation. GIDVis is available online free of charge (http://www.if.tugraz.at/am/GIDVis/).

Flexible TFP showed excellent mechanical and chemical stability. Patterned and flexible TFP can drive the flexible devices market to a new level. This work was supported by BK21 Plus program, the BRL 2015042417, Mid-Career Researcher Program (2016R1A2B2010141).

To develop an advanced thermal interface material (TIM) which can effectively dissipate the problematic heat in the electronic devices, rod-shaped reactive mesogen (RM) was newly synthesized as a building block for the thermally conductive liquid crystal (LC) films. Based on the combined techniques of spectroscopy, scattering and thermal analyses, it was verified that the synthesized RM formed a smectic A (SmA) mesophase between crystalline and isotropic (I) phases. The thermal conducting LC films were fabricated by the photopolymerization of RM in both LC and isotropic phases. Regardless of the molecular packing structures, the thermal conducting LC films exhibited outstanding heat transfer properties over 1 W/mK that surpass the conventional polymeric materials. In addition, the heat conducting performance of LC film can be amplified in a certain direction by the uniaxial orientation of LC molecules in the network. The uniaxially oriented LC film exhibited significant heat guiding performance as TIM than that of conventional organic materials. The highly thermal conducting LC films can be used as an advanced thermal managing material for electronic devices. This work was supported by BK21 Plus program, the BRL 2015042417, Mid-Career Researcher Program (2016R1A2B2010141).

PDI-RM TFP exhibited the property of E-type polarizer with a polarizability of 99.81% at 491 nm (λmax). In addition, the patterned TFP showed excellent mechanical and chemical stability. Patterned and flexible TFP can drive the flexible devices market to a new level. This work was supported by BK21 Plus program, the BRL 2015042417, Mid-Career Researcher Program (2016R1A2B2010141).
Organic electronics offer the premise of low-cost, versatile electronic devices with alternative mechanical, optoelectronic, and chemical properties not afforded by inorganic semiconductors. One of the major limitations continues to be lower conductivity associated with their highly disordered systems. The predominant approach is to use chemical additives (i.e. dopants) that undergo charge transfer with the matrix organic semiconductor to increase carrier concentration and conductivity. Yet, broad application of doping has been limited as precise control has remained elusive, due to partial electron transfer events and/or phase segregation of dopant. Alternatively, electrochemical doping precisely varies conductive polymer properties with only an applied voltage on a thin film in an electrolyte. This allows for direct monitoring of the conductivity and holes/molecules in situ to evaluate critical structure-property relationships. As a proof of concept, and comparison to known chemical doping strategies, the model system poly(3-hexylthiophene) (P3HT) was held at different doping (oxidizing) potentials and subsequent doping effects were characterized using a combination of electrochemical and spectroscopic methods.

Conductivity was demonstrated to vary by ~10^3 from 2x10^4 S/cm for the undoped film exposed to electrolyte to 0.35 S/cm for the highly doped film in solution, with solid state conductivity being retained at 0.24 S/cm. UV-vis absorbance data confirms the presence of both polaronic and bipolaronic levels in the solution doping, although the bipolaronic species are not retained in the solid state. Complementary grazing incidence wide angle x-ray scattering (GIWAXS) demonstrates a voltage-dependent swelling of the film with increasing oxidation potential in the alkyl stacking direction, demonstrating preferential ion uptake while retaining the desired π-π stacking necessary for high electronic transport. These results demonstrate a promising alternative path to increasing conductivity of organic semiconductor films and could eliminate the synthetic bottleneck associated with designing dopants for individual semiconductor systems.

Reversible Doping in Organic Electronics—A Strategy to Finely Tune Electrical Conductivity

Jonathan Harriss, Bharati Neelamraju and Erin L. Ratcliff; University of Arizona, Tucson, Arizona, United States.

Optical and Structural Anisotropy in Pentacene Thin Films Revealed by pMAIRS

Nobutaka Shiyo, Takafuli Shimosa and Takeshi Hasegawa; Institute for Chemical Research, Kyoto University, Uji, Japan.

Pentacene is one of the most basic materials in organic thin-film transistors. The compound is known to form a polycrystalline thin film, in which the molecular long axis is oriented perpendicular to the substrate surface, i.e., end-on orientation. The face-on oriented thin film, on the other hand, where the molecular plane is parallel to the substrate, has never been found on an inert substrate represented by SiO2. As a result, the face-on orientation has long been believed to be generated only on specific substrates such as a metal single crystal.

A low-temperature (LT) deposition technique is suitable for obtaining the metastable face-on crystalline film on an inert substrate. In a low temperature region (<223 K) of the substrate, however, pentacene molecules have long been believed to take a randomly oriented amorphous structure.

In the present study, the LT film of pentacene is re-investigated by using p-polarized multiple-angle incidence resolution spectrometry (pMAIRS) together with two-dimensional grazing incidence X-ray diffraction (2D-GIXD). The combination of the cutting-edge techniques readily reveals that the face-on phase is definitely realized as the dominant component. In short, the present study shows that the conventional schematic of the “amorphous” structure should be revised.

EP01.08.10
Controlling Solution Assembly Behaviors of P3HT-b-P2VP Block Copolymers via Tuning Regioregularity

Younseok Kim1, Hyoeng J. Kim2, Jin-Seong Kim2, Hongseok Yun1, Hyoemyung Park1, Junghun Han1 and Bumjoon J. Kim3; 1Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2University of Massachusetts Amherst, Amherst, Massachusetts, United States.

In selective solvents, poly(3-hexylthiophene) (P3HT)-based block copolymers (BCPs) assemble into crystallized nanowire (NW) structures due to the strong crystalline interactions of the rigid P3HT block. Herein, we report the effect of the crystalline interactions of the P3HT block on the self-assembled structure of the P3HT-based BCPs in solvent by modulating the regioregularities (RRs) of P3HT. We synthesized a series of P3HT-block-poly(2-vinylpyridine) (P3HT-b-P2VP) copolymers that had the same molecular weights but various RRs, ranging from 55 to 95%, and we investigate their behavior in a binary solvent mixture. We observed a remarkable transition from the well-defined 1D NW structure to micelle structures (i.e., spherical micelles) depending on RR. The well-defined NW structures were produced from the P3HT-b-P2VP copolymers with high RR, i.e., 95%. For the RR of 55% in the BCPs, crystallization of the P3HT moiety was suppressed so that only micelle structures were formed. Remarkably, between RR values of 75% and 65% in the BCPs, we observed 1D nanostructures, which are considered to be intermediate morphologies between NWs and micelles. Even though they had distinctive characteristics, such as larger widths and heights, less crystalline properties, and different positions of the P2VP chains than conventional NWs, they still possessed partial crystallinity, which was different from the amorphous assemblies of RR of 55% BCPs. Therefore, we demonstrated the substantial relationships between the solution assembly behaviors and the crystalline interactions of conjugated semicrystalline–coil BCPs, which can be used as important guidelines for designing versatile BCP nanostructures.

EP01.08.12
Discrete Monolayers of a Benzothieno-benzthiophene Derivative at Silicon Oxide Surfaces—Structures Formed by Liquid Crystalline States

Michael Dohr1, Oliver Werzer2, Quan Shen3, Christian Teichert4, Yves Geerts5, Michele Sferrazza6 and Roland Resel1; 1Graz University of Technology, Graz, Austria; 2Institute of Pharmaceutical Sciences, Graz University, Graz, Austria; 3Institut für Physik, Montanuniversität Leoben, Leoben, Austria; 4Faculté des Sciences, Université Libre de Bruxelles, Brussels, Belgium.

During the last years the molecule diocetyl-benzothienobenzothiophene (C8-BTBT-C8) has attracted large attention, since thin film transistors based on this organic semiconductor show outstanding device performance. The high quality of the C8-BTBT-C8 films may be one of the key features for the successful application. The presence of a liquid crystalline smectic state at elevated temperatures together with a highly defined crystalline state at room temperature allows special film preparation methods of high structural perfection. Thin films of C8-BTBT-C8 in the monolayer (thin films) and in the multilayer regime (thick films) are prepared by spin coating, a method far from thermodynamic equilibrium. Heat treatment of the films results in strong islanding (for thick films). The structure of the organic films is investigated by temperature-dependent in-situ methods using atomic force microscopy, x-ray reflectivity, and grazing incidence x-ray diffraction [1]. Already at temperatures few degrees below the phase transition from the crystalline state to the smectic A state (T = 381.5 K), the formation of a single monolayer is observed. The molecular rearrangement takes 30 minutes until the monolayer formation is completed. In case of thick films an increase of the temperature in defined steps induces discrete monolayer formation as bi-layer, triple-layer, etc. Up to 5-layer structures are observed. The reversibility of the discrete layer formation reveals that thermodynamic equilibrium states are observed. Non-equilibrium structures can be stabilised by rapid cooling from the respective temperature [2]. Explanation of these observations are given in terms of the classical film formation models using surface energy of the used silicon oxide surface and the variation of the surface energies / surface tension of the molecule C8-BTBT-C8.

EP01.08.13
Optical and Structural Anisotropy in Pentacene Thin Films Revealed by pMAIRS

Nobutaka Shiyo, Takafuli Shimosa and Takeshi Hasegawa; Institute for Chemical Research, Kyoto University, Uji, Japan.

In short, the present study shows that the conventional schematic of the “amorphous” structure should be revised.
The crystal structures of Ph-BTBT-10 thin films were analyzed by thermal in situ 2D-GIXD at different substrate temperatures. The Ph-BTBT-10 films at RT and 60 °C showed a similar series of peaks assignable to a monolayer structure with a d-spacing of 27 Å. When the substrate temperature was increased to 120 °C, the diffraction peaks clearly changed, which suggests a transformation from a monolayer structure (d = 27 Å) into a bilayer structure with a d-spacing of 54 Å. Since the phase transition temperature to SmE (SmE) mesophase is 144 °C, a series of peaks assignable to SmE were observed when heated to 180 °C. In addition, a mixed layer of monolayer and bilayer structures appeared when the Ph-BTBT-10 thin film was rapidly cooled from 180 °C to RT. This result indicates that the cooling speed might be a significant factor in forming a well-uniformed crystalline thin film structure. Based on these results, Ph-BTBT-10 can be handled through vacuum deposition method, and the phase transition from the monolayer to the bilayer structure can occur in the same way which occurs for solution processed Ph-BTBT-10 thin films. Finally, we demonstrated top-ranked FET performances through vacuum deposition process. This presentation will also include fabrication and evaluation of Ph-BTBT-10-based device via dip-coating method.

EP01.08.15 Understanding Molecular Aggregation of Emissive Guests in Organic Light-Emitting Diodes with Atom Probe Tomography Matthew Jaskot1, Andrew P. Proudnian2, Galen B. Vincent2 and Jeramy D. Zimmerman2; Materials Science, Colorado School of Mines, Golden, Colorado, United States; 2Physics, Colorado School of Mines, Golden, Colorado, United States.

In an organic light-emitting diode (OLED) device, the spatial distribution of dopant molecules in the emissive layer host-guest blend impacts key performance characteristics. Specifically, aggregation of dopant molecules is expected to exacerbate exciton annihilation processes associated with efficiency roll-off and device degradation. We have developed atom probe tomography (APT) techniques that allow us to create a chemically sensitive three-dimensional reconstruction of molecular positions (i.e. nanometer-scale spatial resolution with sub-Dalton mass discrimination). APT allows us to study dopant aggregation in OLED emissive layers based on a blend of multiple molecular constituents. We have used spatial statistics analysis of APT data to show that Ir(ppy)3 aggregates in a number of commonly used hosts; here, we investigate the effects of aggregation in an mCBP:Ir(ppy)3 emissive layer blend. By controlling substrate temperature during deposition, we show that we can control the spatial distribution of the dopant in the film. Hole mobility increases over two orders of magnitude in this system as substrate temperature increases from -50°C to 50°C (mCBP Tg = 97°C), which is consistent with the Gaussian Disorder Model and the assumption that holes are transported on the Ir(ppy)3: Highest Occupied Molecular Orbital (HOMO). We also show that the device triplet-triplet annihilation (TTA) rate increases with substrate temperature, as expected with stronger guest aggregation. Understanding how guest aggregation affects exciton dynamics and annihilation in an OLED emissive layer is an important step in maximizing device efficiencies and reducing the effects of long-term degradation.

EP01.08.16 Molecular Scale Patterning of Photonic Structures via Conformational Control Alice Smith1 and Donal D. Bradley1,2, 1Department of Physics, University of Oxford, Oxford, United Kingdom; 2Department of Engineering Science, University of Oxford, Oxford, United Kingdom.

Patterning structures at the scale of the wavelength of light is central to photonic device fabrication. Whilst standard patterning techniques such as e-beam lithography can be used to pattern the structure of any materials, orientation, configuration and conformation can also be used to control the optical properties of molecular materials. An example of conformation control is formation of the β-phase in the organic semiconductor poly(9,9-dioctylfluorene) (PFO), in which polymer chain segments adopt a rigid, planar structure when subjected to particular solvent interactions. The photophysics of this phase has been studied in great detail, with particular focus on the presence of a new long wavelength absorption peak, which results in a significant change in refractive index within the optical gap (10.9% at 450nm). The index change offers potential for photonic element fabrication, in a fashion that mimics dielectric metamaterial structuring on a molecular length scale. Spatial patterning of the structure defines the photonic elements, with millimeter scale patterning shown in 2009, followed by micron scale in 2012, and nanoscale in 2015. We now report a further study on the use of Dip Pen Nanolithography (DPN) - an AFM derived single step writing process - as a technique to pattern nanoscale structures and discuss their suitability for photonic device applications.

EP01.08.18 Phase Diagrams of poly(3-hexylthiophene):N,N’-alkyl Substituted Naphthalene Diimides Blends Dorota Chleboz1,2, Markus Mezger2, Gunnar Glaser2, Waldemar Goldmann1, Krzysztof Janus1, Kinga Danielowicz1 and Adam Kiersnowski1,3; 1Wrocław University of Science and Technology, Wrocław, Poland; 2Max Planck Institute for Polymer Research, Mainz, Germany; 3Leibniz Institute for Polymer Research, Dresden, Germany.

Fabrication of electronic devices based on organic semiconductors at the fundamental level can be considered a problem of engineering of polycrystalline materials. Tuning the charge transport properties in such materials requires controlling of size, perfection, distribution, and orientation of crystalline domains in the semiconducting films1. Those parameters can be controlled through film formation and post-processing conditions, such as thermal annealing. While the casting parameters (solvent, temperature etc.) exert an influence on the primary crystallization and formation of polycrystalline system, the annealing induces the further growth of crystalline domains, increases perfection of crystal packing but may also trigger phase transitions of the ordered phases crystallized from the solution. Insufficient insight into the processes occurring upon the annealing may lead to erroneous conclusions related to properties - especially when samples reveal a complex phase behavior like the one observed in the case of aromatic, conjugated molecules or polymers. These materials may show multiple packings in crystalline phases as well as multiple thermally-induced transitions between crystalline and liquid crystalline phases before reaching the isotropic state1. Different packing of molecules and hence different geometrical overlap of aromatic moieties may aﬀect charge transport properties. Thus in our research we concentrated on relationships between packing of molecules in the ordered domains and electronic properties of materials.

The study was focused on the blends of poly(3-hexylthiophene) (P3HT) with butyl- or hexyl- or octyl-substituted naphthalene diimides (NDI). In our experimental approach we have applied differential scanning calorimetry (DSC) to determine phase transition points and X-ray diffraction (XRD) to gain insights into the structure of molecular assemblies in the system. These studies were supplemented with images from scanning electron microscopy (SEM) providing information about the morphology of the blends. In order to correlate the structure and morphology with charge transport properties, the blends were tested in organic field effect transistors (OFETs). Results of our experiments indicated that packing of molecules in crystalline phases and mesophases as well as phase transition temperatures were related to molecular architecture of NDI and compositions of the blends. XRD and DSC data were used to determine phase diagrams for the blends of P3HT with NDI. It was found that decreasing content of NDI in the blends caused a notable decrease of the isotropization temperature of the NDI component. The melting point of P3HT also significantly drops as its content in the blend decreases. The profile of the isotropization points of the P3HT:NDI blends plotted as a function of composition revealed a clear minimum resembling the eutectic point. In some of the blends, we observed additional transitions that may suggest formation of new crystalline phases occurring neither in pure P3HT nor pure NDI. The studies of the blends by means of scanning electron microscopy indicated that composition of polycrystalline layers also exerted an influence on the crystalline morphology. The studies electronic properties in the model field-effect transistors (OFETs) revealed that the blends with the uniform, fine-grained polycrystalline morphologies enable balanced ambipolar charge carrier transport. This, once again, indicates that the fine tuning of the blends composition is crucial for engineering of organic electronic devices.

SESSION EP01.09: Material Design and Fabrication IV
Session Chairs: Enrique Gomez and Elizabeth von Hauff
Solution-Processed Photovoltaics—Opportunities Provided By Use of Material Science Tools

Natalie Stimpeling; Georgia Institute of Technology, Atlanta, Georgia, United States.

In the past decade, significant progress has been made in the fabrication of organic photovoltaic devices (OPVs), predominantly due to important improvements of existing materials and the creation of a wealth of novel compounds. Many challenges, however, still exist. Real understanding of what structural and electronic features determine, for instance, the short-circuit current (Jsc), open-circuit voltage ( Voc) and fill factor are still lacking; and the role of charge transfer states and which charge transfer states are critical for efficient charge generation are still debated. Here we attempt to obtain further insight of relevant structure/processing/performance interrelations using classical polymer processing “tools.” We present a survey on the principles of structure development of this material family and how it can be manipulated, with focus on how to control the morphology and important interfaces (molecular and between different phase regions). Goal is to tailor and tune the final “ morphology” towards establishing correlations with relevant device characteristics. Examples are given based on polymer:fullerene solar cells as well as solution-processed perovskite structures.

11:00 AM -EP01.09.02

Nanostructured Liquid-Crystalline Assemblies for Ion and Electron Transport

Takash Kato; Department of Chemistry and Biotechnology, School of Engineering, The University of Tokyo, Tokyo, Japan.

Nanostructured liquid-crystalline (LC) assemblies forming columnar, smectic, and bicontinuous cubic phases can provide 1D, 2D, and 3D nano-channels capable of transport of ion and electron [1,2]. We have developed these nanostructured functional soft materials. Potential applications of these materials as electrolytes electrochemical devices, luminescence materials, and semiconductors have been shown. Here we report design, self-assembled structures, and functions of nanostructured LC materials exhibiting ion and electron transport properties. Nanostructured ionic liquid crystals bearing imidazolium and ammonium moieties and liquid crystals complexed with ionic species exhibit 1D, 2D, and 3D ion transport properties. They can be used for electrolytes for lithium ion batteries [3-4] and photovoltaics [5]. They also show stimuli responsive properties such as conductivity switching [6] and photo-control of ion transport directions [7]. Electron transport LC materials have also been developed [8,9]. Supramolecular hydrogen-bonded electron transport materials exhibit ion recognition properties [9].

Molecular Packing Dependent Photophysics and (Opto)electronic Properties of Functionalized Anthradithiophene Single Crystals

Jonathan Van Scheneck1, Gregory Giesbers1, Keshab Paudel1, John Anthony2 and Oksana Ostrovskov3; 1Oregon State University, Corvallis, Oregon, United States; 2Chemistry, University of Kentucky, Lexington, Kentucky, United States.

Organic semiconductors have attracted attention due to their relative ease of fabrication, cost economy, and uniquely tunable optical and electronic properties via functionalization of the molecules. These properties in the solid state are determined both by the molecular structure and molecular packing, and thus it is important to understand the contribution of each factor to the resulting performance of the material, although separating these contributions remains challenging. Towards resolving the challenge, we present a systematic study of the optical and optoelectronic properties of single crystals of fluorinated anthradithiophene (ADT) functionalized with various side groups R (diF R-ADT) that control the molecular packing.

The optical properties of isolated diF R-ADT molecules are dominated by those of the backbone of the molecule, irrespective of the side groups R. In the solid state, however, only extract the second moment of the transition dipole moment with respect to the film surface, leaving several possible configurations of the investigated molecule within a three dimensional space.

In the past decade, significant progress has been made in the fabrication of organic photovoltaic devices (OPVs), predominantly due to important improvements of existing materials and the creation of a wealth of novel compounds. Many challenges, however, still exist. Real understanding of what structural and electronic features determine, for instance, the short-circuit current (Jsc), open-circuit voltage (Voc) and fill factor are still lacking; and the role of charge transfer states and which charge transfer states are critical for efficient charge generation are still debated. Here we attempt to obtain further insight of relevant structure/processing/performance interrelations using classical polymer processing “tools.” We present a survey on the principles of structure development of this material family and how it can be manipulated, with focus on how to control the phase morphology and important interfaces (molecular and between different phase regions). Goal is to tailor and tune the final “ morphology” towards establishing correlations with relevant device characteristics. Examples are given based on polymer:fullerene solar cells as well as solution-processed perovskite structures.

Unraveling the orientation of emissive dye molecules within organic light-emitting diodes (OLEDs) is of crucial importance to achieve high performing devices. Within the last years vast progress has been made in understanding and predicting the preferential alignment of organic dye molecules using both experimental and computational methods. The most common technique to determine the orientation of the emissive species within a thin film is angular dependent photoluminescence spectroscopy. However this method can only extract the second moment of the transition dipole moment distribution with respect to the film surface, leaving several possible configurations of the investigated molecule within a three dimensional space.1,2

To overcome this limitation we applied a second measurement technique, probing the permanent dipole moment and thus giving information of a second axis within the molecular frame. This method itself already allows for a prediction of the dye alignment. Further, if combined with the optical measurements, the properties of two molecular axes can be deduced.1,2

We applied this novel method to two well-known Ir-complexes, fac-tris(2-phenylpyridine)iridium(III) (Ir(ppy)3)and its heteroleptic counterpart Bis(2-phenylpyridino)acetylacetone)iridium(III) (Ir(ppy)2(acac)). The orientation of the emissive transition dipole moment of both molecules has been determined several times,
revealing the preferential alignment of the Ir(ppy)(acac) molecule, while the homoleptic compound showed isotropic behavior.[4] Nevertheless, the only predictions of the molecular alignment made so far, rely on computational methods such as molecular dynamics simulations. [9]

After carefully taking the amorphous nature of organic guest host systems into account, the application of the combined method revealed the preferential alignment of the heteroleptic compound, which is in agreement with earlier predictions. Furthermore the homoleptic dye molecule was confirmed to be isotropically oriented within a certain threshold of measurement uncertainty.

The application of this novel technique is not only limited to transition metal complexes in organic guest-host systems but can also be applied to any polar film within organic optoelectronic devices.

Combined Optoelectronics and Transparent Electronics for Neural Imaging and Optogenetics Applications Zhongping Ma; University of Wisconsin-Madison, Madison, Wisconsin, United States.

Flexible electronics which can be bent, folded and/or stretched, have been applied to various applications, such as biomedical implants and wearable devices, due to their thin structure to facilitate less invasive clinical operations. Flexible devices combined with optoelectronic systems extend to a range of applications such as biomedical stimulations and recordings using light sources, especially as optogenetics. Because light is the primary stimulation tool for optogenetics, optoelectronics benefit from using transparent devices by precisely matched exposing light on the recording site through transparent electrodes. Recently, many research studies have shown that graphene is an excellent candidate as a recording electrode due to its excellent electrical/thermal conductivity, transferability, and mechanical properties. Furthermore, the biocompatibility and broad-wavelength transparency from the ultraviolet (UV) to the infrared radiation (IR) spectrum of graphene make it ideal for the replacement of metal counterparts in optogenetics stimulations, recordings, and imaging applications. Our preliminary results indicate a viable approach combining a hybrid optoelectrical system with light emitting diodes (LEDs) and graphene to fabricate an implantable optogenetics system capable of simultaneous stimulation and recording. However, in our previous work, a laser was used as the light source for neural stimulation externally. Graphene devices without an internally mounted light source are not capable of operating under fully implanted condition. In this work, we built a multifunctional implantable system utilizing nitride-based microscale light emitting diodes (LEDs) vertically stacked on top of graphene electrodes through which light can pass through, enabling synchronous stimulation and recording on an electrocorticogram (ECoG) system utilizing transparent graphene. As such, this study demonstrates graphene electrodes integrated with high-performance flexible optoelectronics devices in thin-film and flexible platform has unique applications in multifunctional optogenetics systems for various clinical operations. Prospective studies will examine the effects and impact of hybrid optoelectronics on the surface of the animal tissue and performing simple animal behavioral experiments. Acknowledgment: The work was supported by ARO (W911NF-14-1-0652) and partly by DARPA (N66001-17-2-4010).

Soft Electronic Implants Based on Ultrathin Image Sensors and Biodegradable Drug Delivery Devices De-Hyeyong Kim2, 1; 1Seoul National University, Seoul, Korea (the Republic of); 2Institute for Basic Science, Seoul, Korea (the Republic of).

Although recent efforts in materials development, device designs, and fabrication strategies have resulted in meaningful progresses to the goal of high performance soft implantable bioelectronics, significant challenges still remain. In the first part of this presentation, we report our recent achievement in a ultrathin high-density curved image sensor (CurvIS) array for soft retinal prosthesis. The ultrathin image sensors use a heterostructure of inherently soft 2D materials (MoS2 and graphene) and employ ultrathin and strain-isolating array designs for the human-eye-inspired hemispherically curved design. This high-density soft CurvIS array with the single-lens optics successfully acquires pixelated images without optical aberration and infrared noises, whose potential for application to soft subretinal prosthesis was proved through the animal experiment. We then briefly report the recent achievement in the biodegradable drug delivery device for brain tumor treatment. The integration of wireless sensing and actuation function to the biodegradable drug delivery device enables high therapeutic efficacy with long term biocompatibility.

11:30 AM EP02.01.03
Evaluation of Durability of Transparent Graphene Electrodes for Chronic In Vivo Experiments David Ding, Ruoyu Zhao, Xin Liu, Yichen Lu, Ryoma Hattori, Chi Ren, Takaki Koniyama and Duygu Kuzum; University of California, San Diego, La Jolla, California, United States.

Long-term in vivo multimodal studies combining 2-photon microscopy, optogenetics and electrophysiology are essential for investigating functions of neuronal circuits with high resolution and precision. Graphene is a unique neural interface material enabling cross-talk free integration of electrical and optical recording and stimulation techniques in the same experiment. In addition to optical transparency, graphene also offers other desirable properties such as ultra-flexibility, high conductivity and biocompatibility. To date, graphene-based microelectrode arrays have been demonstrated in various multi-modal acute experiments involving electrophysiological sensing or stimulation, optical imaging...
and optogenetics stimulation [1-3]. However, understanding chronic reliability of graphene-based transparent interfaces is very important to expand the use of this technology for long-term behavioral studies with animal models. In this work, we investigate chronic durability of transparent graphene electrodes fabricated on polyethylene terephthalate (PET) and SU-8 substrates using in vitro accelerated aging tests. We present our results on simultaneous 2-photon imaging and electrical recording in chronically implanted transgenic mice over the course of two months.

Enokitake-Like Vertically Aligned Gold Nanowires for Highly Stretchable Electronics
Shu Gong, Yan Wang and Wenlong Cheng; Monash University, Clayton, Victoria, Australia.

One of the most important mission in wearable electronics is to devise thin, soft, stretchable electronics to circumvent fundamental limitation between soft tissues and rigid electronics. However, progress is hampered by non-trivial engineering, materials, biological, energy systems and data science challenges. The most fundamental of these is failure of the soft/rigid material interface due to mismatching Young’s moduli, which limits stretchability and durability of current systems. At the same time, wearable electronic devices are required to be highly biocompatible without fouling and immune responses. Ultimately, they could become parts of our organs, enabling true remote biodiagnostics anytime and anywhere.

One-dimensional (1D) nanomaterials should be a pathway to achieve these unique features simultaneously, owing to their intrinsically high aspect-ratio that enables the construction of conductive percolation network with small amount of material usage while maintaining high optoelectronic performance. Moreover, 1D nanomaterials have better mechanical elasticity than corresponding bulk materials or sphere-like nanoparticles and this is a key requirement for designing electronic skin materials by circumventing material delamination and/or cracking. Here we show that standing enokitake-like gold-nanowire-based films chemically bonded to an elastomer can be stretched up to 900% and are highly durable, with >95% conductivity recovery even after 2000 stretching/releasing cycles to 800% strain. This is attributed to standing enokitake-like nanowire structures, vertically aligned configuration, and strong chemical bonding interactions between standing nanowire films and elastomeric substrates. Consequently, our gold nanowire thin film offers an effective and appealing platform for highly stretchable multifunctional electronic skin system including stretchable interconnects, location- and sharpness-specific sensors, stretchable transistors and energy devices. We believe our technology showed great promise for future wearable and skin-conformal electronics in bio-monitoring and soft robotic applications.

Skin-Inspired Organic Electronics
Zhenan Bao; Stanford University, Stanford, California, United States.

Flexible organic electronics have attracted considerable attention over the past decade. Stretchable electronics represent another type of optoelectronic devices that are intrinsically elastic, that is they are foldable, twistable, and stretchable while maintaining performance, integrity and durability. Incorporated into devices, properly designed stretchable materials may result in more robust devices under bending and strain compared to flexible but not stretchable materials. For intrinsically stretchable electronics, it is desirable to have intrinsically stretchable materials, ranging from stretchable conductors, stretchable dielectric to stretchable semiconductors. In this talk, I will present various molecular design concepts for realizing stretchable electronic polymers without compromising electronic properties. Their applications in bioelectronics will also be presented.

2:00 PM *EP02.02.02/EP03.02.02/EP04.02.02
Flexible Bioelectronics—Enzyme-Based Body-Worn Electronic Devices
Joseph Wang; University of California, San Diego, La Jolla, California, United States.

Wearable bioelectronic devices rely on oxidoreductase enzymes and have already demonstrated considerable promise for on-body applications ranging from highly selective non-invasive biomarker monitoring to epidermal energy harvesting. Critical to such progress is the judicious design of the enzyme-electronic interface, along with flexible platforms with mechanical properties similar to those of biological tissues. Such devices require special attention to the enzyme-electronic interface and to several considerations related to wearable applications, such as mechanical properties (flexibility and stretchability), operational stability in different biofluids and under changing conditions (e.g., pH, temperature), biofouling, selectivity, and low target concentrations. Keeping these requirements in mind, our group has pioneered a variety of wearable biocatalytic sensors and biofuel cells devices. By leveraging the advantages of biocatalysis, electrochemistry, and flexible electronics, and addressing key challenges, wearable bioelectronic devices could have a tremendous impact on diverse biomedical, defense and defense fields.

Human Skin Interactive Bio-e-skin for Self-Powered Health Care Monitoring
Dipankar Mandal, 1, 2 and Sujoy K. Ghosh; 1 Institute of Nano Science and Technology, Mohali, India; 2 Department of Physics, Jadavpur University, India, India.

Among various pressure sensors, transduction mechanisms, piezoresistive, capacitive, triboelectric, and piezoelectric effects are generally considered for converting tactile stimuli into electrical signals. 1, 2 Owing to the fast response time and higher sensitivity, piezoelectric pressure sensors (PEPS) are the most useful for the detection of full-range human activities. It has been found that pressure sensor based artificial electronic skin (e-skin) can mimic the human skin and detects subtle pressure (1 Pa–1 kPa). A broad range of applications is expected to be implemented such as wearable health care systems, human–machine interfacing devices, artificial intelligence and prosthetic skin. Nevertheless, piezoelectric materials with adequate flexibility, high weight, ease of large-area processing, low cost and environmental safety are attractive but several issues are remaining for next-generation pressure/sforce sensors and mechanical energy harvesters. Recent advances on PEPS development is primarily focused on varies types of inorganic and semiconducting piezoelectric materials such as, barium titanate (BaTiO3), zinc oxide (ZnO), zinc sulfide (ZnS) and lead zirconate titanate (PZT). 3 In spite of their superior electromechnical responses, the brittleness and toxic properties limit their implementation in wide range of biomedical and flexible electronics applications. On the other hand, natural piezoelectric materials are not yet extensively investigated as an e-skin for measuring and quantifying human physiological signals. 2 In this context, we have developed human skin interactive self-powered piezoelectric biomaterials based e-skin (Bio-e-skin) which can detect and discriminate acute human physiological signals such as low frequency as subtle as wrist pulse and even intra-body pressures such as intracranial and intracardinal pressure, to relatively high frequency dynamic human motions such as movements of synovial joints of wrist, elbow, knee and finger bending. Natural bio-polymers such as, collagen, chitin, gelatin and cellulose were found to possesses superior mechanosensitivity which was sufficient to fabricate self-powered wearable bio-e-skin that can mimic spatiotemporal human perception and monitors real-time human physiological signals in non-invasive rational strategy. In addition, the bio-skins are found to generate superior output power density which is sufficient to operate the commercial consumer electronics. These observations suggest that fabricated bio-e-skins could eventually find a wide range of applications in autonomous epidermal
electronics, implantable medical device, surgery, e-healthcare monitoring, in vitro and in vivo diagnostics apart from its broad range applications in the field of self-powered personal portable electronic devices.3–5

Fully Implantable Wireless Battery-Free Optoelectronic Systems for Multimodal Optogenetic Neuromodulation
Philippe Gaturol, Vaidhnavi Krishnaanarthi, Abraham Vázquez-Guadado, Zhaoqian Xu, Anthony Banks, Chun-Ju Su, Yeshou Xu, Chad Haun, Emily A. Waters, Irawati Mandela, Siddharth Krishnan, Tyler Ray4, John P. Leshock4, Yonggang Huang4, Debasish Chanda1 and John A. Rogers4; 1University of Arizona, Tucson, Arizona, United States; 2RMIT University, Melbourne, Victoria, Australia; 3University of Central Florida, Orlando, Florida, United States; 4Northwestern University, Evanston, Illinois, United States; 5NeuroX, Evanston, Illinois, United States.

Recently emerging classes of battery free, ultrasmall1, fully implantable devices for optogenetic neuromodulation2 eliminate physical tethers associated with bulky head-stages and batteries in alternative wireless technologies and conventional setups by leveraging cellular scale light emitting diodes on flexible implantable light sources3. These highly miniaturized systems enable untethered, operation for behavioral studies that eliminate motion constraints and enable new experimental paradigms in a range of complex 3D environments and contexts (e.g. social interactions) that cannot be explored with conventional technologies. These devices are, however, purely passive in their design, thereby precluding any form of active control or programmability, resulting in limitations when investigating circuit dynamics where independent operation of multiple light sources with precise active control is needed. Here we present a series of important concepts that enable controlled device operation, independent of position and angle relative to the experimental arena, with advanced wireless power harvesting capabilities and full user-programmability over multiple devices. This level of functionality is demonstrated in integrated platforms that are compatible with noninvasive imaging technologies such as computed tomography and magnetic resonance imaging and have sizes and weights not significantly larger than those of previous, passive systems. The resulting devices qualitatively expand options in brain tissue illumination for optogenetic neuromodulation and multimodal operation, with broad potential applications in neuroscience research, with specific advances in precise dissection of neural circuit function during unconstrained behavioral studies.

3:30 PM *EP02.02.05/EP03.02.05/EP04.02.05
Self-Powered Ultra-Flexible Organic Electronics for Health Monitoring Takao Someya1, 2, Kenjiro Fukuda2 and Tomoyuki Yokot3; 1Electrical and Electronic Information Systems, University of Tokyo, Tokyo, Japan; 2RIKEN Center for Emergent Matter Science, Saitama, Japan.

On-skin sensors have attracted much attention as the next-generation wearable devices, because the conformal contact on human skin enables accurate and continuous detection of physiological signals. One of the most important technologies to improve usability of on-skin sensors is a power source to continuously supply electricity to health-monitoring systems. In this talk, we will report on recent progresses of ultraflexible organic photovoltaic cells for applications to wearable sensors. First, ultraflexible organic power sources that can be wrapped around an object have been developed with mechanical and thermal stability in long-term operation. Then, the integration of these power sources with functional electric devices including sensors has been achieved.

Physical Biology and Material Dynamics at the Semiconductor-Based Biointerfaces Bozhi Tian; The University of Chicago, Chicago, Illinois, United States.

Recent studies have demonstrated that in addition to biochemical and genetic interactions, cellular systems also respond to biophysical cues, such as electrical, thermal, and mechanical signals. However, we only have limited tools that can introduce localized physical stimuli and/or sense cellular responses with high spatiotemporal resolution. Inorganic semiconductors display a spectrum of physical properties and offer the possibility of numerous device applications. My group integrates material science with biophysics to study several semiconductor-based biointerfaces. In this talk, I will first pinpoint domains where semiconductor properties can be leveraged for biointerface studies, providing a sample of numbers in semiconductor-based biointerfaces. Next, I will present a few recent studies from our lab and highlight key biophysical mechanisms underlying the non-genetic optical modulation interfaces. In particular, I will present a biology-guided two-step design principle for establishing tight intra-, inter-, and extracellular silicon-based interfaces in which silicon and the biological targets have matched mechanical properties and efficient signal transduction. Finally, I will discuss new materials and biological targets that could catalyze future advances.

4:30 PM *EP02.02.07/EP03.02.07/EP04.02.07
Autonomic Self-Healing and Intrinsical Stretchability of PEDOT:PSS Films Fabio Cicoira; Chemical Engineering, Polytechnique Montréal, Montréal, Quebec, Canada.

Organic electronic devices, apart from consumer applications, are presently paving the path for key applications at the interface between electronics and biology. In such applications, organic polymers are very attractive candidates, due to their distinct properties of mechanical flexibility, self-healing and mixed conduction. Major group investigated the processing conditions leading to high electrical conductivity, long-term stability in aqueous media as well as robust mechanical properties of the conducting polymer poly(3,4-ethylenedioxythiophene) doped with polystyrenesulfonate (PEDOT:PSS) [1-3]. We have demonstrated that stretchable PEDOT:PSS films can be achieved by adding a fluorosurfactant to the film processing mixture and by pre-stretching the substrate during film deposition. We have achieved patterning of organic materials on a wide range of substrates, using orthogonal lithography and pattern transfer [4-5]. Recently we have discovered that PEDOT:PSS films can be rapidly healed with water drops after being damaged with a sharp blade [6] or show autonomous self-healing if processed in presence of certain additives. My talk will deal with processing, characterization and patterning of conducting polymer films and devices for stretchable, stretchable and healable electronics. I will particularly focus on the strategies to achieve films with optimized electrical conductivity and mechanical properties, on unconventional micro patterning on stretchable substrates, on the different routes to achieve films stretchability and self-healing.

F. Cicoira et al. APL Mat.3, 014911, 2015.

4:45 PM *EP02.02.08/EP03.02.08/EP04.02.08
Implantable Neurotransmitter Monitoring Based on Luminescent MOFs and Flexible Electronics Hang Xu, Wei Ling and Xian Huang; Department of Biomedical Engineering, Tianjin University, Tianjin, China.
In this work, Nd3+ high temperature (400°C) with high external pressure (200 bar), allows for the elaboration of luminescent GSAG:Nd NPs with an average size of 80 nm [3,4]. The liquid-based property (MRI contrast), defining GSAG:Nd NPs as multifunctional nanoprobes. (NPs) are promising candidates for chemical stability and intrinsic luminescence in the near infrared (NIR) region, overlapping with the biological optical transparency window, rare-earth doped oxide nanoparticles are used for all-optical control of cell behaviour [3].

Beyond these unique lasers, my lab develops an implantable high-resolution light source for advanced optogenetics studies. Again, miniaturization of photonic devices to sub-cellular dimensions is the key challenge. Organic light-emitting diodes (OLEDs) are highly attractive in this context, in particular due to their low toxicity, mechanical flexibility, high brightness, and ability to provide patterned illumination at very high spatial resolution. OLED microarrays containing >100,000 individual OLED pixels with µm dimensions are used for all-optical control of cell behaviour [3].

I will present our work on new micro- and nano-photonic devices for studying cell biology and small animals. Our lab is most well-known for the Guinness World Record invention of the biological laser [1]. By inserting sub-µm sized lasers into live cells, we tag and track individual cells in large cell populations and over extended periods of time [2]. We are currently developing this further to perform in vivo intracellular sensing and cell tracking, e.g. in the heart of zebras.

The optofluidic bio-laser is an emerging technology in biosensing and imaging. In contrast to traditional fluorescence based measurement, lasing emission is used as the sensing signal, which has strong intensity, threshold behavior, and narrow linewidth, and is free of background. In this presentation, I will first discuss the principle of optofluidic bio-lasers. Then I will discuss three applications with bio-lasers: (1) cellular analysis using cell laser array; (2) intra-cellular laser probes; (3) tissue analysis for cancer diagnosis; (4) neural network monitoring; and (5) ultrasound modulated lasers.

Nanoscale Thermal Sensors Based on Nd3+ Doped GdSc2Al12O19: Luminescent Nanoparticles

Alexandra Cantarano1, Marija Matulionyte2, Alain Ibanez2, Fiorenzo Vetrone2 and Geraldine Dantelle1, 1Institut Néel, CNRS, Grenoble, France; 2Energie Matériaux Télécommunications, INRS, Varennes, Quebec, Canada.

Accurate and non-invasive techniques as well as temperature measurements at the nanoscale have widely spread out with the major development of nanotechnologies and, more specifically, of nanomedicine [1]. Luminescent nanoprobes (quantum dots, dyes, fluorescent polymers, rare-earth doped nanoparticles, etc) have ever since competed to ensure the best thermal sensitivity in the 20 to 50°C temperature range, as well as high bio-compatibility and appropriate size (below 100 nm) for in vivo applications. Due to their high chemical stability and intrinsic luminescence in the near infrared (NIR) region, overlapping with the biological optical transparency window, rare-earth doped oxide nanoparticles (NPs) are promising candidates for in vivo nanothermometry [2].

In this work, Nd3+ doped GdSc2Al12O19: (GSAG:Nd) NPs are investigated as luminescent nanothermometers. The development of a new solvothermal synthesis method, combining high temperature (400°C) with high external pressure (200 bar), allows for the elaboration of luminescent GSAG:Nd NPs with an average size of 80 nm [3,4]. The liquid-based solvothermal reaction induces the adsorption of hydroxyl and alcohlic molecules onto the NP surface, leading to the stabilisation of GSAG:Nd NPs in water. Typical Nd3+ emission was observed under a 808-nm excitation, with two emission bands centred at 938 and 945 nm, corresponding to the electronic 4I13/2 -> 4I9/2 transition split by the crystal field effect. Thermal sensing properties of Nd3+ doped GSAG NPs were found to be excellent for contactless NIR temperature measurements with even higher relative thermal sensitivity as compared to the conventional Nd3+ doped Y3Al5O12 (YAG:Nd) NPs [5]. Additionally, the presence of Gd3+ ions in the GSAG structure offers a further property (MRI contrast), defining GSAG:Nd NPs as multifunctional nanoprobes.

8:30 AM EP02.03.01 Laser-Emission Based Microscopy for Cell, Tissue and Neural Network Analysis

Xudong S. Fan; Biomedical Engineering, University of Michigan, Ann Arbor, Michigan, United States.

Given the above consideration, this paper presents techniques and materials to fabricate a luminescent MOF-based flexible sensor, and photoelectric detector in the sensor can detect emission changes of MOF represented as functional part in response to DA. Notably, MOF-modified sensor possesses excellent biologically safety that was confirmed using in vivo cell experiments, supplying the foundation for the practical application in living animals. This work represents the first effort in combing luminescent MOFs with flexible sensors, offering in-depth understanding of flexible sensors’ property at molecular level. The excellent results may promote the progress of flexible electronics in biology, healthcare and sensing, etc.

8:00 AM EP02.03.02 Nanolasers Inside Living Cells and Other Photonics for Bioimplants

Malte C. Gather; School of Physics and Astronomy, University of St Andrews, St Andrews, United Kingdom.

The aim of this work is the synthesis, optimization and functionalization of organic@inorganic core-shell nanoparticles (NPs), which constitute a novel class of tracers, to be used for deep tissue imaging through two-photon fluorescence microscopy of tumor vascularization. These core-shell NPs, which comprise an organic dye nanocrystal core (ca 40-50 nm) surrounded by a silicate shell, are synthesized using an original ‘spray-drying’ method: atomization of the initial sol-gel solutions followed by the drying of the resulting spray in a horizontal furnace, at 150-200°C, under laminar inert gas flow [1]. This one-step synthesis is made possible thanks to the control of both the sol-gel chemistry (hydrolysis and polycondensation of silicon alkoxides used as shell precursors) and the confined nucleation and growth of the organic core, which occur simultaneously, by tuning the physical parameters of the spray-drying reactor: temperature of the furnace and electrostatic filter, gas flow and atomization parameters. Alkoxide precursors, TMOS (tetramethoxysilane)
and TMSE (1,2-bis(trimethoxysilyl)ethane) were particularly selected to form the organosilicate shell. Additionally, an organosilane, (3-azidopropyl) triethoxysilane (AzPTES), is used to impart an azide functionality to the NPs for further functionalization with azide-modified moieties using the Cu(I)-catalyzed 1,3-dipolar cycloaddition of organic azides to azides (CuAAC). The organic dyes for the nanocrystalline core are non-commercial and designed to exhibit high fluorescence intensity in the crystal-state under two-photon excitation in the red and near infrared (biological window) and the appropriate physico-chemical properties to enable their nanocrystalization [2]. The obtained core-shell NPs feature a very high organic loading (around 30-40%/wt). These very high dye concentration is an important advantage of these core-shell NPs to impart strong brightness by enhancing absorption and emission cross sections through the high number of fluorescent molecules. Thus, NPs suspensions showed intense fluorescence emissions around 600 nm. The NPs were then functionalized with different forms of azide-modified polyethylene glycol (PEG), differing in chain length and structure using CuAAC to render them furtive and increase their circulation time in the bloodstream of mice [3]. The effects of the NP functionalization and colloidal stability were studied using different characterization tools such as IR and fluorescence spectroscopies, dynamic light scattering and zeta potential under physiological conditions. First in vivo tests of two-photon fluorescence imaging in mice showed bright emissions of these new fluorescent tracers with good circulation time higher than 20 min, while fluorescence was still faintly visible in the blood flow even after a day. These preliminary results are promising for vascular and deep-tissue imaging, particularly for angiography to study for example angiogenesis mechanisms in cancer tumors and associated therapeutic treatments.

Semiconductor Laser Particles for Biomedical Applications Seek-Hyun Andy Yun; Wellman Center for Photomedicine and Harvard Medical School, Harvard Medical School, Cambridge, Massachusetts, United States.

Laser particles with sizes of optical wavelengths that are injectable and implantable into biological systems are new, promising light sources and probes for biomedical applications. We present biocompatible semiconductor micro-laser particles for tagging and tracking many cells.

11:00 AM EP02.03.06
Photoluminescence Spectra in ZnO Microspheres—The Interplay of Whispering Gallery Modes and Purcell Effect Ching-Hang Chien1, Bui Trong Huynh Ngo1, 2 and Yin-Chung Chang1, 4. Research Center for Applied Sciences, Academia Sinica, Taipei, Taiwan; 1Electrical Engineering, University of Alberta, Edmonton, Alberta, Canada.

Both theoretical and experimental studies of photoluminescence of ZnO microspheres and examine the Purcell effect on spontaneous and stimulated emission related to whispering gallery modes are presented. A Mie-basis Green function method, which incorporates contributions from leaky modes, spontaneous as well as stimulated emission processes, and Purcell effect is presented. We show that the spontaneous emission spectrum calculated according to Mie theory (without the Purcell effect) is related only to the contribution of leaky modes, while the spontaneous and stimulated emission both enhanced by the Purcell effect are responsible for the main WGM resonance peaks observed experimentally. It is found that the stimulated emission peaks are doubly enhanced by their respective mode quality factor Q: one factor from the Purcell effect and the other factor from the photon density derived from the rate equation. After taking into account this double enhancement in stimulated emission, the Purcell effect on spontaneous emission, and the leaky-mode contributions, the theory can provide a quantitative description of the detailed fine features of both TE and TM modes observed in the photoluminescence spectra in the whole visible region of ZnO microspheres with various degrees of porosity. The quantitative understanding of the interplay of these emission mechanisms should prove useful for optimizing the performance of light-emitting devices based on micro resonators.

11:15 AM EP02.03.07
Precise Ultrasound-Cell Biointerface Mediated by Fiber-Based Photoacoustic Converter with Controllable Frequency Linli Shi and Chen Yang; Boston University, Boston, Massachusetts, United States.

Ultrasound technique arouses great interests in biomedical and clinical application since it holds promise in noninvasive therapeutic studies. Thus, the ultrasound-cell biointerface for drug delivery, neuron stimulation and gene transfection attracted great attention. However, the insufficient resolution and the large device size of current ultrasound technology limit its applications. In this work, we developed a miniaturized optical fiber-based photoacoustic converter. The converter is with a diameter of ~500 microns to 1 millimeter and composed of nanoparticle-polymer material to produce localized acoustic wave with controllable frequency in a biomedical relevant range of 0.2-1.9 MHz. A coating scheme with a diffusion layer and expansion layer was designed on the tip of the fiber converter. The inverse proportionality between the diffraction layer thickness and the peak frequency was observed. Meanwhile, the light penetration depth of the absorption/thermal expansion layer also exhibited similar inverse proportionality to the peak frequency, offering two approaches toward controllable frequency. Moreover, the acoustic frequency spectrum shows narrow bandwidth (Full width at half maximum FWHM <2.5 MHz), high angular stability as well as a longitudinal penetration depth of 12 cm in chicken breast, enabling a level of precise control for biomedical ultrasound application. Importantly we demonstrated localized neuron stimulation in vitro and in vivo utilizing the optical photoacoustic converter. Based on these results, the new miniaturized fiber optoacoustic converter exhibits capability for in-depth study about the biointerface between localized acoustic with tunable frequency and specific cells, benefitting further research and clinical study for imaging, molecule delivery and other therapeutic applications.

11:30 AM EP02.03.08
Direct Laser Writing of Silk Fibroin Optical Waveguides Molilia Santos, Sabrina Santos, Renato Martins, Juliana Almeida, Kelly Paula, Gustavo Almeida, Sidney Ribeiro and Cleber Mendonca; State University of Sao Paulo, Sao Carlos, Brazil.

Silk fibroin is an abundant natural polymer, which in the last years has been studied as an attractive high-technology material platform, offering new opportunities for photonics and optoelectronics applications. In the field of photonics, silk fibroin-based films have been identified as an interesting optical material due to its transparency from the visible to the near infrared, favoring the development of several devices, such as photonic crystals, diffraction gratings and waveguides. Concomitantly, femtosecond laser direct writing (fs-DLW) has proven to be an important method for materials processing, enabling the fabrication of optical devices in a wide variety of materials, being useful for the obtaining of optical waveguides, microfluidic channels, and 3D flexible electronic circuits. One of the main advantages of fs-DLW is the reduction of thermal effects, which is of foremost importance for processing biomaterials. In spite of that, the usage of femtosecond laser to produce optical elements in silk fibroin has not been demonstrated yet. Therefore, in this work we demonstrate the ability to write optical waveguides in silk fibroin using fs-DLW. Homogeneous, 10-mm long waveguides were fabricated by irradiating a 42-µm thick silk fibroin film with femtosecond pulses, employing a pulse energy of 26 nJ and a scan speed of 100 µm/s. The guiding profile was simulated using the finite element method and experimentally observed by coupling light at 632.8 nm. Such waveguides, having the property of being biocompatible, are promising to be used in the frontier of biophotonics, from implantable medical devices to biosensors.

SESSION EP02.04: Photonic Materials and Devices for Biointerfaces III
Session Chairs: Wenlong Cheng and Xiaoting Jia
Wednesday Afternoon, April 24, 2019
PCC North, 200 Level, Room 223

1:30 PM EP02.04.01
Flexible and Stretchable Integrated Photonics Juejuan Hu; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Integrated photonics, which involves a multitude of miniatuized optical components connected by an optical waveguide network on a single substrate, has thrived over the past decades and is now widely regarded as a transformative paradigm shift in optics and photonics analogous to integrated circuits revolutionizing the electronic industry. Integrated photonics platforms demonstrated thus far are predominantly fabricated on rigid substrates. By imparting mechanical flexibility to integrated photonic structures, the technology bodes significant application potential for imaging, sensing, communications, and consumer electronics. Over the past few years, we have developed a suite of active and passive photonic devices and systems integrated on plastic substrates which can be repeatedly bent, twisted, and stretched without damage. This is accomplished through coherent optical/mechanical co-design, which ensures superior mechanical flexibility and ruggedness of the devices while maintaining, and in some cases enhancing their optical performances. In this talk, the design rationale, fabrication protocols as well as strain-optical coupling behavior in these devices will be reviewed, and their applications in biomedical monitoring and high-speed data communications will be discussed.

2:00 PM EP02.04.02 Plasmonic Nanostuctures Modified Multifunctional Fiber for Optical Biochemical Sensing and Electrical Neural Recording Yuimo Zhang, Jungyeob Song, Li Yu, Meitong Nie, Wei Zhou and Xiaoting Jia; Bradley Department of Electrical & Computer Engineering, Virginia Tech, Blacksburg, Virginia, United States.

Plasmonic nanostructured surfaces have received great attention over recent years. The unique optical properties of plasmonic nanostructures enable chemical and biological sensing using refractive index sensing and surface-enhanced Raman scattering (SERS). However, there are few reports about the combination of optical biochemical sensing and electrical neural recording. Here, we present plasmonic nanostucture modified multifunctional fiber probes that allow for both optical biosensing and neural recording. These fibers are fabricated by thermal drawing process and nanostuctured surface modification. We demonstrate the usefulness of this device as a sensitive refractive index sensor as well as SERS substrate. Also, neural recording in wild-type mice confirms that our probes can be used for electrical interrogation of neural circuits in vivo. Technology developed here can be potentially used for in situ in vivo optical biochemical sensing and electrical neural recording.

2:15 PM EP02.04.03 Bioconjugated Semiconductor Polymer Nanotransducers for Minimally Invasive Optoacoustic Neurostimulation Yimin Huang1, Ying Jiang1, Jiayingzi Wu1, Ji-Xin Cheng2 and Chen Yang3; 1Boston University, Boston, Massachusetts, United States; 2Purdue University, West Lafayette, Indiana, United States.

Neuromodulation has been an invaluable approach for treating neurological diseases. Optogenetics has been developed as a powerful method that is capable of modulating neural activity in rodents. However, application of optogenetics in humans is limited due to its requirement of viral infection. Recently, nanostructures showed great promise for modulating neuronal activities through a minimally invasive manner. Yet, the local temperature rise induced by the thermal effects of nanostructures impose a fundamental challenge for neuromodulation under physiological condition. To address these challenges, we developed an optoacoustic neuro-stimulation platform via semiconducting polymer nanotransducers (SPN) that efficiently convert pulsed laser energy into acoustic waves to enable highly localized stimulation of a neural tissue. Here, we demonstrated that the designed SPNs can strongly absorb light in the near-infrared second window (NIR-II, 1030nm), enabling enhanced light penetration depth through the skull. We further bioconjugated the surface of SPNs with antibodies targeting mecano-sensitive channels, TRPV4, to specifically bind to the neural membrane within 1 hour. By locally perturbing the mechano-sensitive channel, SPN can trigger repeatable action potential firing of embryonic cortical neurons with a laser duration of 3 ms. With enhanced temporal and subcellular spatial resolution, the as-designed SPNs showed potential in precise control of the neuronal circuits in the brain for basic neuroscience studies and treatment of neurological disorder diseases.

3:30 PM *EP02.04.04 Monocrystalline Silicon Nanomembrane Micro- and Nano- Structures for Bioreosorbable Optical Sensors Weidong Zhou1, Zhonghe Liu1, Jiho Shin2, Wuhin Bai2, Yonghao Liu2, Yuze A. Sun2 and John A. Rogers1,3; 1Department of Electrical Engineering, The University of Texas at Arlington, Arlington, Texas, United States; 2Department of Chemical and Biomolecular Engineering, University of Illinois at Champaign-Urbana, Urbana, Illinois, United States; 3Department of Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States; 4Center for Bio-Integrated Electronics, Northwestern University, Evanston, Illinois, United States.

We report here monocrystalline silicon nanomembrane based optical waveguides, photonic crystals, and Fabry-Perot cavities for bioreosorbable sensors. Both micro- and nano-scale structures have been designed, fabricated, and characterized for gas, liquid, pressure, temperature, and other physiological parameter monitoring.

4:00 PM *EP02.04.05 Stretchable Microscale Surface-Emitting Lasers as a Patternable Coherent Light Source for Biointegrated Optoelectronics Jongseung Yoon; Chemical Engineering and Materials Science, University of Southern California, Los Angeles, California, United States.

Vertical cavity surface emitting lasers (VCSELs) represent a ubiquitous coherent light source that can provide unique performance characteristics superior to those possible with edge-emitting lasers or light-emitting diodes. Despite such compelling advantages, existing VCSEL technologies rely on millimeter scale dies produced by wafer-sawing, robotic pick-and-place, and wire bonding, thereby imposing fundamental limitations on the device size, spatial density, level of power, choice of substrate materials, and efficiency of materials utilization. Furthermore, VCSELs, built on rigid and brittle semiconductor wafers, intrinsically restricted their conformal, bio-compatible integration onto soft, curvilinear surfaces of biological systems. This talk will provide an overview of recent advances in materials design and fabrication strategies of printable microscale VCSELs (micro-VCSELs) capable of overcoming above-described limitations and providing new capabilities in various unconventional areas of applications including flexible laser displays, flexible optofluidic sensors, and skin-conformal blood flow sensors.

4:30 PM EP02.04.06 Metal Oxide in Photovoltaic BioInterfaces Enables Capacitative Photostimulation of Neurons Shashi B. Srivastava1, Rustamzhon Melikov1, Ugur M. Dikbas1, Ibrahim H. Kavakali1-4 and Sedat Nizamoglu1-2; 1Electrical and Electronics Engineering, Koc University, Sariyer, Turkey; 2Graduate School of Biomedical Sciences and Engineering, Koc University, Sariyer, Turkey; 3Department of Molecular Biology and Genetics, College of Science, Koc University, Sariyer, Turkey; 4College of Engineering, Chemical and Biological Engineering, Koc University, Sariyer, Turkey.

Development of safe and efficacious neural interfaces is important for the treatment of a broad range of neural diseases such as Alzheimer’s disease, restoration of motor activity, and blindness due to retinal degeneration [1]. Two basic charge transfer mechanisms, Faradaic and capacitive processes, have been widely used for neural interfaces [2,3]. Faradaic charge transfer involves the charge carrier injection in the extracellular medium with chemical reactions, which may generate harmful side products. Alternatively, capacitive charge transfer is originated by the movement of ions via electromagnetic interactions without any reaction. For neural photostimulation, semiconducting polymers have engrossed significant attention due to their easy solution processability, biocompatibility, flexibility and conformability [4], and capacitive photostimulation by organic interfaces offers a safe and long-term neural stimulation strategy. Here, we demonstrate a photodetector architecture that can generate capacitative photostimulation. We use a bulk heterojunction of P3HT(Poly(3-hexylthiophene-2,5-diyl)):PCBM[(6,6)-phenyl-C61-butyric acid methyl ester) for the phototactive layer, which is biocompatible and can stimulate neurons [4, 5]. We explore the phototactive layer on zinc oxide nanoparticles, which is deposited on ITO layer. The photocurrent measurements suggest that the photodetector shows capacitive charge transfer mechanism. Further, electrophysiology experiment using patch pipette in voltage clamp mode is performed on SH-SY5Y neuronal cells and strong depolarization is observed by 10 ms light pulses in the visible range. Moreover, the results are confirmed by theoretical two-domain-stimulation model as well. In perspective, utilization of metal oxide for controlling photostimulation mechanism provides a new opportunity for safe and extended photostimulation of neurons.

Stain-Resistant Superomniphobic Flexible Optical Plastics Based on Nano-Enoki Mushrooms
Saied Hashanifar and Paul Leu; University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

In this paper, we demonstrate the stain-resistance and high-pressure stability of superomniphobic flexible optical plastics. A scalable method for creating nano-enoki mushrooms in plastics is presented that provides for the re-entrant geometry needed to prevent infiltration from a variety of liquids. The surface demonstrates static contact angles over 150° and low contact angle hysteresis under 20° for a wide variety of organic liquids. The re-entrant tops and fluorination of the nano-enoki, as well as the few micron spacing between nanostructures, provide for robust metastable solid-liquid-air interfaces in the presence of Laplace pressures of at least 900 Pa. In addition, compared to the initial bare plastic, the nano-enokis demonstrate comparable transmission values (86.4% versus 88.4% at a wavelength of 550 nm) and ultrahigh haze values (96.4% versus 1.1%). The surfaces exhibit stain-resistance for a variety of liquids including mustard and blood, where dried blood and mustard both flake off the samples without any residue. We also performed durability experiments which demonstrate that nano-enoki plastics are robust from bending with similar transmission, haze, wetting contact angle and hysteresis values after 5000 cycles of bending.

In the presence of incident light, the current between the protruding electrodes is proportional to the photodiode area and light intensity and serves to stimulate nearby neurons. The tuning of this current by the light intensity means that stimulation thresholds need not be known a priori, allowing dynamic in vivo testing. Further, the voltage applied between the electrodes is proportional to the number of photodiodes in series, allowing the applied voltage and electrode spacing to be engineered for a particular specific application. We discuss possible applications for these devices, especially in shallow brain regions such as the rat motor cortex.

Optically-Powered Wireless Electronics for Neural Stimulation
Samantha Norris, Alejandro Cortese, Conrad Smart, Teja Bollu, Michael Reynolds, Yanxin Ji, Jesse Golberg and Paul L. McEuen; Cornell University, Ithaca, New York, United States.

We describe the fabrication and characterization of wireless, implantable devices for the electrical stimulation of neural tissue. The devices consist of silicon photodiodes created by selectively doping the top of the device layer to create a vertical PN junction. The photodiodes are then electrically isolated by dry etching to the underlying oxide layer, and connected in series to drive two metal electrodes on either end of the device. The photodiodes are encapsulated with SU8, leaving the metal electrodes protruding. The devices are releasable into solution using a combination of dry and wet etches, and then can be dried and inserted into tissue using custom microencapsule insertion techniques. The entire process utilizes silicon-on-insulator substrates and traditional photolithographic techniques, which enables the production of these devices and their release from the substrate to be performed in massive parallel.

In recent years, there has been a tremendous advancement in bio-inspired electronic devices. Multiscale structures of biological materials exhibit inherent multifunctional integration. Special properties of biological materials provide motivation to scientists and engineers to design highly efficient electronic devices. Inspired by this, we used a protein photosystem I to make efficient photovoltaic solar cells. Photosystem I (PSI, ~500 kDa protein super complex) has been widely used to efficiently capture sunlight, which can create efficient biohybrid photon energy conversion devices. During photosynthesis, photoexcited electrons are transported at a 1 μs time scale across the thylakoid membrane by using PSI as a photodiode at a quantum efficiency closing to 100%. Since PSI photosystem I protein has light induced property, it can be utilized to convert solar energy to electrical energy in Photovoltaic devices. We used this light inducing property of PSI and made biohybrid photovoltaic solar cell using gold surface. Biohybrid photovoltaic solar cell provides novel results on the relationship between surface plasmon generation (SPG) efficiency of nanoslit and the experimentally obtained photocurrent generation, by immobilizing PSI on gold nanoslit electrode surfaces. Semi-analytical reduced calculations were used to calculate SPG (Surface Plasmon Generation) efficiency for varying nanoslits (50 nm, 100 nm, 200 nm, 300 nm or 400 nm). FDTD (finite difference time domain) simulation was also done to find which nanoslits have maximum electromagnetic field enhancement around their surface. Different Nanoslits (50nm, 100 nm, 200 nm, 300 nm or 400 nm) were fabricated with the help of photolithography technique and FIB (focused ion beam). After that, the PSI protein was immobilized on the Nanoslits with the help of self-assembly monolayer formation, and photocurrent generation for each nanoslits was measured using electrochemistry setup. The results show the relationship between SPG efficiency of nanoslits and experimentally obtained photocurrent generation, by immobilizing PSI on the gold nanoslit electrode surface. The photocurrent generation (G) and SPG efficiency for the nanoslit electrochemical devices (D) is a function of nanoslit width. The energy conversion (photocurrent) is greatly enhanced, which is correlated to the SPG efficiency and EM field enhancement in the nanoslit. This finding can be attributed to the phenomenon of plasmon-exciton coupling effect on the PSI in the nanoslits. The enhanced photocurrent generation was explained on the basis of plasmonic light trapping and plasmon-induced resonance energy transfer.

Lightfast and Mechanically Stable Black Coatings on Aluminum Based on Bio-Inspired Structurally Colored Porous Anodic Alumina Layers
Mikhail Pashchanka and Jörg J. Schneider; Technical Univ-Darmstadt, Darmstadt, Germany.

Optical and photonic properties of porous anodic alumina (PAA) layers have gained considerable attention of late.[1] Although pure alumina is known to be a reflective, transparent and intrinsically colorless insulating material, the absorption of light of certain wavelengths can be achieved in PAA due to photonic effects and destructive interference.[2] It is known from previous studies that there is a correlation between such parameters as the pore size and inter-pore distance and the nominal wavelength of the maximal destructive interference, and consequently also observable optical characteristics. Therefore, PAA with different introduced degree of disorder should demonstrate the absorption in a larger wavelengths interval. Black coloring of PAA films is frequently observed when the phenomenon called “burning” (that is a strong increase of the electrical current, accompanied by local etching and distortion of the ordered structure) occurs during the electrochemical synthesis.[3] However, the nature of this coloring remains relatively unexplored.

Here, we demonstrate that the black coloration mechanism in PAA is identical to the one that already exists in natural structurally colored surfaces, or in some artificially created biomimetic structures (similar to the ‘moth eye effect’ or the coloration of the pied paddy skimmer dragonfly wings surface). According to our measurements, the chemical composition of the PAA films has only a minor influence on the coloring and the increase of the optical density, and that the light absorbing properties mostly likely result from the
Electronic devices have been widely used by modern people for everyday life and industry. To achieve both portability and performance goals, devices have become increasingly smaller and more highly integrated, making them more susceptible to interference from electromagnetic waves. To prevent this, there is an increasing demand for an electromagnetic shielding film which is lightweight, thin, and excellently absorbs electromagnetic wave. In case of the nano-fiber which has one-dimensional structure, the electrical conductivity increases and it can be positively affected to absorb an electromagnetic wave. We have fabricated the composite nanofibers including iron, nickel and zinc nitrate using electrospinning method which can easily make a uniform fiber structure. The composite nanofibers were heat-treated to volatilize and crystallize to obtain Ni3Zn5Fe2O4 spinel ferrite phase, and its microstructure, crystal phase, and magnetic hysteresis loop were analyzed. The spinel ferrite phase and average diameter of ~200 nm in Ni3Zn5Fe2O4 nanoparticles were confirmed by X-ray diffraction and field-emission scanning electron microscope, respectively. The magnetic properties of Ni3Zn5Fe2O4 nanofibers with average diameter were observed through the vibrating sample magnetometer. The film to absorb an electromagnetic wave was fabricated using the Ni3Zn5Fe2O4 nanofibers as a filler. The absorbing properties of 11 dB at 10 GHz were measured by a vector network analyzer. The microstructure of the Ni3Zn5Fe2O4 nanofibers was optimized and suggested to apply to electromagnetic wave shielding.

**EP02.05.06**

Controlling the Surface Chemistry of Quantum Confined Silicon Nanoparticles for NIR to Visible Upconversion Carter S. Gerke and Pan Xia; University of California, Riverside, Riverside, California, United States.

Silicon nanoparticles have large absorption coefficients compared to the bulk while also being highly emissive with reported photoluminescent quantum yields as high as 90%. These nanoparticles would be of great interest as sensitizers for triplet fusion based photon upconversion to convert low energy light from the NIR window into the visible spectrum. Photosensitized triplet excitons can be harvested from the nanoparticle by grafting organic transmitter ligands to the surface of the Si nanoparticle. These bound transmitter ligands will mediate energy transfer from the nanoparticle, and ultimately to a free molecular emitter. The emission wavelengths from this upconversion platform will be highly tunable by altering the layers of conjugation in the organic ligands i.e. perylene to anthracene to tetracene. These silicon nanoparticle systems would be useful for light sensitized biological disciplines as it is biologically benign and the NIR excitation light is physically transparent allowing for high penetration depths.

**EP02.05.07**

New Findings on GaAs:Mg Micro-Pyramidal Structures Base Solar Cells by Morphological Study Leon Hamui; Engineering, Anahuac University, Mexico City, Mexico.

We studied GaAs:Mg doped nanostructures grown by MBE on GaAs (001) oriented substrate. A pyramidal structure (~3–10 Microns) has been obtained for several deposition conditions and varying the temperature it has been observed a change on the density of these pyramids. Complementary to direct optical imaging by microscope, Confocal Raman Spectroscopy which is widely applied to study nanostructures, has been used to determine the different phonon modes presented. In order to study the pyramidal structures, Confocal Raman Spectroscopy analysis of the surface allows profiling the Raman intensity of the different phonon modes over a scan area. Raman spectroscopy allows not only structural parameters such as superlattice periodicity and layer composition to be determined, but also by scanning it provides information of the pyramidal structures size, shape and strain. Moreover, we have been able to scan an area with depth profiles giving as a result a stack used to obtain 3D (tomographic) spatial information of the sample. Therefore we were able to determine the composition and strain of the pyramids via 3D imaging compared to the flat film area. Although, it has been observed by Raman Spectroscopy that the GaAs TO signal is downshifted due to the Mg doping which is more intense with-in the pyramid area, indicating that the micrometric structures are mainly related to the incorporation of Mg to the GaAs. The confocal area image was color pattern for the different phonon modes to be able to study the growth of the pyramidal structure and relate it to the deposition temperature.

SESSION EP02.06: Photonic Materials and Devices for Biointerfaces IV
Session Chairs: Anthony Banks and Xing Sheng
Thursday Morning, April 25, 2019
PCC North, 200 Level, Room 223

8:30 AM *EP02.06.01
Conformal Electrodes for Electrophysiological Monitoring Xiaodong Chen; Nanyang Technological University, Singapore, Singapore.

Microelectrode arrays, which interface living tissues with electrical hardware, constitute powerful tools for the transduction of original electrochemical signals in living tissues to electronic-based currents in external electrical circuits, and vice versa. They play a vital role in promoting the understanding of underlying physiological mechanisms, as well as improving diagnostics and therapy of neurological disorders and disabilities. However, the crucial aspects toward the advancement of this direction include the development of mechanically durable microelectrodes, facile fabrication, diminished foreign-body response, conformable electrodes and circuits, and so on. In this talk, I will present our latest progress in rational design of conformal electrodes for electrophysiological monitoring.

9:00 AM *EP02.06.02
Highly Integrative Optical Components for Lab-in-a Tube and Microrobotic Systems Oliver G. Schmidt; Leibniz IFW Dresden, Dresden, Germany.

On-chip fabricated rolled-up microtubes act as ultra-compact components in fully integrative lab-in-a tube systems for single cell analysis [1]. These microtubes are equipped with photonic functionalities to generate new types of optofluidic and opto-plasmonic components for novel sensing and detection schemes in 3D microtubular optical cavities [2,3]. Microtubes also sit at the core of microrobots, which in the ultimate limit should perform relevant biomedical tasks in the human body. However, tracking and imaging medical microrobots in deep tissue represent a major challenge in this field [4]. A decisive step in tackling this challenge will be presented in the talk.

Patterning Vertically-Grown Gold Nanowire Arrays for Intrinsically Stretchable Electrodes

Bowen Zhu, fiance Lin, Shu Gong and Wenlong Cheng; Monash University, Melbourne, Victoria, Australia.

Advances in large-area organic electronics for electronic skins and biointerfaces demand highly stretchable, patternable and conformal electrodes to minimize contact resistance when sensors such as pressure sensors are mechanically deformed. Gold is an excellent electrode material with work function matching well with p-type organic transistors. However, it is non-trivial to fabricate highly stretchable gold electrodes for stretchable organic electronics. Here by combining the advantages of both top-down patterning and bottom-up synthesis, we introduce a new materials platform of patterned vertically-grown gold nanowires (AuNWs) for constructing intrinsically stretchable electrodes, with high conductivity of 1,288 S/cm at 0% and 152 S/cm at 170% strain. Such patterned vertical AuNWs can be embedded in elastomer matrix, leading to stretchable electrodes that are mechanically robust and durable. The interface between AuNWs electrodes and poly(3-hexylthiophene) (P3HT) thin film shows ohmic contact for the entire strain regime from 0% to 100%, indicating low contact resistance. We further demonstrate a stretchable organic transistor with ion gel as dielectric, which can survive up to 100% without much performance degradation. The results presented here indicate that our methodology may be extended to other organic semiconducting materials and devices, hence, offering a general electrode materials platform for devising high performance intrinsically stretchable organic electronics.

9:45 AM EP02.06.04
Femtosecond Laser Micromachining on Multifunctional Polymer Fiber-Based Neural Probes for Multisite Chronic Neural Interfacing
Shan Jiang1, Yuanyuan Guo2, Jongwoon Kim1, Shuo Yang1, William A. Mills III1, Anbo Wang1, Ian Kimbrough1, Harald Sontheimer1 and Xiaotong Ju1; 1Virginia Tech, Blacksburg, Virginia, United States; 2Tohoku University, Sendai, Japan.

In order to understand the functional network in the brain and to treat brain-related disorders effectively, it is of great importance to discover the relationship between different brain regions, and many technologies have been developed based on that need. The widely adopted neural interfacing devices are metal-based microwires and silicon-based multichannel arrays, which have excellent recording capability with high signal to noise ratio. However, the mechanical property mismatch between these rigid devices and soft brain tissue can lead to neuron death and device failure in long term implant. Recently, polymer fiber-based neural probes have shown advantages over conventional neural interfaces in terms of flexibility and biocompatibility. However, so far the functions of fiber-based probes have been restricted to the tip area, significantly limiting the application of these devices. Here we present the femto-second laser micromachining on the longitudinal surface of the multifunctional polymer fiber, which can expose multisite electrodes, microfluidic channels, and waveguides along the fiber length. Using this micromachining technique, we can pattern the fiber surface with arbitrary geometry and spacing on the fiber longitudinal surface with a submicron resolution. Therefore, we can investigate different brain regions’ responses toward stimulation at different locations, and have a better understanding of the signal correlation in between. In this study, we performed simultaneous optical stimulation and multisite electrical recording in transgenic mouse brain using a single fiber probe, and analyzed the correlation between the signals recorded from different brain regions. We also patterned microfluidic channels and delivered fluorescence dyes into multiple locations in the brain, which can be used for multisite drug delivery in the brain. Furthermore, chronic recording and long term tissue responses were examined to evaluate our multifunctional neural probes as chronic neural interface devices. The femtosecond laser micromachining significantly expands the capability of multifunctional fiber-based neural interfaces, which can lead to wide applications in neuroscience.

New Forms of Microscopy Enabled by Nanostructured Surfaces
Brian Cunningham; Electrical and Computer Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Since the advent of optical microscopy, a flat glass microscope slide has been the standard surface upon which tissues, cells, and biomolecules are attached for observation. Recently, we have utilized the optically resonant properties of nanostructured photonic crystal (PC) surfaces to enable several new microscopy modalities where the nanostructure provides new forms of contrast for a wide variety of compelling applications. By designing PC surfaces with resonances that match the excitation and emission spectra of photon emitters such as fluorophores and quantum dots, PC enhanced fluorescence (PCEF) microscopy reduces the detection limits of any surface-based fluorescence assay. By generating spatial images of the PC resonant reflection intensity, we can selectively and dynamically visualize the cell-extracellular matrix interface during processes that include stem cell differentiation, cancer cell response to drugs, and chemotaxis – including the ability to observe the formation and evolution of cell membrane focal adhesion sites. We call this approach Photonic Resonator Outcoupler Microscopy (PROM), as we observe highly localized outcoupling of light from the PC that occurs due to scattering by dense regions in the cell membrane. Further, by utilizing metallic nanoparticle tags with plasmon resonances that match the PC resonance, we obtain highly efficient coupling of light into nanometer-scale electromagnetic hotspots, that is accomplished by highly localized “quenching” of the PC reflection efficiency, which we use for digital-resolution detection of miRNA biomarkers for cancer with 100 aM limits of detection, using an approach called Photonic Resonator Absorption Microscopy (PRAM). The seminar will describe the physical principles, nanostructure design/fabrication, instrumentation, and applications for nanostructure-enabled microscopy for disease diagnostics, personalized medicine, and life science research.

11:00 AM *EP02.06.06
Graphene-Related Materials for Electronic Skins
Guozhen Shen; Institute of Semiconductors, CAS, Wuhan, China.

Electronic skin (e-skin) which can mimic pressure, humidity, and temperature sensing capabilities of human skin has obtained great attention due to its superior abilities to detect slight pressure changes. It has potential application in human health monitoring, medical diagnostics, tactile sensor, artificial intelligence, and so on. Graphene, as a novel 2D carbon nanomaterial, possesses excellent characteristics which are required for E-skins, such as the good electrical property, high thermal conductivity, chemical stability, and good mechanical strength. In this talk, I will briefly introduce our recent progress on fabricating high performance e-skins with graphene-related materials. By wrapping reduced graphene oxide (rGO) nanosheets on PVDF nanofibers, a planar piezoresistive tactile sensor was fabricated, exhibiting a high sensitivity of 3.1 kPa−1 in very low pressure regime (below 60 Pa) and 15.6 kPa−1 in high-pressure regime (above 20 kPa). Using the same material, we further fabricated a multifunctional e-skins. Four kinds of planar devices namely micro-supercapacitors, pressure sensor, photodetector and gas sensor were modularly manufactured, all with rGO encapsulated PVDF nanofibers as the functional materials. Inspired by these works, we also fabricated other kinds of high performance e-skins.

11:30 AM EP02.06.07
Textured Si Nanowires for Highly Localized Optical Modulation of Cellular Dynamics
Yin Fang1, 2, Yuanwen Jiang1, 2 and Bozhi Tian1, 2; 1JFI, University of Chicago, Chicago, Illinois, United States; 2Department of Chemistry, University of Chicago, Chicago, Illinois, United States.

Engineered silicon-based materials display photoelectric and photothermal responses when illuminated by light, which allows for innovation at silicon-biology interfaces. Silicon nanowires have small radial dimensions, which are promising for use as highly localized cellular modulators. However, so far the functions of silicon nanowire materials have been restricted to the tip area, significantly limiting the application of these devices. Here we present the femtosecond laser micromachining on the longitudinal surface of the multifunctional polymer fiber, which can expose multisite electrodes, microfluidic channels, and waveguides along the fiber length. Using this micromachining technique, we can pattern the fiber surface with arbitrary geometry and spacing on the fiber longitudinal surface with a submicron resolution. Therefore, we can investigate different brain regions’ responses toward stimulation at different locations, and have a better understanding of the signal correlation in between. In this study, we performed simultaneous optical stimulation and multisite electrical recording in transgenic mouse brain using a single fiber probe, and analyzed the correlation between the signals recorded from different brain regions. We also patterned microfluidic channels and delivered fluorescence dyes into multiple locations in the brain, which can be used for multisite drug delivery in the brain. Furthermore, chronic recording and long term tissue responses were examined to evaluate our multifunctional neural probes as chronic neural interface devices. The femtosecond laser micromachining significantly expands the capability of multifunctional fiber-based neural interfaces, which can lead to wide applications in neuroscience.

Enabling Intracellular Recordings on Commercial High-Density Multi-Electrode Arrays by Optoacoustic Poration and Meta-Electrodes

Michele Dipalo1, Giovanni Melle1, Laura Lovato1, Andrea Jacassi1, Valeria Caprettini1, Francesca Santoro1, Denis Garoli1, Francesco Tantussi1, Giulia Bruno1, Alessandro Alabastri1 and Francesco De Angelis1
1 Istituto Italiano di Tecnologia, Genova, Italy; 2 Rice University, Houston, Texas, United States.

The accurate monitoring of cell electrical activity is of fundamental importance for pharmaceutical research and pre-clinical trials that impose to check the cardiotoxicity of all new drugs. Such a strong interest stimulated the development of methods for intracellular recording of action potentials on a large scale. Currently, the most promising results are represented by multi-electrode arrays (MEA) refined with 3D nanostructures that were introduced in pioneering seminal papers1,2, culminating with the recent work from the group of H. Park2, who show intracellular recordings on high-density CMOS-based MEA refined with 3D nanopillars. However, the requirement of 3D nanostructures limits the practical exploitation of these techniques. First, the fabrication of 3D nanopillars is an extremely complex and expensive procedure, hardly applicable to large area production. Second, cells’ interaction with 3D nanopillars is still under investigation3-6, with unresolved questions about their interaction, especially in case of mechanically contracting cardiomyocytes. Finally, most of the works exploited electroporation, which complicates considerably the circuit design of high-density CMOS circuits. Thus, despite pioneering results have been obtained on both passive and active MEAs, these technologies have not yet been applied to practical cases nor reached the commercial phase. Here, we introduce the concept of planar meta-electrodes and we show for the first time that high quality intracellular signals can be recorded on high-density commercial CMOS-MEAs without any rework of the devices, with 3D nanostructures nor circuitry for electroporation7. The intracellular recording is obtained by means of laser optoacoustic poration mediated by a meta-electrode, which is a porous platinum electrode with a dual optical/electrical function. Optically, it behaves like a strong broadband absorber in the near-infrared, as it has been recently shown for metasurfaces in general8. Electrically, it provides strong cell coupling due to the tight sealing of the cell membrane on the porous morphology. When illuminated with a short laser pulse, the plasmonic response of porous platinum enables the generation of localized high electric field hot-spots that produce shockwaves9-10 able to open the cell membrane. This enables high quality intracellular recordings with no side effects. We will show sharp intracellular action potentials of human derived cardiomyocytes on a commercial CMOS-MEA. To prove the direct application to pharmacological screening, we will also show the exploitation of our approach to detect the effects of typical drugs and toxins on the cell cultures, thus confirming the high potential of the technique to improve pharmaceutical tests. The technique offers lower development and recurring costs due to the “already commercial” nature of the employed devices. Our work paves the way to a completely new set of affordable and effective methods for studying electrogenic cells. Moreover, the new meta-electrodes may have extreme impact on combining optical and electrical investigations for biochemistry and biology that require today new multifunctional tools11.

Engineering Transparent Graphene Microelectrodes to Overcome Quantum Capacitance Limit

Yichen Lu, Xin Liu, Ryonna Hattori, Chi Ren, Xingwang Zhang, Takaki Komiyama and Duygu Kuzum; University of California, San Diego, La Jolla, California, United States.

Substantial progress has been made in development of graphene-based transparent optical interfaces enabling concurrent integration of electrophysiological recordings, optical imaging and optogenetics. However, a big challenge toward the transparent graphene electrodes is relative high, limiting its scalability and its use for microstimulation. As a result, high impedance of graphene constitutes a big challenge toward the widespread use of transparent electrodes. Here, we experimentally investigate the origins of high impedance in graphene microelectrodes and demonstrate that the impedance of graphene microelectrodes is fundamentally limited by quantum capacitance. We overcome this quantum capacitance limit by creating a parallel conduction path using electrochemically deposited platinum nanoparticles. This approach achieves a 100 times reduction in graphene electrode impedance, while maintaining the high optical transparency crucial for deep two-photon microscopy. Using a transgenic mouse model, we demonstrate simultaneous electrical recording of cortical activity with high fidelity while imaging calcium signals at various cortical depths right beneath the transparent microelectrodes. Multimodal analysis of Ca2+ spikes and cortical surface potentials offers unique opportunities to bridge our understanding of cellular dynamics and brain-scale neural activity.

Plasmonic Response of Light-Activated, Nano-Gold Doped Polymers

Jessica M. Andriolo1,2, McKenzie L. Joseph1,2, Mark Griep3 and Jack L. Skinner1,2; Mechanical Engineering, Montana Technological University, Butte, Montana, United States; 1,2 Montana Nanotechnology Laboratory, Montana Technological University, Butte, Montana, United States; 3, U.S. Army Research Laboratory, Adelphi, Maryland, United States.

Incorporation of metallic nanoparticles (NPs) in polymer matrix is well known to be employed to enhance and control dissolution and release of drugs, for targeted drug delivery, antimicrobial agents, localized heat sources, mechano-responsive nanocomposites, and for unique optoelectronic applications. Colloidal gold NPs (AuNps) in particular exhibit a plasmonic response that can be utilized for photothermal applications. Dispersion of Au nanoparticles in polymers creates a hybrid material with increased robustness, responsiveness, and flexibility while intrinsic nanoparticle properties are maintained. In previous work, colloidal gold (AuNps) were incorporated into electrospun (ES) polyethylene glycol fibers (AuNps/PEG) to utilize the nanoparticle plasmonic response for localized heating of the polymer. Applications of this work were anticipated for localized heating and melting of drug-carrying polymer fibers for light-activated release. Using broad spectrum white light interrogation, the AuNps used exhibited a maximum absorbance at 522 nm on ultra violet visible spectroscopy (UV-Vis) which was the same when AuNps was incorporated into bulk polymer (AuNps/PEG8000 MW). Using trapezoidal integration of the energy absorption difference curve, the theoretical energy absorption for AuNps/PEG was calculated to have an efficiency enhancement of 9.6% under white light illumination and 38.3% under green light illumination compared to PEG alone. Maximum absorbance of these materials in fiber form was recorded at 504 nm. AuNps/PEG fibers were ES directly onto resistance temperature detectors (RTDs) so that resistance of the materials could be measured. To maximize the response of the polymer, white light was substituted for green laser light (λ=533 nm), and resistance measured was converted to optical, thermal-cycling and delamination effects. The encapsulation acts as a thermal insulator, so if it is too thin, there can be hot-spots at neighbouring electrodes. However, bond wires and bonded surface components such as the photonic microemitters need encapsulation to prevent shorting between anode and cathode contacts by the saline. As such, we encapsulate our system in poly-dimethyl-siloxane. For acute research purposes, electronics fabricated from standard complementary metal oxide semiconductor (CMOS) processes, can rely on the silicon oxy-nitride top layer. We have demonstrated efficacy of our optoelectronic probes in the acute setting and with recordings and stimulus on both rodent and non-human primate animal models. We are placing active electronics which can multiplex hundreds/thousands of optical and/or electrical interfaces.

Developing Clinical Grade Implantable Optoelectronics

Patrick Degenaar; Newcastle University, Newcastle upon Tyne, United Kingdom.

Implantable electronic systems are being increasingly utilised to provide therapeutic benefit. Exemplars include pacemakers for the heart and brain, neuromodulators for bladder and pain control, and sensory prosthetics for sound and vision. Traditionally such systems would comprise two primary units: A hermetic case which contains the control electronics, and a lead with electrodes which provide recording or stimulus. Such systems are typically limited to a few dozen electrodes, as such, there is now a strong interest in placing active electronics which can multiplex hundreds/thousands of optical and/or electrical interfaces.

In Newcastle University, we are developing a new type of clinical-grade implantable device to prevent seizures in patients with focal, drug-resistant epilepsy, and a project called CANDO. We are utilising a gene therapy technique called optogenetics which renders the brain tissue light sensitive. We can then electrically record and optical stimulate at the brain unit. However, we have chosen our brain unit to consist of active electronics, to allow for multiplexing of multiple optical stimulation points whilst simultaneously recording. The CANDO control unit is similar to others in the domain – i.e. battery and control electronics sitting in a hermetic case with hermetic feedthroughs to cables connecting to a brain unit. However, we have chosen our brain unit to consist of active electronics, to allow for multiplexing of multiple optical stimulation points whilst simultaneously recording. The active electronics is fabricated from a standard complementary metal oxide semiconductor (CMOS) process by a foundry (Austria Microsystems) under a commercial process. The chips have been designed to incorporate a digital communication and control scheme as well as drive electronics for individual light emitting diodes, self-diagnostic circuitry, and amplifiers and analog to digital converters to acquire neural signals. The active electronics connect to penetrating shafts with electrodes and optical microemitters to stimulate.

Developing Clinical Grade Implantable Optoelectronics

We have demonstrated efficacy of our optoelectronic probes in the acute setting and with recordings and stimulus on both rodent and non-human primate animal models. We are now beginning long term chronic animal studies to understand the efficacy of different control algorithms for preventing seizures. For acute research purposes, electronics fabricated from standard complementary metal oxide semiconductor (CMOS) processes, can relax the silicon oxy-nitride top layer. However, bond wires and bonded surface components such as the photonic microemitters need encapsulation to prevent shorting between anode and cathode contacts by the saline. As such, we encapsulate our system in poly-dimethyl-siloxane.

There are important considerations in the design of encapsulation of such devices:

Insulation and hot spots: Light emitting diodes are typically 5-40% efficient. The rest of the energy provided to them is emitted as heat. However, the regulations state that the surface of implantable devices should not exceed 2°C. The encapsulation acts as a thermal insulator, so if it is too thin, there can be local hot-spots above the LED. However, if it is too thick, there can be hotspots at neighbouring electrodes.

Failure mechanisms: Implantable devices need to last perhaps decades to last a human lifetime, perhaps decades in the brain. We are therefore exploring accelerated lifetime studies of failure modes including optical, thermal-cycling and delamination effects.
Nanostructure-Enhanced Devices for Flexible and High-Performance Electronics and Optoelectronics - Zhiyong Fan; Department of Electronic and Computer Engineering, Hong Kong University of Science and Technology, Hong Kong, China.

Nanostructured materials possess a number of unique properties such as tunable optical and electronic property, high surface-to-volume ratio, mechanical flexibility, etc. These intriguing properties can be harnessed for a variety of applications in flexible electronic and photonic devices. In the past, we have fabricated an assortment of nanostructures that consist of nanowires, nanopillars, nanocubes, etc., using a variety of materials from inorganic semiconductors to organic-inorganic hybrid materials. These nanomaterials/nanostructures have been fabricated into a variety of functional devices including solar cells, supercapacitors, light-emitting diodes, gas sensors, etc. By manipulating light and charge interactions with nanostructures, the performance of these devices can be largely tuned. And if the nanostructures are rationally designed, the performance of devices can be significantly improved. Here we will present the fabrication methods of nanostructures and design rules of nanostructures for these high performance electronic and optoelectronic device. And the integration of these devices into concept proof wearable systems will also be demonstrated.
Biodegradable and Biocompatible Microelectromechanical Systems

Mark G. Allen; Electrical and Systems Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Fabrication approaches to biodegradable and biocompatible microelectromechanical (MEMS) devices suitable for implantation in the body will be discussed. Three topical areas will be touched upon: biodegradable wireless pressure sensors; biodegradable batteries; and MEMS fabricated from protein materials.

Biodegradable Wireless Pressure Sensors: A wireless pressure sensor made entirely of biodegradable materials will be discussed. Such biodegradable sensors may be appropriate for short-term, acute medical implantation applications as they potentially eliminate the need for implant extraction when sensing is no longer required. Metallic bilayers with controllable corrosion characteristics are utilized as conductors, and biodegradable polymers poly-L-lactide (PLLA) and polycaprolactone are used as dielectric and structural materials. The fabricated sensor is based on a resonant variable capacitance technique and was wirelessly tested in both air and 0.9% saline. The sensor exhibited a linear resonant frequency response to external applied pressure, over the physiologically-relevant 0-20 kPa applied pressure range. Sensors remained stable and functional for approximately 86 hours in saline solution.

Biodegradable Batteries: Implantable and biodegradable batteries play an important role in the fully degradable medical systems; however, in such systems compactness and energy density are of great importance. Harnessing liquid from the body to serve as the battery electrolyte may, therefore, be desirable; however, for stable operation, maintaining a constant environment inside the electrochemical cell is required even in the presence of changing body conditions. A biodegradable battery featuring a solid electrolyte of sodium chloride and polycaprolactone will be discussed. This approach harnesses the body fluid that diffuses into the cell as an element of the electrolyte; however, the large excess of sodium chloride suspended in the polycaprolactone holds ionic conditions inside the battery relatively constant. A constant discharge profile can then be achieved even in the presence of varying external aqueous conditions, enabling compact, stable-performing cells.

Protein MEMS: The use of extracellular matrix (ECM) protein materials in the fabrication of MEMS offer the possibility of MEMS-based devices that are more easily integrated with the body, are better tolerated by the immune system, and/or which have mechanical properties that are well-matched to potential biological applications. However, the incorporation of these relatively delicate materials into standard MEMS fabrication processes can result in significant fabrication challenges. Suitable fabrication approaches to Protein MEMS will be discussed, and their use will be illustrated in a collagen-based cortical neural electrode, which has demonstrated reduced inflammation and superior persistence of functionality in in vivo models when compared to similarly-sized MEMS electrodes fabricated from conventional materials.

Fully Biodegradable Batteries for Self-Powered Transient Implants

Lan Yin and Xueying Huang; Tsinghua University, Beijing, China.

Biodegradable transient devices is an emerging type of electronics that could play an essential role in medical therapeutic/diagnostic processes, such as wound healing, tissue regeneration, etc. The associated biodegradable power sources, however, remain a major challenge towards future clinical applications, as the demonstrated electrical stimulation and sensing functions are limited by wired external power or wireless energy harvesters via near-field coupling. We propose novel materials strategies and fabrication schemes that enable a high-performance fully biodegradable magnesium-molybdenum trioxide battery as an alternative approach for in vivo on-board power supply. The battery can deliver a stable high output voltage as well as prolonged lifetime that could satisfy requirements of representative implantable electronics. The battery is fully biodegradable, and demonstrates desirable biocompatibility. The battery system provides a promising solution to advanced energy harvesters for self-powered transient bioresorbable implants as well as eco-friendly electronics.

Bioresorbable Electronics for Minimally Invasive Medical Sensing and Treatment of Nervous System

Seung-Kyun Kang; Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

Nanoscale thin-film technology has opened an era of soft, flexible and stretchable electronics and has also changed the timescale of dissolution of materials. Silicon nanomembranes of 10-100 nm thickness have dissolution behavior on the order of days to months. This feature lets us construct Si electronics for water-soluble and biodegradable performance using unusual fabrication processes and combining soft/biodegradable polymers. Here we introduce two representative examples of bioresorbable Si electronic devices useful in monitoring and modulating the nervous system. First, a bioresorbable pressure sensor using piezoresistive Si strain gauge and 3D microstructured diaphragm was demonstrated to provide accurate measurement of intracranial pressure during the incubation period of traumatic injury. Wireless interfaces made of polymer-coated bioresorbable metal strips offer stable and continuous pressure monitoring. In-vivo functional and immunotoxicological demonstrations in a rat model suggests the potential validation of bioresorbable sensors in the clinical stage. In the other example, bioresorbable wireless electrical stimulator interfacing the peripheral nerve was demonstrated as a therapeutic modulator. An integrated circuit of Si diode, capacitor, and inductor with all-biodegradable metal, semiconductor and dielectric materials generate therapeutic electrical pulses by near-field inductive energy transfer. The accelerated functional recovery of transected nerve with electrical stimulation suggests the capability of bioresorbable stimulator to promote and/or modulate the nervous system in the treatment and rehabilitation stage.

Digitally Inkjet-Printed Electro(Fluoro)Chromic Devices Consisting of Biodegradable and Biocompatible Materials

Manuel Pietzsch1,2, Martin Held1,2, Luca Porcarelli3, Ana Sanchez-Sanchez4,5, David Mecerreyes1 and Gerardo Hernandez-Sosa1,2 – 1, LIT, Karlsruhe Institute of Technology, Karlsruhe, Germany; 2InnovationLab, Heidelberg, Germany; 3POLYMAT, University of the Basque Country UPV/EHU, San Sebastian, Spain; 4Bioelectronics Laboratory, University of Cambridge, Cambridge, United Kingdom.

Electrofluorochromic devices (EFCD) receive increasing attention in investigation in the past years, because they offer the possibilities for various optical devices. Besides that, the little power consumption, the low voltage requirement and simple device architecture (i.e. electrochemical cell) provide the opportunity for low-cost display devices. To provide a cost-effective method with the freedom of design necessary for smart windows and display applications, inkjet printing can be used as a suitable method with high throughput, low-material waste and up-scaling capabilities to industrial fabrication. These exceptional properties can be extended with the use of bioresorbable and biodegradable materials for their use in medical applications or to reduce the waste after usage to a minimum.

Here, we report on inkjet-printed electro(fluo)chrome devices consisting of biodegradable and biocompatible components on biodegradable deformable gelatin substrates. To simplify the device architecture for the inkjet printing process we chose a parallel electrode configuration with PEDOT:PSS as electrode material. We used two different solid polymer electrolytes, one on the basis of gelatin coated from water and the other on the basis of Poly(D,L-lactide-co-glycolide) (PLGA) from a Dimethyl sulfoxide (DMSO) solution, whereby all of these polymers and solvents are biodegradable and biofriendly. As ionic species we used tetrabutylammonium bis-oxalato borate (TBABOB) which was developed as a non-fluorinated biodegradable salt. The electro(fluo)chrome layers were made out of two different polymer derivatives consisting triarylamine, namely polyyindeno-fluorene-8-triarylamine (PIF8-TAA) and polytriarylamine (PTAA). The fabricated devices exhibit a sufficient contrast, efficiency and lifetime to be used in deploy-and-forget or short-life-lifecycle applications with potential use in disposable consumer and health care biofriendly disposable applications.
Skin-Inspired Organic Electronics Zhenan Bao; Stanford University, Stanford, California, United States.

Flexible organic electronics have attracted considerable attention over the past decade. Stretchable electronics represent another type of optoelectronic devices that are intrinsically elastic, that is they are foldable, twistable, and stretchable while maintaining performance, integrity and durability. Incorporated into devices, properly designed stretchable materials may result in more robust devices under bending and strain compared to flexible but not stretchable materials. For intrinsically stretchable electronics, it is desirable to have intrinsically stretchable materials, ranging from stretchable conductors, stretchable dielectric to stretchable semiconductors. In this talk, I will present various molecular design concepts for realizing stretchable electronic polymers without compromising electronic properties. Their applications in bioelectronics will also be presented.

Flexible Bioelectronics—Enzyme-Based Body-Worn Electronic Devices Joseph Wang; University of California, San Diego, La Jolla, California, United States.

Wearable bioelectronic devices rely on oxidoreductase enzymes and have already demonstrated considerable promise for on-body applications ranging from highly selective non-invasive biomarker monitoring to epidermal energy harvesting. Critical to such success is the judicious design of the enzyme-electronic interface, along with flexible platforms with mechanic properties similar to those of biological tissues. Such devices require special attention to the enzyme-electronic interface and to several considerations related to wearable applications, such as mechanical properties (flexibility and stretchability), operational stability in different biofluids and under changing conditions (e.g., pH, temperature), biofouling, selectivity, and biofouling. Keeping these requirement in mind, our group has pioneered a variety of wearable biocatalytic sensors and biofuel cells devices. By leveraging the advantages of biocatalysis, electrochemistry, and flexible electronics, and addressing key challenges, wearable bioelectronic devices could have a tremendous impact on diverse biomedical, fitness and defense fields.

References

Recently emerging classes of battery free, ultrasmall1, fully implantable devices for optogenetic neuromodulation2 eliminate physical tethers associated with bulky head-stages and batteries in alternative wireless technologies and conventional setups by leveraging cellular scale light emitting diodes on flexible injectable filaments as light sources1. These highly miniaturized systems enable untethered, operation for behavioral studies that eliminate motion constraints and enable new experimental paradigms in a range of complex 3D environments and contexts (e.g. social interactions) that cannot be explored with conventional technologies. These devices are, however, purely passive in their design, thereby precluding any form of active control or programmability, resulting in limitations when investigating circuit dynamics where independent operation of multiple light sources with precise active control is needed. Here we present a series of important concepts that enabled controlled device operation, independent of position and angle relative to the experimental arena, with advanced wireless power harvesting capabilities and full user-programmability over multiple devices. This level of functionality is demonstrated in integrated platforms that are compatible with noninvasive imaging technologies such as computed tomography and magnetic resonance imaging and have sizes and weights not significantly larger than those of previous, passive systems. The resulting devices qualitatively expand options in brain tissue illumination for optogenetic neuromodulation and multimodal operation, with broad potential applications in neuroscience research, with specific advances in precise dissection of neural circuit function during unconstrained behavioral studies.

On-skin sensors have attractive much attention as the next-generation wearable devices, because the conformal contact on human skin enables accurate and continuous detection of physiological signals. One of the most important technologies to improve usability of on-skin sensors is a power source to continuously supply electricity to health-monitoring systems. In this talk, we will report on recent progresses of ultraflexible organic photovoltaic cells for applications to wearable sensors. First, ultraflexible organic power sources that can be wrapped around an object have been developed with mechanical and thermal stability in long-term operation. Then, the integration of these power sources with functional electric devices including sensors has been achieved.

Recent studies have demonstrated that in addition to biochemical and genetic interactions, cellular systems also respond to biophysical cues, such as electrical, thermal, and mechanical signals. However, we only have limited tools that can introduce localized physical stimuli and/or sense cellular responses with high spatiotemporal resolution. Inorganic semiconductors display a spectrum of physical properties and offer the possibility of numerous device applications. My group integrates material science with biophysics to study several semiconductors-based biointerfaces. In this talk, I will first pinpoint domains where semiconductor properties can be leveraged for biointerface studies, providing a sample of numbers in semiconductor-based biointerfaces. Next, I will present a few recent studies from our lab and highlight key biophysical mechanisms underlying the non-genetic optical modulation interfaces. In particular, I will present a biology-guided two-step design principle for establishing tight intra-, inter-, and extracellular silicon-based interfaces in which silicon and the biological targets have matched mechanical properties and efficient signal transduction. Finally, I will discuss new materials and biological targets that could catalyze future advances.

Organic electronic devices, apart from consumer applications, are presently paving the path for key applications at the interface between electronics and biology. In such applications, organic polymers are very attractive candidates, due to their distinct properties of mechanical flexibility, self-healing and mixed conduction. My group investigated the processing conditions leading to high electrical conductivity, long-term stability in aqueous media as well as robust mechanical properties of the conducting polymer poly(3,4-ethylenedioxythiophene) doped with polystyrilene sulfonate (PEDOT:PSS) [1-3]. We have demonstrated that stretchable PEDOT:PSS films can be achieved by adding a fluorosurfactant to the film processing mixture and by pre-stretching the substrate during film deposition. We have achieved patterning of organic materials on a wide range of substrates, using orthogonal lithography and pattern transfer [4-5]. Recently we have discovered that PEDOT:PSS films can be rapidly healed with water drops after being damaged with a sharp blade [6] or show autonomous self-healing if processed in presence of certain additives. My talk will deal with processing, characterization and patterning of conducting polymer films and devices for flexible, stretchable and healable electronics. I will particularly focus on the strategies to achieve films with optimized electrical conductivity and mechanical properties, on unconventional micro patterning on flexible and stretchable substrates, on the different routes to achieve films stretchability and self-healing.

Dopamine (DA), as a crucial neurotransmitter, can transfer chemicals in human brain to affect our emotion and behaviors, and DA disorders in secretion and transportation can cause some incurable disease, such as Parkinsonism and Alzheimer’s disease. Implantable flexible sensors offer a feasible approach to monitor the content and distribution of DA, cause some incurable disease, such as Parkinsonism and alzheimer’s disease. Implantable flexible sensors offer a feasible approach to monitor the content and distribution of DA, and may assist us to overcome those disease. Up to now, mainly reported investigations were conducted using electrochemical sensors modified by metallic oxide and graphene, but rough structures and limited types of above materials restrict its further development in function modulation. One of the promising strategy to meet this challenge is employing adjustable materials to combine with flexible sensors, and metal-organic frameworks (MOFs) that possess designable structures and adjustable functions can be considered as the suitable candidate for fabricating functional devices. Additionally, flexible sensors integrated with MOFs have already been achieved by our group, allowing more explorations on MOF-based flexible electronics.

Given the above consideration, this paper presents techniques and materials to fabricate a luminescent MOF-based flexible sensor, and photoelectric detector in the sensor can detect emission changes of MOF represented as functional part in response to DA. Notably, MOF-modified sensor possesses excellent biologically safety that was confirmed using live cell experiments, supplying the foundation for the practical application in living animals. This work represents the first effort in combing luminescent MOFs with flexible electronics.

### SESSION EP03.03: Poster Session: Materials Strategies and Device Fabrication for Biofriendly Electronics

**Session Chairs:** Hui Fang and Lan Yin  
**Tuesday Afternoon, April 23, 2019**  
5:00 PM - 7:00 PM  
PCC North, 300 Level, Exhibit Hall C-E

**EP03.03.01**  
**Application of Active Transiency Mechanism in Design of Biodegradable and Environmentally Friendly Polymeric Electronics**

Transient materials/electronics is an emerging class of functional devices that are capable of undergoing rapid degradation at prescribed time and controlled rate once transiency is triggered. Application of these materials in circuit boards and environmental sensors eliminates the need for their retrieval, thus minimizing electronic waste production. Transiency rate in solvent-triggered devices is strongly dependent on the chemical composition of the constituents, as well as their interactions with the solvent, upon exposure. Such chemical interactions are typically slow, passive, and diffusion-driven. In this study, we present integration of gas forming reactions into transient materials/electronics to achieve selective, expedited, controlled, and active transiency. Integration of more complex chemical reaction paths to transiency, not only increases selectivity of the process, but also enhances pre-transiency chemical stability of the system while under operation. A proof-of-concept transient electronic device, utilizing sodium-bicarbonate/citric-acid pair as gas forming agents is studied vs. control devices, consisting of polymeric substrate and metal colloid as electronic component, in the absence of gas forming agents. While exhibiting enhanced transiency behavior, substrates with gas forming agents also proved sufficient to be applied as substrates, concerning pre-transiency mechanical properties and...
Biopolyimides for Transparent Insulators

Shrini S. Chhatre, Vivek Subramanian, Nicholas Valdes, Bruce Chase and David C. Martin; Material Science and Engineering, University of Delaware, Newark, Delaware, United States.

Polyimides have been widely investigated for use in a variety of applications including photovoltaics, sensors and electrochromic displays. However, they have been of particular interest to the biomedical community because of their simultaneous electronic and ionic conductivity. They also are mechanically softer than inorganic materials, making it possible for them to be more compatible with living wet tissues. Poly(3,4-ethylenedioxythiophene) (PEDOT) and its copolymers, including the polymer formed from the carboxyl-substituted monomer P(EDOTacid), have been of specific attention because of their chemical stability and excellent charge transport properties. Despite the continued interest in PEDOT, there are still many unknown questions about the details of its polymerization process. One of the major challenges is that PEDOT polymers are relatively insoluble, making an accurate analysis of the degree of polymerization during the reaction difficult.

We have been investigating the use of vibrational spectroscopy techniques along with Gaussian molecular simulations to get a better understanding of the electropolimerization process. The experiments have used microfocused Raman and Fourier Transform Infrared (FTIR) techniques, and compliment ongoing research in our laboratory using in-situ Transmission Electron Microscopy (TEM) and hot stage optical microscopy (OM).

We have identified critical peaks associated with the reactive hydrogens on the thiophene ring that allow us to monitor the process of polymerization. We studied the vibrational modes associated with the reactive proton and conjugation of the thiophene network. The 3110 cm\(^{-1}\) thiophene C=H stretch peaks is of particular interest to us, since it decreases with intensity as the molecules react. In addition, we are monitoring the peak at 1422 cm\(^{-1}\) associated with the C=C stretch and the peaks at 835-1184 cm\(^{-1}\) associated with the conjugation in PEDOT. The peaks at 1540 cm\(^{-1}\) and 1573 cm\(^{-1}\) are associated with the quinoidal structure of the PEDOT. These checks provide insight about the changes occurring during the polymerization reaction. By correlating these vibrational spectroscopic results with data using microscopy, we are developing a deeper understanding of the thiophene electropolymerization reaction.

Honey as Gate Dielectric for Organic Thin-Film Transistor

Oliver Peter Ammuayh1, Kuan Yew Cheong2 and Feng Zhao3; 1Washington State University, Vancouver, Washington, United States; 2Universiti Sains Malaysia, Pulau Pinang, Malaysia.

In this work, natural organic honey as gate dielectric in organic thin-film transistor has been systematically investigated. In recent years, organic materials for electronic applications have gained wide research interests due to their advantages such as environmentally friendly, biodegradable, biocompatible, and do not require chemical synthesis. Thin-film transistor using organic materials as semiconductors (C60, pentacene, etc.), dielectrics (Aloe vera, chicken albumen, benzocyclobutene), and substrates (Silk, PLGA, etc.) have been developed and investigated. This work reports the usage of honey as a gate dielectric layer in a C60-based thin-film transistor. Different curing temperature and duration for honey solidification were applied. Honey film thicknesses under different spin rates and water ratio were measured and compared. MOS capacitors and transistors were fabricated with standard microfabrication processes including photolithography and metal deposition. Effects of solidification conditions of honey including drying temperature and duration on the quality of the honey film such as electrical breakdown, leakage current, hydrophobicity, smoothness, etc. were examined. The results with optimized process parameters and device properties will be reported in the paper and presentation.

Plasma Cleaning of Organics on Bio-mineralized Nanopores

Nishant Satapathy, Srisuda Rojsatien and Michael Goryll; School of Electrical, Computer and Energy Engineering, Arizona State University, Tempe, Arizona, United States.

The effectiveness of using oxygen plasma to clean the organic residue from bio-mineralized nanoporous valves of marine diatoms (Coscinodiscus wailesii) was investigated. Two plasma processes were employed, one using a commercial 13.6 MHz oxygen plasma cleaner with a maximum plasma power of 30 Watts, the other using a microwave oven with a 2.4 GHz microwave output power of 900 Watts. A reference experiment using photoresist-coated silicon wafers was conducted to determine the etch rate for a planar organic film. While the planar organic layers were being etched in either plasma process, optical microscopy on the actual diatom nanopore frustules showed organic residue (chloroplasts) remaining even for the longest plasma treatment times. This reduced etch rate can be attributed to the shape of the frustules themselves, with the nanopore membrane encapsulating the chloroplast, limiting the diffusion of the reacting species through the nanopores.

Biopolymides for Transparent Insulators

Tatsuo Kaneko and Maiko Okajima; Japan Advanced Institute of Science and Technology, Nomi, Japan.

Bioplastics are indispensable for establishment of green-sustainable society. Conventional bioplastics were composed of aliphatic polymers like poly(lactic acid) having not very high softening temperature and no specific functions. In order to open the world of high-performance bioplastics, we have prepared aromatic biopolymers derived from exotic amino acid. Here we used 4-aminocinnamic acid (4ACA) which was bioavailable by a microorganismal genetic-engineering. The photodimer of 4ACA was successively prepared as a bio-derived aromatic diamine via [2+2] cycloaddition in the solid state with a perfect conversion degree. The biodiamines were polymerized with tetraciod dianhydrides to produce aromatic polyimides. Especially the aromatic polyimides derived from the biodiamine with cyclotpreneetetracarbonlyc dianhydrides, which is also a photodimer of bio-available fumaric acid, showed a good thermomechanical performance as well as low density around 1.05-1.28 g/cm\(^3\), and additionally showed a high transparency and a breakdown voltage as high as conventional polyimide. Additionally, we hybridized the biopolymides with silica by sol-gel methods to get the increased insulating performed with keeping high transparency. The transparent biomaterials can be used for next-generation transparent and flexible materials.

Enroute Towards Biodegradable Organic Electronics Materials and Devices

Clara Santato1, Eduardo Di Mauro2 and Denis Rho2; 1Engineering Physics, Polytechnique Montreal, Montreal, Quebec, Canada; 2National Research Council Canada, Montreal, Quebec, Canada.

Electronics have become indispensable in our daily routine. A great part of the electronic equipment that surrounds us belongs to what is known as conventional electronics, based on inorganic materials such as silicon and gallium arsenide. However, with the life of the electric and electronic equipment becoming shorter and shorter, two major issues arise for both the scientific community and municipalities: the increasing amount of Waste of Electrical and Electronic Equipment (WEEE) and the depletion of natural resources. Taking into account the definition of sustainability provided by the United Nations (the ability of satisfying one generation’s needs without compromising the possibility of future generations to satisfy), those two issues point to the lack of sustainability in the electronics field of the current generation, at least so far. Consequently, great attention has been given to green (sustainable) electronics in the last years, having as core values (i) the use of abundant and low-cost precursors, leveraging on processing routes that (ii) lack toxic solvents as well as toxic waste and (iii) are low cost and (iv) involve biodegradable materials. In this contribution, we will present our preliminary results on the biodegradability and compostability of organic electronic materials of interest for electronics and energy storage devices, focusing on the case of study of melamin biopigments used in transistors, batteries and supercapacitors.

Fully Bioabsorbable Natural-Materials-Based Triboelectric Nanogenerators

Zhuo Liu1, Yubo Fan2 and Zhou Li2; 1School of Biological Science and Medical Engineering,
Implantable medical devices provide an effective therapeutic approach for neurological and cardiovascular diseases. With the development of transient electronics, a new power source with biocompatibility, controllability, and bioabsorbability becomes an urgent demand for medical sciences. Here, various fully bioabsorbable natural-materials-based triboelectric nanogenerators (BN-TENGs), in vivo, are developed. The triboelectric series of five natural materials is first ranked, providing a basic knowledge for materials selection and device design of the TENGs and other energy harvesters. Various triboelectric outputs of these natural materials are achieved by a single material and their pairwise combinations. The maximum output voltage, current, and power density reach up to 55 V, 0.6 μA, and 21.6 mW m⁻², respectively. The modification of silk fibroin encapsulation film makes the operation time of the BN-TENG tunable from days to weeks. After completing its function, the BN-TENG can be fully degraded and resorbed in Sprague–Dawley rats, which avoids a second operation and other side effects. Using the proposed BN-TENG as a voltage source, the beating rates of dysfunctional cardiomyocyte clusters are accelerated and the consistency of cell contraction is improved. This provides a new and valid solution to treat some heart diseases such as bradycardia and arrhythmia.

Bioresorbable Electronics Based on Solvent Treatment Stabilizing the Room-Temperature Sintering Xian Huang, Hang Xu and Jianming Li; Biomedical Engineering, Tianjin University, Tianjin, China.

Bioresorbable electronics can be developed using various fabrication approaches that involve conventional CMOS fabrication following by transfer printing on bioresorbable substrates or printing techniques that demand high performance bioresorbable inks. Bioresorbable inks based on transient metal typically require high temperature sintering processes or photonic sintering that will lead to improvement in both electrical conductivity and mechanical strength. However, the resulting devices have not yet satisfied the requirement of high performance electronics and are mechanically weak to withstand large deformation. Here, new ink materials, electronics devices, and the concept of spontaneous room-temperature sintering will be presented. Environmental humidity or UV light treatment activate surface chemistry in the new ink materials, causing removal of surface oxidation of transient metal nanoparticles as well as intimate contact between neighboring particles. The highly conductive metal particle network and robust polymer binders ensure improved electrical conductivity and mechanical strength, leading to flexible devices that are presented as RFID circuits, passive components, and sensors. The new composition and processing techniques have minimum requirements to the temperature and environmental conditions, and offer effective solutions to mass fabricate bioresorbable electronics that can be potentially used in implantable monitoring, sensitive data storage, and consumer products.

9:55 AM *EP03.04.05
Biodegradable Elastomers for Stretchable Light-Emitting Electrochemical Cells Martin Held, Natalie Lam, Manuel Pietsch, Philip Hindenberg, Carlos Romero-Nieto and Gerardo Hernandez-Sosa; Light Technology Institute, Karlsruhe Institute of Technology, Heidelberg, Germany; Institute of Organic Chemistry, Heidelberg University, Heidelberg, Germany.

Achieving biodegradability in optoelectronic devices, such as light-emitting electrochemical cells (LECs), requires assessing every component for its degradability in a biologic environment. The substrate makes up the vast majority of the device’s mass, thus governs its biodegradability and mechanical behavior. While biodegradable thermoplastic foils provide mechanical flexibility by bending, they don’t offer any elastic stretchability. However, replacing biodegradable thermoplastics with elastomers would extend the range of potential applications in packaging and medicine. Silicone-based elastomers are frequently used as stretchable substrates but are merely biocompatible, not biodegradable. We present four different biodegradable options as elastic substrates for LECs with different processing concepts: A commercially available compostable thermoplastic elastomer (Terratek Flex), two synthesized poly(glycerol-sebacate) elastomers being either photo- or thermally cross-linked and a gelatin-blend from commercial ingredients. Their suitability as substrates is investigated by the optoelectronic performance of LECs. These are composed of biodegradable and biocompatible materials and fully printed via inkjet printing and doctor blading. Their charge transport and light-emission is characterized under increasing isotropic strain of the elastic substrate. The combination of stretchable biomaterials with up-scalable manufacturing techniques will enable the fabrication of transient and disposable electronic products ranging from biodegradable smart packaging via soft robotics to skin-adhered wearable healthcare applications, without adding to the global plastic carpet.

10:30 AM *EP04.03.04
Solvent Treatment Stabilizes the In Vitro Response of Enzymatic Sensors Dongliang Wang; University of Connecticut, Storrs, Connecticut, United States.

Long-term stability of enzymatic devices present great challenges toward the realization of long-term implantable glucose sensors. Semi-permeable polyurethane (PU) membranes situated above the glucose oxidase enzyme, are typically used to balance the glucose to oxygen ratio and afford linearity over the entire physiological glucose range. Here is shown that the as cast PU membranes are prone to an initial swelling and subsequent densification that result in a large drift in sensor sensitivity over a period of 2 months. Exposing the PU-coated sensor to solvent vapors eliminates the aforementioned morphological changes. This eliminates the sensitivity drifts and provides exceptional, long-term, glucose sensor stability. The close zigzag packing of PU chains alongside the formation of ordered H-bonding that stabilizes and provides stable diffusion characteristics for such segmented PU membranes. The ability to maintain the stability provides a crucial advance in the fabrication of long-term enzymatic devices and implantable biosensors.

10:45 AM *EP04.03.04
Silicon Nanomembrane-Based Visible/Infrared Phototransistors and Their Applications in Transient Electronics Gongjin Li, Ruobing Pan, Enming Song, Qinglei Guo, Gaoshan Huang and Yong Feng Mei; Fudan University, Shanghai, China.

A remarkable superiority of silicon electronics is its biological affinity and excellent semiconductor processing property. Among various synthesized forms of silicon materials (e.g. bulk silicon, silicon quantum dots, silicon nanowires or tubes), silicon nanomembranes (Si-NMs) show great optoelectronic application potential due to its low flexural rigidity and self-assemble adaptability into novel 3D origami structures. The traditional strategies for Si-NMs based optoelectronic devices is a device-last process, which depends on releasing the Si-NMs by etching the buried oxide (BOX) layers of silicon-on-insulator (SOI) wafers and transfer it to the desired substrate with wet or dry processes.

We proposed flexible phototransistors and their multifunctional applications by the use of wafer-compatible Si-NMs synthesis strategy. This process is suitable for the transferring of continues large area nanomembrane in the wafer scale. An efficient gate modulation significantly restrains the dark current to 10⁻¹² A and yields an ultrahigh photo-to-dark current ratio of >10⁶ with a responsivity of 1.34 A/W. Based on the mechanism of surface plasmon polariton hot holes injection, we demonstrated that the spectrum response of Si-NM phototransistors can be tuned to near-infrared range (e.g. 1550 nm) by decorating the light-sensitive channel with nano groove gold arrays. Such high-sensitivity phototransistor could be applied in the application of biological sensors and biochips. Optoelectronic sensing of hydrogen concentration and environment humidity have been realized by decorating the top surface of phototransistor with certain sensitive materials.

To satisfy the requirements for the transient form of flexible electronics capable of working at high-temperature, Si-NMs electronics was integrated with a 4-μm thick high-temperature degradable (~300 °C) poly-α-methylstereine (PAMS) interlayer, which enables distinct and irreversible transient process for Si-NM devices. The function expandability of the Si-NM phototransistors as well as the wafer-compatible fabrication exhibit great potential for the sensing functions in the future portablewearable bio-friendly electronic integrating system with multifunctional applications.

The growing demand for implementing wearable and implantable devices that can sense and harvest energy from human motion and biomechanical vibrations, is motivated to build next-generation smart sensors, flexible circuits, and artificial electronic skin devices. Recently, triboelectric nanogenerator devices based on electrostatic induction have been demonstrated to scavenge mechanical vibrations. For the seamless interface between the devices and human tissue, it is required that the devices are composed of soft, flexible, and biocompatible materials. In addition, obtaining conductive electrodes for the bio-devices is still challenging due to the tradeoff between the flexibility and conductivity. Attractive properties of silk protein such as biocompatibility, flexibility in thin film form, compatibility with the aqueous solution, and highly optical transparency have made it to be a promising candidate for realizing wearable and implantable electronic devices. Herein, we present the fabrication of flexible, transparent, and biocompatible single-electrode silk bio-triboelectric nanogenerators (SBTENG) to sense and harvest energy from biomechanical vibrations. We constructed a SBTENG using a 0.12 mm thick silk film with the grating structure of periodicity of 1.5 μm and the buried silver nanowires (Ag-NWs) network with a sheet resistance of 35 Ω sq⁻¹. The fabricated SBTENG devices offer biocompatibility, flexibility and transparency (average transmittance of 85%) in the visible region, which are essential for bioelectronics. The SBTENG is capable of outputting an open circuit voltage of 90 V (V\text{max}) and the maximum power density of 2 mW/m² on a load of 1 MΩ under light finger tapping, which can drive five commercial green light emitting diodes instantaneously. The mechanism of SBTENG is based on the tribo-charge generation on the surface of silk upon tapping it with human finger. Owing to the transparency of the SBTENG devices, they can be attached to electronic devices (commercial cell phone and electrical mouse) to harvest the biomechanical energy with an output power of 1 μW. The low cost, ease of fabrication, biocompatibility, flexibility and transparency of SBTENG devices enable their potential usage in applications including human-machine interface, touch sensor, and biomechanical energy harvesting.

**Hydrogel-Based Electronics—Ultracompliant Electrodes for Neural Interfaces and Beyond**

**Christopher J. Bettinger; Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.**

Flexible electronic devices underpin many biomedical technologies that record and stimulate neuronal activity from organs in the central and peripheral nervous systems. Reliable and stable chronic recording from excitable tissues using implantable multielectrode arrays has been elusive to date due, in part, to host tissue interactions that contribute to device failure. Local tissue damage and device failure is worsened by the mechanical mismatch between materials used to fabricated rigid silicon-based microfabricated multielectrode arrays (E\text{HEA} ~ 100 GPa) and tissues in the nervous system (E\text{PNS} ~ 10 kPa). Hydrogel-based electronics could reduce the mechanical mismatch across the tissue-device interface and enhance performance. Furthermore, adhesive ultraflexible hydrogel-based electrodes have potential applications in wearable devices ranging from EEG electrodes to consumer electronics. Here we present materials and companion fabrication strategies to create ultraminiaturized electronic devices for use in peripheral nerve interfaces. Integrated strategies for polymer synthesis, processing, and microfabrication are described. Details regarding the in vitro and in vivo performance of these devices will also be presented.

**Biologically Produced Fluorescent Proteins for Advanced Photonic Devices**

**Malte C. Gather; School of Physics and Astronomy, University of St Andrews, St Andrews, United Kingdom.**

Organic materials offer attractive properties for solid-state lasers, including large oscillator strength, high exciton binding energy, spectral tunability, and compatibility with low-cost fabrication processes. However, despite impressive proof-of-principle demonstrations and dramatic improvements in performance, important fundamental limitations remain. Particular challenges are concentration quenching and bi-molecular exciton recombination which limit the available gain under practical pumping conditions. Here, I will summarize key results from a number of studies that we performed on a rather unconventional class of organic materials, the biologically produced fluorescent proteins. The nano-scale barrel-like molecular structure of fluorescent proteins like GFP prevents concentration-induced quenching of fluorescence and drastically reduces singlet-singlet annihilation at high exciton densities. This facilitates low-threshold lasing in various configurations and has recently enabled the realization of the first organic polariton laser that can be pumped in a quasi-continuous ns-regime.

**Photothermally Tunable Biodegradation of Implantable Triboelectric Nanogenerators for Tissue Repairing**

**Zhe Li and Zhou Li; Beijing Institute of Nanoenergy and Nanosystems, Beijing, China.**

Implantable triboelectric nanogenerators (iTENGs) are promising to work as sustainable power source for implanted healthcare electronic devices. In this study, we fabricated a serial of biodegradable (BD) iTENGs and effectively tuned their degradation process in vivo by employing Au nanorods (AuNRs), which responded to the near-infrared (NIR) light sensitively. The implanted BD-iTENG worked well for more than 28 days in vivo, without NIR treatment. When NIR treatment was applied, the output of AuNRs-BD-iTENG rapidly reduced to 0 within 24 h and the device was mostly degraded in 14 days. This showed that the in vivo degradation of our BD iTENG could be triggered and come into effect very quickly with rational manipulation. The peak value of in vitro and in vivo output voltage generated by the AuNRs-BD-iTENG were 28 V and 2 V, respectively. Moreover, the in vivo output voltage was applied on fibroblast cells and demonstrated a significant acceleration for cell migration across the scratch, which was very beneficial to wound healing process. In addition, we discovered that the alternating BD-iTENG output was as efficient as direct current (DC) stimuli. The mechanisms were investigated. Our work has demonstrated the feasibility of building a photothermally tunable BD-iTENG as a transient power source for biomedical healthcare electronics.

**Biomimetic and Bioactive Strategies Towards Seamless Neural Implants/Tissue Integration**

**Tracy Cui; University of Pittsburgh, Pittsburgh, Pennsylvania, United States.**

Microelectronic devices placed in the nervous system present tremendous potentials for investigating neural circuits and treating neurological disorders. Currently, these devices often experience failures in part due to the electrical, mechanical, and biochemical, mismatch between the artificial device and neural tissue. Quantitative histology and 2 photon imaging have revealed neuronal damage and degeneration, inflammatory gliosis, blood brain barrier leakage and oxidative stress as a result of implantation. Several biomaterial strategies have been investigated to minimize the mismatches and achieve seamless and stable device-tissue interface. First, various conducting polymer based nanocomposites have been investigated as electrode coatings and facilitate the signal transduction/charge transfer between ionically conductive tissue and electrical device. Secondly, to minimize the mechanical mismatch at the device-brain tissue interface, novel soft and elastomeric electrode materials have been developed with Young’s modulus approaching that of neural tissue (less than 1 MPa). Soft implants demonstrated reduced inflammatory tissue response in both CNS and PNS compared to stiff implants of similar geometry and surface
All Organic Piezoelectric E-Skin Sensor for Self-Powered Wearable Electronics and Human Physiological Signal Monitoring

**Kuntal Maity** and Dipankar Mandal

4:00 PM EP03.05.05

Rapid developments of smart electronics, flexible and wearable e-skin sensors are attracting a great deal of attention due to their smart sensing applications in next-generation devices. Interestingly, it can eventually measure and quantify electrical output signals generated by various human activities.[1,2] However, the flexibility, biocompatibility, sensing capability, cost-effectiveness and packaging are the main concerns, which immensely drive to carry out this present work.[3,4] In this framework, organic piezoelectric materials such as poly(vinylidene fluoride) (PVDF) and its copolymers are of particular interest towards device integration, having adequate advantages over inorganic materials.[5,6] In addition, it should be mentioned that the choice of electrodes and their compatibility with organic and hydrophobic surfaces of PVDF remain challenging tasks, particularly when device performance, durability and implant ability are concerned. The brittleness, toxicity and high cost of inorganic materials have prohibited its use as a conducting electrode; in addition, direct adherence on electrospun nanofibers (NFs) surface is one of the major challenges to build the permanent electrodes in device structures. In contrast, organic conducting polymers are being presented as a viable alternative for organic electronic device, particularly if one can achieve adequate coating on the electrospun polymer fibers.[7]

Here we present an all-organic piezoelectric e-skin sensor (AOPESS) based on highly aligned poly(vinylidene fluoride) (PVDF) NF arrays and conducting polymer i.e. polyaniline (PANI) coated PVDF NFs mat as electrode; for energy harvesting from various types of mechanical motions and self-powered human physiological signal sensing. The electropinning technique in combination with vapor phase polymerization (VPP) enables such aligned structure followed by successive coating of PANI upon PVDF NFs surface. The Fourier transform infrared spectroscopy (FT-IR), Raman spectroscopy and Field emission scanning electron microscope (FE-SEM) clearly indicate the successful coating of PANI upon the PVDF NFs surface. The electrical performances were clarified by measuring the current-voltage (I-V) characteristic under the application of external pressure. Owing to highly aligned structure with superior piezoelectric β-phase contained (~98%) and excellent electrode contact-adherence, AOPESS exhibits a effective conversion of mechanical energy of human finger movements into electrical energy (~10 V). The coating of PANI upon PVDF NFs opens the use of organic electrode in various applications especially for e-skin devices solving the so called electrode issues. Recently, human physiological signal monitoring is an effective approach for the assessment of various human health problems. So, we can monitor our physiological signals such as body temperature and heartbeat rates.[8,9] More importantly AOPESS can show ultra-sensitivity towards various human movements such as wrist bending, neck stretching, arm compressions, throat movement, and phonation recognition to name a few. Thus it will play an essential role in future wearable electronics and shed light on multiple advancements like electronic skins to human–machine interfaces.

**Tattoo Paper as a Platform for Bio-Friendly and Skin-Contact Conformable Electronics**

Francesco Greco;

1 Institute of Solid State Physics, Graz University of Technology, Graz, Austria; 2 Center for Micro-BioRobotics, Istituto Italiano di Tecnologia, Pontedera, Italy; 3 Department of Life Science and Medical Bioscience, Waseda University, Tokyo, Japan.

The combination of conformable and organic bioelectronics can enable a full range of unprecedented applications, from perceivable personal monitoring systems -to- be used in healthcare and sport, especially in skin contact applications- to bio-friendly and edible electronics.

To this aim we chose Temporary Tattoo paper as an unconventional substrate for developing ultra-thin and transferrable devices which are able to conform to surfaces with complex topography. Such a layered material is composed of (i) a support paper, (ii) a water-soluble starch/dextrin sacrificial layer, and (iii) a releasable ethylcellulose nanosheet (thickness ~ 500 nm). It is commercially available in the form of large area sheets or rolls at very low cost.

In a first part of this talk I will report about a robust, low cost and safe strategy for producing disposable ultraconformable electrodes for skin-contact electrophysiology recordings. Temporary Tattoo Electrodes (TTE) and multielectrode arrays (TTMEA) based on conducting polymer PEDOT:PSS are fabricated by ink-jet printing, laser cutting/engraving and lamination. Thanks to this choice, several different configurations of arrays can be customized for different applications. They can be transferred on skin as temporary transfer tattoos and the overall thickness of such electrodes is < 1 μm. We demonstrated their successful performances as stable, dry electrodes for several electrophysiological recordings: skin impedance, surface electromyography (sEMG) on limbs and face, electrocardiography (EKG), and the most challenging electroencephalography (EEG). TTEs demonstrated stable adhesion and operation on skin. Long-term recording was assessed which favorably compares with state of art Ag/AgCl electrodes. Moreover myographic control of a robotic hand through TTE was demonstrated paving the way to novel applications as perceivable sensors in human and brain machine interfaces.

Temporary Tattoo-paper is furthermore proposed as a simple and versatile platform for the integration of electronics onto food and pharmaceutical capsules. In particular, the fabrication of all-printed organic field-effect transistors on untreated commercial tattoo-paper, and their subsequent transfer and operation on edible substrates with a complex nonplanar geometry is demonstrated.

**Conductive Polyhydroxybutyrate/Reduced Graphene Oxide Biocomposite Temperature Sensor**

Dan Li and Anastasia L. Elias; Chemical and Materials Engineering, University of Alberta, Edmonton, Alberta, Canada.

As wearable devices gain traction, inexpensive and simple sensors that can connect with an internet of things platform are promising devices for continuous wellness data monitoring. One approach to making such sensors is using stimulus-responsive (i.e. smart) materials. Inspired by nature, smart materials sense a stimulus in their surroundings and undergo a measurable change in property. Smart materials based on nanoparticle- polymer composites can be designed to sense various stimuli and exhibit changes in color, resistance, capacitance, etc. In our composite systems, conducting nanoparticles (carbon-based materials) impart electrical conductivity to the composite, while the bio-compatible and bio-derived polymer matrix provides mechanical stability. Either the polymer or the nanofiller (or both) may act as the sensing element, undergoing changes in electronic properties in response to an external stimulus. In this presentation, a negative temperature coefficient (NTC) temperature-sensitive composite is reported (where the NTC is defined as (R-R0)/R0△T). Our materials consist of a high melting point biopolymer (polyhydroxybutyrate (PHB)) and graphenic nanomaterial (reduced graphene oxide (rGO)). At a given temperature, the electronic properties of the composites are strongly dependent on the concentration of rGO within the polymer matrix. Upon heating, these materials exhibit large and reversible changes in resistivity (NTC of ~ 0.08°C and fast response time (less than 70 ms for a 3 wt% rGO composite). This response results from the semiconducting properties of the rGO where the number of charge carriers in the conduction band increases with temperature, thereby reducing the overall resistivity of the composites. These responsive conductive composites are good candidate for low-cost sensing devices. The composites are solution processable and thus are compatible with many printing techniques such as direct printing. Devices are capable of measuring dynamic change of temperature subjects with curved surfaces and of thermomapping a large area. Devices are further connected to the wireless system to monitor wellness data in a time-controlled manner.
Facile Non-Invasive Electrical Probe for Studying Photoinduced Events in Primary Explants C.S. Deepak, Sumukh Purohit, Anil Krishna Konduri and K.S. Narayan; School of Advanced Materials (SAMAT) and Neuroscience Unit, Jawaharlal Nehru Center for Advanced Scientific Research, Bangalore, India.

Quantitative assessment involving non-contact electrical methods without the involvement of microscopy can enable a remote user to monitor the cell growth and development at different stages. We introduce and demonstrate a facile approach to probe the ensemble of cells and the role of environment and substrates in the growth and functions. Specifically, cell lines which are of neuronal like and primary explant from chick-embryo retina are studied closely using this novel monitoring method along with conventional from multielectrode array (MEA) type electrical recording approaches. The studies using this technique of the cells at different stages of growth and the changes introduced upon differentiation point to the versatility of the approach. The environment of the cells are varied by choice of different substrates including a variety of non-rigid substrates with different degrees of electrical properties. Optoelectronic substrates with the ability to absorb light and change the surface potential to trigger stimulated responses from the cells and blind-retina explants are also demonstrated. A specially designed microfluidic setup which eliminates air bubbles and is integrated to the measurement assembly was developed to carry out long-term recordings. A systematic development studies of chick retina from the blind-stage (day 12) to a fully mature state (day 21) was carried out. We utilize this chick-model system to study the signal transduction mechanism and pathways upon introducing artificial photoreceptors.

Organic Electrochemical Transistor Response to Liquid and Solid Bacteria Growth Media Eric Frantz, Ashkan Tirgar and Andrew J. Steckl; University of Cincinnati, Cincinnati, Ohio, United States.

Ion generation in bacteria cells is a central component in their life cycle. Ion generation helps us understand bacterial responses to stimuli, as well as the mechanisms by which ion transport is regulated. Recent attention has been given to ion-based communication within and between bacteria colonies [1]. Two methods of detecting bacterial ions are fluorescent and electronic detection. Fluorescent dyes provide a view of ion concentrations spatially, allowing detection of ion movement and position both within and outside cells. Electronic measurements are limited to extracellular ion concentrations and are typically performed using ion selective electrodes (ISEs) or ion-selective FETs (ISFET) to measure specific ion concentrations or changes in pH. We report on the use of organic electrochemical transistors (OECTs) to sense ion concentrations in bacteria growth media. OECTs high transconductance, bio-compatibility, low cost, and small size have made them a popular sensor for detection and characterization of whole cells [2]. OECT switching is driven by ions from either a liquid or solid source. Understanding changes in OECT behavior for different solid and liquid ion sources is needed to fully optimize device for specific applications. These changes can come from ion concentration and species (or other particulates) and significantly affect device operation. Cells captured or cultured onto OECTs can induce a change in effective gate voltage, or a change in transconductance due to their effect on medium pH. While the OECT response to the presence of various cells has been reported, the effect of the culture medium has not been reported. Characterization of the driving electrolyte, or culture medium, is needed to optimize OECT performance and sensitivity for whole cell detection. We have tested transconductance, ON/OFF ratio, and peak transconductance gate voltage of PEDOT:PSS based OECTs operating in several media: KCl, NaCl, PBS, LB broth, YT broth, and water solutions. Our results show peak device transconductance utilizing 0.1M KCl, which is in line with literature [3]. A decrease of 37.7 μs (57%) and 55.1 μs (84%) is shown for LB and YT culture media compared to the 0.1M KCl solution. An increase in ON/OFF ratio of LB and YT broth of 300% and 224% is obtained, compared to 0.1M KCl solution. Interestingly, a reduction in peak transconductance gate voltage from −0.6V to −0.3V was measured for both broth solutions compared to pure electrolyte solutions (KCl, NaCl, etc.). This is beneficial for operating under low OECT power conditions. Overall, these results indicate that cell culture media play an important role in OECT-cell interactions.

Organic Electronic Devices as Multi-Modal Transducers of Cellular Activity Roisin Owens and Charalampos Pitsalidis; Chemical Engineering and Biotechnology, University of Cambridge, Cambridge, United Kingdom.

In vitro models of biological systems are essential for our understanding of biological systems. In many cases where animal models have failed to translate to useful data for human diseases, physiologically relevant in vitro models can bridge the gap. Many difficulties exist in interfacing complex, 3D models with sensing technology adapted for monitoring function of cells within these models. Polymeric electroactive materials and devices can bridge the gap between hard inflexible materials used for physical transducers and soft, compliant biological tissues. An additional advantage of these electronic materials is their flexibility for processing and fabrication in a wide range of formats. In this presentation, I will discuss our recent progress in adapting conducting polymer devices, including simple electrodes and transistors, to integrate with 3D cell models. We go further, by generating 3D electroactive scaffolds capable of hosting and monitoring cells. In some cases, it is useful to zoom in on interactions occurring at the molecular level, to read out events happening at the level of the cell membrane. In addition to monitoring properties of cells and tissues, electrical monitoring is a powerful tool to monitor transmembrane protein function. I will highlight recent research using biomimetic models of cell membranes interfaced with organic electronic devices for drug discovery.

Electrolyte-Gated Carbon Nanotubes Transistors for Electrical Monitoring of Cell Cultures Francesca Scarratti1,2, Giorgio Bonacchini1,2, Caterina Bossio1, Jorge Mario Salazar-Roos1, Wytse Talsma1, Maria Antonietta Loi1, Maria Rosa Antognazza1 and Mario Carrelli1; Istituto Italiano di Tecnologia, Milano, Italy; Politecnico di Milano, Milano, Italy; University of Groningen, Groningen, Netherlands.

Solution-processed, carbon based electrolyte-gated transistors represent an ideal ionic/electronic hybrid device that bridges biology and electronics. These devices are being investigated for a wide range of applications, from drug delivery to neuromodulation and highly sensitive biosensing. Cell-based electrical bio-sensors are of particular interest because they can enable a high level of automation and parallelization in real-time in vitro monitoring of cells cultures, highly desirable for dianostics and toxicology tests. While typical sensing platforms rely on impedance measurements, we propose here an electrolyte-gated transistor for cell viability monitoring, based on a network of solution-processed, polymer-wrapped semiconducting carbon-nonotubes. Our sensors display extended stability to water-gating and allow an easy signal read-out, without requiring complex modeling and/or parameters fitting, as this corresponds to variations in the static transistor channel current. We demonstrate successful cell-proliferation monitoring in excess of 70 h of three different cell models.

Light-Responsive Materials for Bioelectronics from Photosynthetic Microorganisms Gianluca M. Farinola1, Massimo Trotta2, Roberta Ragni1, Francesco Milano2, Angela
Photonsynthetic microorganisms can be envisaged as sources of active materials for bioelectronic devices for photocconversion or light-induced processes. In particular, photosynthetic Reaction Centers (RCs) are enzymes capable to convert solar energy into charge separated states with efficiency close to 100%. We have first reported the highly selective covalent functionalization of the bacterial RC with several classes of tailored molecular fluorophores which act as antennas to enhance its light harvesting capability. The resulting hybrid systems outperform the native protein in the photogeneration of charges and in the photoenzymatic activity. We have also built up smart supramolecular architectures combining multiple enzymes assembled with tailored linkers, which are able to perform manifold functions. Finally, we have developed protocols for addressing the RC on thin films of molecular or polymeric semiconductors deposited onto metal electrodes by covalent or weak collective interactions, obtaining RC-sensitized electronic and electrochemical devices. Biomimetic polymers, such as polydopamine mimics of melanin, have also been investigated as efficient electronic interfaces of RC with electrodes in photoelectrochemical cells.

Our study discloses new concepts for the generation of bio-hybrid materials for sunlight photocconversion and for light-triggered bioelectronics, by combination of tailored functional molecules with highly efficient photo-active natural structures optimized in billions of years of evolution.

11:00 AM EP03.06.06 Conductive Biopolymeric Proteins for Bio-Hybrid Devices Noemie-Manuelle Dorval Courchesne; Chemical Engineering, McGill University, Montreal, Quebec, Canada.

Using proteins as active device components is of particular interest for the fabrication of next-generation electronic devices. Proteins provide soft, biocompatible and genetically tunable surfaces that can be rationally engineered to participate in charge transport processes. In addition, proteins can retain biological functions, to produce multifunctional bioelectronics materials that could be applied to a variety of bio-sensing and bio-energy applications. Here, we report the fabrication of conductive protein gels and films with novel opto-electronic properties. We fabricated these protein-based materials using genetically engineered amyloid proteins as building blocks and introduced desired functionalities via synthetic biology. Using bio-inspired and bio-derived syntheses, we have developed strategies to produce and isolate macroscopic quantities of functional protein materials. We have explored the synthesis of electronically conductive protein fibers and films, by introducing aromatic residues within the core of the self-assembling amyloid proteins. We have characterized the electrical properties of these proteins, and examined factors that influence the conductivity in such protein systems. In addition, we are investigating the potential of engineered proteins to participate in light harvesting in bio-hybrid energy devices. Our scalable biosynthesis process allows us to produce engineered protein materials in sufficient quantities to integrate them, in the future, in bio-hybrid functional devices.

Organometallic halide perovskites are fast grown photocative material in the field of solar cell technology due to high absorption coefficient, almost 100 % internal quantum efficiency, high diffusion length, and broader absorption wavelength (visible to near IR spectrum) [1,2]. Their advantageous optical properties provide high potential to use perovskites as biointerface. But, low stability in aqueous environments and the presence of toxic lead content in commonly used perovskite semiconductors make it difficult to use in the biological environment. Although there is significant focus on lead-free perovskites, their performance remained far from the lead-based perovskites. In order to use perovskites as photodetector for neuronal prostheses, three important conditions including stability in water, biocompatibility, and generation of safe photostimulation need to be satisfied. The present work demonstrates the first use of perovskite for neural interfaces. The photodetector consist of a perovskite photocoactive layer sandwiched between transparent conducting oxide (ITO-Indium tin oxide) and biocompatible PDMS (dimethylpolysiloxane, a silicon-based organic polymer):P3HT (Poly(3-hexylthiophene), a semiconducting polymer) hybrid layer. The coverage of PDMS layer over perovskite thin film blocks the direct contact of neuron cells with toxic perovskite for biocompatibility. It also functions as an encapsulant against water that lead to enhanced stability in aqueous medium. Furthermore, we observed that the thickness of the perovskite layer is critical to generate safe capacitive photostimulation. We studied the perovskite biointerface with ShSy-5Y neuronal cells using whole-cell patch clamping and observed depolarization of the cells.

Blood is the most intensely studied human biofluid and is used as the main indicator (so-called “gold standard”) of the health status of the individual. Blood is a biologically renewing fluid with ~1 million red blood cells (RBCs) injected every second from the bone marrow into the blood stream (equivalent to ~10^11 RBCs being created every day) of an adult human body and a similar number cleared or recycled. Blood is a very complex fluid, containing a multiplicity of components, including cells and cell fragments (red and white blood cells, platelets), proteins, and many other organic molecules and ions. Laboratory-based blood analysis is a well-established procedure that provides a wealth of information about the concentrations of key blood components and enables medical personnel to establish diagnoses and treatments. It is typically performed in hospital or laboratory settings using a variety of methods and equipment, with the emphasis on accuracy and measurement automation. To date, options for point-of-care blood analysis are limited and very low-cost options even more so. One analytical platform that contains the promise to fill this need utilizes cellulose-based microfluidic devices. Cellulose, the most abundant naturally occurring organic compound (polysaccharide), is the main constituent of cell walls in plants and is available in many practical forms, including conventional paper. Paper microfluidics utilizes the self-wicking ability of paper by capillary action to implement simple device that do need external pressure to transport fluids. This has opened the door to simple paper-based point-of-care (PoC) or point-of-use (PoU) devices for monitoring various medical conditions (e.g. pregnancy testing, virus assays, etc.). This research area has exhibited significant growth in the past few years, primarily because of its simplicity, fundamental low cost, and versatility. This presentation provides a review of several important applications, including blood grouping, glucose and coagulation monitoring, biomarker detection. The presentation concludes with a discussion of current challenges of paper-based blood diagnostics and a look forward to future prospects.

Aqueous Electrolyte Compatible Electrochromic Polymers Processed from Environmentally Sustainable Solvents
Graham Collier, Ian Pelse, Anna Osterholm and John Reynolds; School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, Georgia, United States.
Developing aqueous electrolyte compatible, redox-active polymers that can be processed from environmentally sustainable solvents is desirable because these traits will effectively reduce environmental impact and human health hazards during processing procedures and in the final device architecture. Additionally, the ability to dope and dedope conjugated polymers in aqueous media may allow for conjugated polymers to find applicability in biological systems. In an effort to address these criteria, we have synthesized two ester-functionalized 3,4-propylenedioxy-thiophene polymers that are sufficiently soluble in environmentally sustainable (2-methyltetrahydrofuran) and benign (ethyl and propyl acetate) solvents to allow for processing as thin, electroactive films. Moreover, as the ester-functionality on the side chains is increased, the polymer films are able to be reversibly switched in aqueous electrolytes. The polymers were studied as electrochromic films as a case study and it was revealed that optical, electrochemical, and morphological properties showed slight variations depending on the casting solvent. However, properties such as switching time and contrast were unaffected. Our work highlights a simple design strategy to synthesize aqueous electrolyte compatible electrochromic polymers processable from sustainable solvents without post-polymerization modifications, which will ultimately reduce the environmental impact of electrochromic device fabrication and testing.

Helix-Rich Silk Fibroin Thin Films for Biocompatible Memory Devices
Mohammad Tahiib Sharbat, Se Youn Cho, Qionghou Wan, Golnaz Najafl Tomarazi, Nolan D Ardolino, Joshua Schleu, Mostafa Bedewy and Feng Xiong; University of Cincinnati, Cincinnati, Ohio, United States.
Silk fibroin produced by Bombyx mori silkworm, a fibroin protein-based biopolymer, has been used as a material for high-quality clothing since ancient times due to its superior textile properties such as lightness, fineness, and a unique luster. Moreover, because of its excellent strength and attractive biological properties, regenerated silk fibroin has been widely studied as a biomaterial over the past decades. Recently, silk fibroin has been considered as a promising candidate for biocompatible and green electronics due to its interesting resistive switching behavior. However, while prior works demonstrated promising proof-of-concept resistive switching, the high programming voltage, subpar on/off ratio, and limited endurance have hindered the development for silk-based resistive memory devices.
In this work, we present a comprehensive study to investigate how we may improve the electrical switching properties of silk memory devices by tuning its crystalline structure. First, as an initial effort, we fabricated 60+ devices and compared them with 20 of similar fibroin films that were able to be reversibly switched in aqueous electrolytes. The polymers were studied as electrochromic devices as a case study and it was revealed that optical, electrochemical, and morphological properties showed slight variations depending on the casting solvent. However, properties such as switching time and contrast were unaffected. Our work highlights a simple design strategy to synthesize aqueous electrolyte compatible electrochromic polymers processable from sustainable solvents without post-polymerization modifications, which will ultimately reduce the environmental impact of electrochromic device fabrication and testing.

Multi-Functional Nanocomposites from Naturally Derived Materials—Crystalline Celluloses and Conductive Melanin

Bong Sup Shim, Taesik Eom, Kyeonga Her and Seunghyeon Lee; Chemical Engineering, Inha University, Incheon, Korea (the Republic of).

Natural systems utilize multifunctional biocomposites by a bottom-up self-assembly of nanomaterials for creating multiscale, hierarchical, and multiphasic structures. While conventional man-made synthetic composites increase one functionality by sacrificing the others, the biocomposites often synergistically utilize their multi-functionalities. Here, by molecularly organized layer-by-layer assembly as well as thermodynamically driven orientation, we introduce multifunctional nanocomposites, recently developed from our laboratory, from natural biocomposites including high crystalline cellulose nanofibers and conductive melanin nanoparticles. High crystalline cellulose nanofibers, extracted from tunicates, have shown almost perfect crystallinity, straight fibrous shape, and liquid crystalline alignments. Thus, their nanocomposites showed uniquely oriented structures as well as excellent optical, mechanical, and barrier properties. On the other hand, naturally derived melanin nanoparticles are molecularly structured to possess finely tunable electrochemical conductivities, optical reflectivity, and casting shape stability with inherent biocompatibility. These composites can be used as key functional materials in the emerging applications such as biotic-abiotic smart interfaces, implantable electronics, and eco-electronics.

Photophysical and (Opto)Electronic Properties of Fungi-Derived Pigments and Their Polymer Blends

Gregory Giesbers, Jonathan Van Schenck, Sarath Vega Gutierrez, Rachel Van Court, Seri Robinson and Oksana Ostoverykhova; Oregon State University, Corvallis, Oregon, United States.

Organic semiconductors are of interest for optoelectronic applications due to their low cost, solution processability, and tunable properties. Recently, naturally product-derived organic pigments attracted attention due to their extraordinary environmental stability and unexpectedly good optoelectronic performance, in spite of only partially conjugated molecular structure. We present a study of the optical and electronic properties of several fungi-derived pigments and of their use in organic (opto)electronic devices. Fungi-derived pigments are a naturally sourced, sustainable class of materials that are yet to be explored as organic semiconductor materials. Examples of such pigments under study are a blue-green pigment xylindelmin, which is secreted by the wood-staining fungi Chlorociboria (C.) aeruginosa and C. aeruginascens, red pigment draconicin derived from Scytalidium cuboidenum, and a yellow pigment derived from Scytalidium ganodermorphthorum.

Photophysics of pigments is explored using absorption and photoluminescence (PL) spectroscopy combined with density functional theory calculations. In xylindelin and the red pigment (a novel naphthoquinone derivative), our studies reveal contributions of several tautomers to the optical properties and solvent-dependent pigment aggregation and crystallization. Molecular packing-dependent properties of aggregates and crystals were studied using polarization- and temperature-dependent absorption and PL and related to film or crystal structure and morphology obtained from the SEM and XRD. Photostability and thermal stability of pigments was also quantified.

(Opto)electronic properties of pristine pigments and their blends with synthetic polymers and naturally derived biopolymers, developed to improve film morphology and processability, were explored in several device structures. Charge carrier mobilities were obtained from space-charge limited currents and from measurements of thin film transistor characteristics and related to film structure and morphology. Some blends such as xylindelin:PMMA revealed ambipolar charge transport with charge carrier mobilities of up to ~0.01 cm²/Vs. Photoresponse was observed throughout the pigment absorption range, and photocurrent spectroscopy was carried out to obtain wavelength-dependent charge generation efficiencies. Charge and energy transfer in donor-acceptor combinations of pigments with several benchmark donors such as P3HT and PTB7-Th and acceptors such as PCBM were also investigated to determine the feasibility of using pigments under study in bulk heterojunction solar cells.

Directly Written Digital Microfluidic Systems for Ion Sensing Applications

Xin Min, Chao Rao and Woo Soo Kim; School of Mechatronic Systems Engineering, Simon Fraser University, Surrey, British Columbia, Canada.

Digital Microfluidic (DMF) devices have been developed recently as its promising ability to replace conventional laboratory processes. Small sample consumption and high controllability make the device suitable for electrochemical or biochemical applications. However, the fabrication of current DMF device is limited to rigid substrates, which confine its potential on flexible, fabric substrates for further applications. Here, we present DMF devices fabricated through additive manufacturing method with integrated on-chip ion-selective test function. The DMF electrodes are printed directly with conductive silver ink, followed by spin coating and spray coating of dielectric and hydrophobic layers. The overall fabrication procedure is easy and fast, which can be applied to various substrates. In addition, a capacitance monitoring system has been added to the device to obtain the droplet position and speed data in real-time for providing feedback signals. The ion-selective function is tested with a layer of ion-selective membrane on one of DMF electrodes. Fabricated DMF device demonstrated droplet manipulation functions including moving, mixing, and testing sequence. The on-chip membrane shows targeted ion selectivity from the droplet containing mixed interference ions.

Biofriendly Ionic Electromechanically Active Polymer Actuators

Fred Elhi, Pille Rinne, Karl Karu, Tarmo Tamm, Urmass Johanson, Vladislav Ivanistsev, Alvo Aabloo and Kaiaa Pohako-Esko; University of Tartu, Tartu, Estonia.

Electromechanically active materials change their shape under external electrical stimulation or generate electrical signal upon mechanical stimulus. These materials are in the focus of intense research as bioinspired devices need replacement for traditional actuators.

The present study aims to development of biofriendly ionic electromechanically active polymer actuators (IEAPs). A typical IEAP is a soft thin laminate composed of a microporous ion-permeable polymer membrane containing electrolyte (for example ionic liquid (IL)) placed between electrodes with a high specific surface area (for example conductive polymers). IEAPs can work as actuators and sensors transducing between electric current and mechanical deformation. In addition, IEAPs can sense temperature, humidity and chemical composition of the environment. Migration of ions in response to electrical stimulation enables controlled release. Combining all these functionalities leads to smart devices, which sense surroundings and react accordingly. Potential applications for IEAPs include implantable or disposable biomedical devices, smart prostheses, soft haptic devices and wearable electronics. Mentioned applications require biocompatible materials, which has still remained challenging during decades of research in the field.
Our approach towards biofriendly of IEAPs was to use biocompatible materials for different parts of IEAPs without compromising in performance. A key component hereby was low-toxicity IL as electrolyte. For electrode material polypropylene (PPy) was chosen due to proven biocompatibility: PPy is a suitable substrate for cell growth, implantable and can be functionalized to be biodegradable. Medically approved synthetic polymer PVDF and inherently biofriendly and biodegradable gelatin were applied and compared as membrane materials. So far mostly the conventional imidazolium based ILs had been used as electrolytes in IEAPs despite the well-known toxicological issues of these salts and a large variety of alternative ILs available. In the present study low-toxicity choline based ILs were applied instead.

In the presentation preparation, characterization, and electrochemomechanical performance of the developed biocompatible IEAPs will be discussed. Significant differences in actuation were found in case of different ILs as electrolytes although the actuators were found to be cation active and all of the ILs contained the same choline cation. Experimental results were explained using computational methods: formation of ionic clusters was studied with molecular dynamics (MD) simulations and with density functional theory (DFT) calculations.

8:15 AM EP03.09.02
Application of Biodegradable Polymers in Design of Green Printed Circuit Boards Reihaneh Jamshidi and Reza Montazami; University of Hartford, West Hartford, Connecticut, United States; Mechanical Engineering, Iowa State University of Science and Technology, Ames, Iowa, United States.

Owing to the burgeoning waste electrical and electronic equipment is the effort to recycle the printed circuit board (PCB), which if improperly disposed of results in health hazards and environmental pollution. This study describes a new PCB substrate that would vanish in water leaving the metals on it for re-use. A preliminary substrate made from water, gelatin, and poly vinyl alcohol was coated with polyurethane for the purpose of preservation under humid conditions and a voltage divider circuit was attached. Dynamic mechanical analysis and thermomechanical analysis were performed to characterize the PCB for its physical characteristics, while Fourier transformed infrared spectroscopy was used for chemical characterization. It was demonstrated that the metal components including solder, copper, and electronic components can be fully recovered without generation of any toxic byproducts or negative impact on the environment.

8:30 AM EP03.09.03
Biodegradation of Organic Semiconductor Materials Luis F. Baptista, Natalia González, María del Carmen Molina, Carolina Vargas and Raquel Simarro; Department of Biology and Geology, Physics and Inorganic Chemistry, Rey Juan Carlos University, Mostoles, Spain; Department of Chemical and Environmental Technology, Rey Juan Carlos University, Mostoles, Spain.

Nowadays, the demand for electronic devices is exponentially increasing in our society. This fact, together with a shortening in their life cycle drive the depletion of non-renewable resources and the production of huge amounts of highly polluting electronic wastes. This is environmentally unsustainable at medium and specially at long term. Organic semiconductors arises as a promising alternative to traditional inorganic-based semiconductors for the fabrication of electronic circuits and devices. Besides other technological strengths, organic semiconductor devices can be designed to allow its biodegradation to avoid the pollution problem of traditional inorganic-based electronic devices. Therefore, the assessment of biodegradability of individual components of the electronic circuits and of the whole fabricated devices is a key issue for the future development of this environmentally friendly technology.

In the present work, efficient biodegradation processes for epindolidione, quinacridone and 2,8-difluoroepindolidione have been developed using different microorganism and microbial consortia under aerobic and anaerobic conditions. With respect to the biodegradation of epindolidione, among all tested bacteria, Stenotrophomonas sp. showed largest growth whilst the best microbial consortium capable live in that medium was the one isolated form Tinto river (South-West of Spain). We observed that during the first 21 days, the biodegradation was almost negligible for both Stenotrophomonas and for Tinto river consortium. However, at 73 days, the uptake of epindolidione with the consortium reached approximately 40% and 60% with Stenotrophomonas. After 100 days, epindolidione was not detected in both experiments, proving that the biodegradation was complete. The abiotic control experiment (i.e., without microbial inoculation) showed that no significant degradation of epindolidione was measured, indicating that the reduction in epindolidione concentration in biodegradation experiments were due to biotic causes. For the development of a biodegradation process of epindolidione at larger scale, the operating cultivation conditions were optimized in a 1.5L bioreactor using Stenotrophomonas sp. Then, we observed that the organic semiconductor steadily decreased, reaching a biodegradation of 50% during the first 10 days. This value is clearly remarkable for this type of recalcitrant compounds. For the assessment of quinacridone biodegradation, Tinto river consortium achieved a 20% removal after 20 days, but the biodegradation did not progressed at longer times. With respect to Stenotrophomonas, this bacterial strain did not show a significant capability to degrade quinacridone under these conditions. Although quinacridone is more soluble, and thus more bioavailable than epindolidione, it seems to be more recalcitrant too towards the attack of microorganisms.

The biodegradation of 2,8-difluoroepindolidione was tested with and without oxigen. Thus, under aerobic conditions, more than 70% of the initial amount of that organic semiconductor was rapidly biodegraded during the first week, reaching an approximately constant plateau were the remaining concentration of the organic compound was not affected at longer times. However, the anaerobic biodegradation process progressed more slowly, reaching a maximum biodegradation of 30% after 5-6 weeks of operation. This difference in the biodegradation extent between the aerobic and anaerobic processes is likely because the decomposition of organic compounds by bacteria preferably uses oxygen as the final electron acceptor.

9:00 AM EP03.09.04
Sustainability Assessment of Biofriendly Electronics—Establishing Best-Practice Analysis Frameworks Eric Masanet; Northwestern University, Evanston, Illinois, United States.

Sustainability assessment is an important approach for emerging technologies, as it can shed light on their potential environmental impacts and benefits when deployed at large scales, identify possible unintended consequences, and expose specific technology characteristics which can be optimized during the innovation and deployment phases to maximize future societal benefits. While there have been many life-cycle assessments (LCA) of bio-based fuels and products, applications of LCA to emerging biofriendly electronics have been much more limited. Moreover, because biofriendly electronics are a rapidly emerging class of technologies, any sustainability analysis must move beyond retrospective LCAs and be largely prospective in nature (because technological development and market data are scarce/nonexistent), requiring special care with respect to uncertainty analysis and scenario design for meaningful feedback on potential impacts and benefits. Finally, in a future requiring deep decarbonization of all economic sectors, there may be competition with prospective applications of limited global sustainable biomass resources, notably for biofuels in the transport sector, bio-feedstocks in the chemicals sector, and bioenergy with carbon capture and storage (BECCS) in the power sector; this competition may affect the sources and quality of biomass available for biofriendly electronics applications. As such the integration of LCA with dynamic energy and resource systems modeling and scenario analysis will also be necessary. Therefore, to be useful, sustainability assessment of biofriendly electronics demands a dynamic, prospective, integrated, and life-cycle systems modeling approach. This presentation will explore the development of such a best-practice assessment approach to meet this analytical vision, by reviewing strengths and weaknesses of existing modeling methods (e.g., LCA) and data sources, known data gaps and possibilities for filling them, exploring the role of lab-analysis partnerships to accelerate data availability and conduct R&D relevant scenario analyses, and propose a research roadmap for building a sustainability assessment community of practice for biofriendly electronic applications.

9:30 AM EP03.09.05

E-waste is one of the fastest growing waste streams in the world in terms of volume and its subsequent environmental impact on the planet. The global growth rate for the e-waste stream is 3–5% (Cucchiella et al., 2015) and expected to reach 50 million tonnes worldwide by the end of 2018 (Balde 2015). This e-waste stream provides an economic stream is 3–5% (Cucchiella et al., 2015) and expected to reach 50 million tonnes worldwide by the end of 2018 (Balde 2015). This e-waste stream provides an economic.
palladium but also the presence of hazardous chemicals. There are many challenges associated with the recovery of metals and non-metal fractions from e-waste due to the composite nature of these materials. The recovery of metals is the main economic driver for e-waste recycling and downstream reprocessing. The existing technologies for metal recovery from e-waste are mostly designed to capture metals. When hydrometallurgical methods are used to extract metals, fine grinding is usually required and all components are ground to very fine particle sizes. Very corrosive chemicals are commonly used to extract metals of interest, and as a result, hydrometallurgical techniques are very energy intensive and toxic residues are left after processing. Pyrometallurgical methods are also quite often used to recover metals by smelting. Both hydrometallurgical and pyrometallurgical methods are energy intensive and destructive, particularly if the focus is to only recover metals. The physical separation and step-by-step preceding final end processing allows for recovery of metals at much coarser sizes and the other non-metal materials like plastic, fiber glass, and resins to be recovered in a form that could be reused as a secondary raw material in the manufacturing of new products. This will provide an opportunity to design processes that will focus on minimizing the final residue after the recycling and end reprocessing of e-waste. The presentation will discuss current research on the step-by-step recovery of metal and non-metal fractions from e-waste.

SESSION EP04.01: Liquid-Material Embedded Soft Structures I
Session Chairs: Marc Ramuz and Cunjiang Yu
Tuesday Morning, April 23, 2019
PCC North, 200 Level, Room 222 A

10:30 AM *EP04.01.01
Liquid Metals Encased in Functional Elastomers for Soft and Stretchable Electronics Michael Dickey; North Carolina State University, Raleigh, North Carolina, United States.

This talk will discuss recent work in our group (and through collaborations) to utilize liquid metals as electrical conductors for soft and stretchable electronics. Gallium and its alloys have low viscosity, low toxicity, and negligible volatility. Despite the large surface tension of the metal, it can be patterned into non-spherical 2D and 3D shapes due to the presence of an ultra-thin oxide skin that forms on its surface. Because it is a liquid, the metal is inherently soft and flows in response to stress to retain electrical continuity under extreme deformation. By embedding the metal into elastomer or gel substrates, it is possible to form soft, flexible, and conformal electrical components, stretchable antennas, and ultra-stretchable wires that maintain metallic conductivity up to ~800% strain. In addition to introducing the advantages of these materials for stretchable electronics, this talk will focus on recent advances with (1) patterning the metal and metal composites, (2) integrating liquid metal into functional devices including energy harvesters and transistors (in collaboration with the Ozturk and Franklin groups, respectively), and (3) encasing the metal within optimized and functional elastomers that are less prone to fail mechanically (and warn the user colorimetrically before failure, done in collaboration with the Craig group). These advances have implications for creating electronics that are softer than skin and with stretchability limited only by the encasing elastomer.

11:00 AM *EP04.01.02
Polymerized Liquid Metal Networks for Activatable Stretchable Conductors and Sensors Carl Thrasher¹, Zachary Farrell², Nicholas J. Morris¹,² and Christopher Tabor¹; ¹Materials and Manufacturing Directorate, Air Force Research Laboratory, Wright-Patterson AFB, Ohio, United States; ²UES, Inc., Dayton, Ohio, United States.

Robust stretchable conductors with advanced capabilities such as stimuli-responsiveness and high power delivery over large strains are needed for advanced soft robotic, physically reconfigurable, and wearable electronic applications. Room temperature liquid metals such as eutectic gallium-indium (EGaIn) have shown potential in next generation stretchable electronic systems, but suffer from problems with containment, fabrication, and metal oxide formation. Here we synthesize phosphonic acid-functionalized reactive EGaIn core-shell particles and polymerize them on elastomer substrates to create polymerized liquid metal networks consisting of ~99.9 wt% EGaIn. Under strain the polymerized particles in the network rupture and release their encapsulated liquid metal, rapidly transitioning the network from an electrically resistive to a conductive state (10⁴ fold conductivity increase from 0-100% strain). Once activated, these network composites adopt microstructures which mitigate the deleterious effects of strain on electronic performance. As a result of these microstructures, these networks show many remarkable characteristics including increasing volumetric conductivity with strain to over 20,000 S/cm at ~700% elongation, electronic memory of previous strain states, and R/R₀ < 1 between 0-300% strain. The unique electromechanical properties of these activated liquid metal networks present a superior design strategy to provide ultra-stretchable (~300%) conductors with near-zero change in resistance and can find additional use for powerless active strain indication and triggered healing in stretchable conductors.

Micro-Patterned Liquid Metal Based Conductors for Large-Area Stretchable Electronics Laurent Deijace and Stephanie Lacour; Laboratory for Soft Bioelectronic Interfaces, Ecole Polytechnique Federale de Lausanne (EPFL), Geneva, Switzerland.

Gallium is a metal in a liquid state at room temperature that offers unique electromechanical properties when integrated within a soft, elastic carrier material. However, precise patterning and manipulation of the liquid metal are challenging. High surface tension prevents homogeneous spreading of liquid gallium on lyophobic silicone carriers. A thin gallium oxide skin forms immediately at the gallium surface upon exposure to ambient conditions and sets the shape of the material. We overcome these peculiar properties to pattern reliably thin gallium features with μm-scale resolution, high surface density and over centimeters side surface areas.

Our manufacturing process combines soft lithography, self-assembly and physical vapor deposition techniques, all compatible with wafer scale manufacturing. First, a PDMS layer is cast on a photoresist mold lithographically patterned with a matrix of 1.5μm thick, 5μm wide holes distributed across the entire 4in. wafer. The PDMS layer is then demolded and transferred to another carrier for further processing on the patterned side. A 160nm thick gold film is blanket-sputtered on the textured surface, so as to increase the chemical affinity of gallium to the silicone substrate. Next a tilted Ion Beam Etching (IBE) process is used to selectively remove the gold layer only above the patterned recesses. Finally,
gallium is evaporated on the substrate, where it alloys with gold and fills all empty spaces in-between the PDMS micro-posts. This process enables a range of channel designs and geometries leading to soft conductors displaying highly stable electromechanical properties when reversibly and repeatedly stretched to 50% elongation for hundred cycles. This work represents a significant advance towards the miniaturization of gallium-based technology for robust and reproducible, soft and mechanically compliant electronic circuits.

**Stretchable Elastic Shape Memory Fibers with Electical Conductivity**
Sungju Park¹, Hardil Shah², Neil Baugh³, Dishit Parekh³, Ishan Joshipura², Yubo Ouyang² and Michael Dickey¹; ¹Department of Polymer Nanoscience & Technology, Chonbuk National University, Jeonju, Korea (the Republic of); ²Department of Chemical & Biomolecular Engineering, North Carolina State University, Raleigh, North Carolina, United States.

This paper describes shape memory polymer fibers consisting of an elastic shell and a gallium liquid metal core. These fibers are interesting because they have metallic electrical and thermal conductivity, elastic mechanical properties, and excellent shape memory properties due to the ability to change the phase of the core from a low viscosity liquid to a solid metal. It is straightforward to form the fibers by via melt processing followed by injection of the liquid metal into the core. The elastic energy stored in the fiber allows it to relax back to its original geometry upon melting the solid gallium. The ability to change the core of the fiber from liquid to solid allows an enormous modulus change in the range of from 4.5 to 1618.3 MPa and the ability to have shape-memory effect; that is, the fiber can preserve a deformed shape and then return to its original shape upon heating. The shape memory behavior of these fibers is quantitatively characterized in terms of fixity (i.e. the ability to retain deformed temporal shape) and recovery (i.e. the ability to return to its original geometry). The use of a rigid metallic core provides perfect fixity. Recovery rate time is effectively minimized due to the elastomeric shell with having minimal viscous dissipation as well as rapid conversion of the metallic core to a liquid with a low viscosity. Notably, the use of gallium—with a melting point above room temperature but below body temperature—allows the user to melt and deform local regions of the fiber by hand. These stretchable elastic shape memory fibers may enable new applications in soft robotics, stretchable and wearable sensors, and bioinspired electronic skin.

**The Freeze/Thaw Properties of the Conformable Conductor Eutectic Gallium-Indium-Tin**
Amanda Koh¹,²; Randy Mrozek¹ and Geoffrey Slipher³; ¹U.S. Army Research Laboratory, Adelphi, Maryland, United States; ²Chemical and Biological Engineering, University of Alabama, Tuscaloosa, Alabama, United States.

Room-temperature eutectic liquid metals have become an exciting basis of research into soft materials for sensors, actuators, and robotics. This work relies on the low melting point of the liquid metal, which allows for a material which is both conformable and conductive. While the melting point of metals such as eutectic gallium-indium (EGaIn) and eutectic gallium-Indium-Tin (Galinstan) are often cited, their mechanical and electrical properties around the melting point are not well-studied. These properties, particularly the mechanical transition between a liquid and solid phase, are crucial to understanding the use of EGaIn and Galinstan as conformable conductive elements in a wide variety of environments. This work focuses on Galinstan, which is reported to have a melting point ~10°C and a low room-temperature modulus. By measuring the rheology of Galinstan between 50°C and -20°C, the range at which Galinstan can truly be called “soft” with respect to common elastomer matrices was determined. Mechanical changes caused by the effects of the freeze/thaw cycle on Galinstan were also observed. The transition between the solid and liquid state were also observed using powder x-ray diffraction to determine if a crystalline solid was formed, and what changes the freeze/thaw cycles may cause in the material. The mechanical properties of Galinstan-in-PDMS dispersions were also measured through freeze/thaw to better understand the use of Galinstan as a conformable conductor in a stretchable, electronic device. Through this work, we were able to add important mechanical performance detail to the description of Galinstan as a conformable conductor, as well as point out important considerations when manufacturing a device intended for hot and cold environments.
SELF-POWERED ULTRA-FLEXIBLE ORGANIC ELECTRONICS FOR HEALTH MONITORING

FULLY IMPLANTABLE WIRELESS BATTERY-FREE OPTOELECTRONIC SYSTEMS FOR MULTIMODAL OPTOELECTRONIC NEUROMODULATION

2:45 PM

Philipp Gritsun1, Vaishnavi Krishnamurthi2, Abraham Vázquez-Guardado3, Zhaoyan Xie4, Anthony Banks5, Chun-Ju Su6, Yeshou Xu4, Chad Haney2, Emily A. Waters7, Iwährand Kandel8, Siddharth Krishnan9, Tyler Ray4, John P. Leshock9, Yonggang Huang4, Debashis Chanda2 and John A. Rogers4, University of Arizona, Tucson, Arizona, United States; 9RMIT University, Melbourne, Victoria, Australia; 3University of Central Florida, Orlando, Florida, United States; 4Northwestern University, Evanston, Illinois, United States; 2Neurolyx, Evanston, Illinois, United States.

Recently emerging classes of battery free, ultrasmall, fully implantable devices for optogenetic neuromodulation2 eliminate physical tethers associated with bulky head-stage and batteries in alternative wireless technologies and conventional setups by leveraging cellular scale light emitting diodes on flexible injectable filaments as light sources. These highly miniaturized systems enable untethered, operation for behavioral studies that eliminate motion constraints and enable new experimental paradigms in a range of complex 3D environments and contexts (e.g. social interactions) that cannot be explored with conventional technologies. These devices are, however, purely passive in their design, thereby precluding any form of active control or programmability, resulting in limitations when investigating circuit dynamics where independent operation of multiple light sources with precise active control is needed. Here we present a series of important concepts that enable controlled device operation, independent of position and angle relative to the experimental arena, with advanced wireless power harvesting capabilities and full user-programmability over multiple devices. This level of functionality is demonstrated in integrated platforms that are compatible with noninvasive imaging technologies such as computed tomography and magnetic resonance imaging and have sizes and weights not significantly larger than those of previous, passive systems. The resulting devices qualitatively expand options in brain tissue illumination for optogenetic neuromodulation and multimodal operation, with broad potential applications in neuroscience research, with specific advances in precise dissection of neural circuit function during unconstrained behavioral studies.

Self-Powered Ultra-Flexible Organic Electronics for Health Monitoring

Takao Someya1,2, Kenjiro Fukuda3 and Tomoyuki Yokota1; 1Electrical and Electronic Engineering and Information Systems, University of Tokyo, Tokyo, Japan; 2RIKEN Center for Emergent Matter Science, Saitama, Japan.

On-skin sensors have attract much attention as the next-generation wearable devices, because the conformal contact on human skin enables accurate and continuous detection of physiological signals. One of the most important technologies to improve usability of on-skin sensors is a power source to continuously supply electricity to health-monitoring systems. In this talk, we will report on recent progresses of ultraflexible organic photovoltaic cells for applications to wearable sensors. First, ultraflexible organic power sources that can be wrapped around an object have been developed with mechanical and thermal stability in long-term operation. Then, the integration of these power sources with functional electric devices including sensors has been achieved.

4:00 PM

Physical Biology and Material Dynamics at the Semiconductor-Based Biointerfaces

Bozhi Tian; The University of Chicago, Chicago, Illinois, United States.

Recent studies have demonstrated that in addition to biochemical and genetic interactions, cellular systems also respond to biophysical cues, such as electrical, thermal, and mechanical signals. However, we only have limited tools that can introduce localized physical stimuli and/or sense cellular responses with high spatiotemporal resolution. Inorganic semiconductors display a spectrum of physical properties and offer the possibility of numerous device applications. My group integrates material science with biophysics to study several semiconductor-based biointerfaces. In this talk, I will first pinpoint domains where semiconductor properties can be leveraged for biointerface studies, providing a sample of numbers in semiconductor-based biointerfaces. Next, I will present a few recent studies from our lab and highlight key biophysical mechanisms underlying the non-genetic optical modulation interfaces. In particular, I will present a biology-guided two-step design principle for establishing tight intra-, inter-, and extracellular silicon-based interfaces in which silicon and the biological targets have matched mechanical properties and efficient signal transduction. Finally, I will discuss new materials and biological targets that could catalyze future advances.

4:30 PM

Autonomic Self-Healing and Intrinsical Stretchability of PEDOT:PSS Films

Fabio Cicora; Chemical Engineering, Polytechnique Montréal, Montréal, Quebec, Canada.

Organic electronic devices, apart from consumer applications, are presently paving the path for key applications at the interface between electronics and biology. In such applications, organic polymers are very attractive candidates, due to their distinct properties of mechanical flexibility, self-healing and mixed conduction. My group investigated the processing conditions leading to high electrical conductivity, long-term stability in aqueous media as well as robust mechanical properties of the conducting polymer poly(3,4-ethylenedioxythiophene) doped with polystyrenesulfonate (PEDOT:PSS) [1-3]. We have demonstrated that stretchable PEDOT:PSS films can be achieved by adding a fluorosurfactant to the film processing mixture and by pre-stretching the substrate during film deposition. We have achieved patterning of organic materials on a wide range of substrates, using orthogonal lithography and pattern transfer [4-5]. Recently we have discovered that PEDOT:PSS films can be rapidly healed with water drops after being damaged with a sharp blade [6] or show autonomous self-healing if processed in presence of certain additives. My talk will deal with processing, characterization and patterning of conducting polymer films and devices for flexible, stretchable and healable electronics. I will particularly focus on the strategies to achieve films with optimized electrical conductivity and mechanical properties, on unconventional micro patterning on flexible and stretchable substrates, on the different routes to achieve films stretchability and self-healing.

Highly Conducting MXene Composite Fibers with Conductive Polymer Binder for Fiber-Shaped Supercapacitors

Dopamine (DA), as a crucial neurotransmitter, can transfer chemicals in human brain to affect our emotion and behaviors, and DA disorders in secretion and transportation can cause some inurable disease, such as Parkinsonism and Alzheimer's disease. Implantable flexible sensors offer a feasible approach to monitor the content and distribution of DA, and it may assist us to overcome those disease. Up to now, mainly reported investigations were conducted using electrochemical sensors modified by metallic oxide and graphene, but rough structures and limited types of above materials restrict their further development in function modulation. One of the promising strategy to meet this challenge is employing adjustable materials to combine with flexible sensors, and metal-organic frameworks (MOFs) that possess designable structures and adjustable functions can be considered as the suitable candidate for fabricating functional devices. Additionally, flexible sensors integrated with MOFs have already been achieved by our group, allowing more explorations on MOF-based flexible electronics.

Given the above consideration, this paper presents techniques and materials to fabricate a luminescent MOF-based flexible sensor, and photoelectric detector in the sensor can detect emission changes of MOF represented as functional part in response to DA. Notably, MOF-modified sensor possesses excellent biologically safety that was confirmed using live cell experiments, supplying the foundation for the practical application in living animals. This work represents the first effort in combining luminescent MOFs with flexible sensors, offering in-depth understanding of flexible sensors' property at molecular level. The excellent results may promote the progress of flexible electronics in biology, healthcare and sensing, etc.

Vapor-Phase Synthesis of Organic-Inorganic Hybrid Gate Dielectric for Flexible Electronics

Min Ju Kim1, Kwanyong Pak1, Wan Sik Hwang2, Sung Gap Im1 and Byung Jin Cho1
1Electrical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Material Engineering, Korea Aerospace University, Goyang-si, Korea (the Republic of); 3Chemical and Biomolecular Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Organic-based thin film transistors (OTFTs) are beneficial for wearable architecture because of their lightweight, flexibility and low cost. One of the critical issues in flexible OTFTs is gate dielectric for high performance flexible electronics. The hybrid materials consisting of organic and inorganic materials have emerged as a feasible gate dielectric for high-performance flexible electronics. Therefore, it is necessary to develop ultrathin hybrid organic-inorganic dielectrics and correlate their material properties with device performance at different bending strains. In this work, we propose a one-step synthesis method to form a high-k, ultrathin and homogeneous organic-inorganic hybrid dielectric via initiated chemical vapor deposition (iCVD). iCVD is a well-established process to deposit various functional polymer films based on a radical polymerization via a vapor-phase deposition. In this study, trimethylaluminum (TMA) and 2-hydroxyethyl methacrylate (HEMA) were used as the inorganic precursor and monomer, respectively, leading to the formation of an AlOx-embedded polymer matrix hereafter called a hybrid dielectric. The chemical bonds of the synthesized hybrid dielectric were characterized using Fourier transform infrared spectroscopy (FTIR) and X-ray photoelectron spectroscopy (XPS) which clearly demonstrated that the hybrid dielectric was successfully synthesized and deposited via iCVD process. The X-ray diffraction (XRD) spectra show that the amorphous AlOx moiety is dispersed in the polymer matrix to achieve high dielectric strength and mechanical flexibility. No apparent grain-like or pinhole-like morphologies are observed from the atomic force microscopy (AFM) images, which indicated that the hybrid dielectrics were homogeneously synthesized without any phase separation. To characterize the electrical properties of the hybrid dielectric with various Al contents, crossbar-type metal-insulator-metal (MIM) devices were fabricated. The dielectric constant was extracted from the capacitance (C) measured at a frequency (f) of 10 kHz and film thickness measured via scanning transmission electron spectroscopy (STEM). The dielectric constant (k values) increased from 3 to 7 as the Al concentration in the hybrid dielectric increased, which was attributed to a greater number of dipoles in the polymer matrix. Unlike the higher k values with higher Al concentrations, the electrical breakdown field (Ebreak) decreased linearly from 6 to 3 MV/cm, and the gate leakage current (J) at 2 MV/cm increased exponentially from 1.0 × 107 to 3.0 × 109 A/cm2. The electrical results revealed that there was a trade-off between performance and power consumption. The electrical energy bandgap (Eg) was extracted from the electron energy loss spectroscopy (EELS) with low loss spectra resulting in a wide Eg of 7.0 - 7.5 eV. Based on these preliminary experiments, the hybrid dielectric with an Al concentration of around 18% exhibited a decent k value of 6 and J value of lower than 107 A/cm2 at 2 MV/cm. The MIM device with the hybrid dielectric exhibited negligible J changes of up to 2.6 % applied strain, where the soft polymer matrix effectively released the applied strain. Finally, the iCVD hybrid dielectrics were applied to the bottom-gated OTFTs with p-type pentacene and n-type N,N′-ditridecylperylene-3,4,9,10-tetracarboxylic diimide (PTCDI-C13). Two typical linear and saturation operating regions emerged, revealing well-behaved transistor characteristics. The mechanical flexibility of the –p-type pentacene OTFTs with the hybrid dielectric was investigated at different bending strains. The transfer characteristics of the OTFTs were found as a function of mechanical bending strain, showing negligible changes while maintaining a low gate leakage current. The results suggest that the hybrid dielectric synthesized via the iCVD process is a promising candidate for high-performance low-power consumption flexible electronics.

EP04.03.02
Highly Conducting MXene Composite Fibers with Conductive Polymer Binder for Fiber-Shaped Supercapacitors

Jizhen Zhang, Shayan Seyedin, Zhiyu Wang, Si (Alex) Qin and Joselito M. Razal, Deakin University, Geelong, Victoria, Australia.

Fiber-shaped organic-inorganic hybrid dielectric (FSC) electrodes are beneficial for wearable architecture because of their lightweight, flexibility and low cost. Unlike the higher k values with higher Al concentrations, the electrical breakdown field (Ebreak) decreased linearly from 6 to 3 MV/cm, and the gate leakage current (J) at 2 MV/cm increased exponentially from 1.0 × 107 to 3.0 × 109 A/cm2. The electrical results revealed that there was a trade-off between performance and power consumption. The electrical energy bandgap (Eg) was extracted from the electron energy loss spectroscopy (EELS) with low loss spectra resulting in a wide Eg of 7.0 - 7.5 eV. Based on these preliminary experiments, the hybrid dielectric with an Al concentration of around 18% exhibited a decent k value of 6 and J value of lower than 107 A/cm2 at 2 MV/cm. The MIM device with the hybrid dielectric exhibited negligible J changes of up to 2.6 % applied strain, where the soft polymer matrix effectively released the applied strain. Finally, the iCVD hybrid dielectrics were applied to the bottom-gated OTFTs with p-type pentacene and n-type N,N′-ditridecylperylene-3,4,9,10-tetracarboxylic diimide (PTCDI-C13). Two typical linear and saturation operating regions emerged, revealing well-behaved transistor characteristics. The mechanical flexibility of the –p-type pentacene OTFTs with the hybrid dielectric was investigated at different bending strains. The transfer characteristics of the OTFTs were found as a function of mechanical bending strain, showing negligible changes while maintaining a low gate leakage current. The results suggest that the hybrid dielectric synthesized via the iCVD process is a promising candidate for high-performance low-power consumption flexible electronics.

EP04.03.03
Wearable Organic Memory Fiber for Low Voltage Operation and Conformable Data Storage

Wearable electronics have attracted attention as an emerging technology to realize practical e-textile and smart garments. For future wearable automatic systems, robust data storage media are required and process the electrical signals generated under various unpredictable strain conditions. Here, we report an organic field-effect transistor (OFET)-type memory integrated on a thin and flexible metal wire. A new fiber coating technique by using a capillary tube and controlling the solution viscosity allows the
formation of a thin and uniform organic ferroelectric film on the wire. The uniform morphology imparts excellent switching stability, long-term retention time and low-voltage operation to the flexible fiber organic memory devices. The fiber-shaped memory achieves reliable data storage even under tough environments when sewn in a stretchable textile fabric, providing the possibility of the practical, wearable fiber memory for recording electronic signals in smart textile applications.

Stretchable Location Sensor Based on Transparent AgNWs Electrodes
Hang Guo, Liming Miao, Haobing Wang, Ji Wan, Xiaoliang Cheng and Haixia Zhang; Institute of Microelectronics, Peking University, Beijing, China.

In the recent years, the smart electronic skin (E-skin) has attracted extensive attention due to the human skin provides remarkable sensor networks such as touch, temperature, vibration and pressure sensors, etc. There are many wearable electronic devices integrated with glasses and watches in the consumer electronics with the rapid development. However, all of these devices face an important issue about the stretchability which could sustain complex deformation and conformal contact with irregular surfaces. The stretchable materials are mainly required as a substrate such as organic polymer in order to make the devices stretchable. Apart from these, nanomaterials, such as carbon nanotubes, graphene and metal nanowires have been utilized to realize stretchable electronics. And the special structure designs have also played a very important role in improving stretchability. Wave, island-bridge structure, porous structure and grid structure are widely applied in these novel designs.

Herein, we developed a transparent conductive membrane which is uniform and stable even under elongation through spin-coating AgNWs solution on the stretchable substrate. The motion detection and location is indispensable for human-machine interfaces. However, as most devices work in digital method, there has been limited progress in the resolution enhancement that may lead to an increase in the number of electrodes. Therefore, the stretchable analog devices play an essential role in wearable devices, which owns higher resolution with a few electrodes. We demonstrate these new properties by using PDMS/AgNWs thin film.

A novel stretchable, transparent location sensor has been demonstrated in this work. Through the spin-coating process, the AgNWs are deposited on the surface of the PDMS substrate, which enhances the transparency and stretchability of the device. It can be attached to the human skin with conformal coverage and keep the function under the elongation of 60%. When the sensor is pressed, the position of the contact point can be acquired by the relative resistances in the analog method, which can enhance the resolution without increasing in the number of electrodes. All of the excellent properties makes the sensor have much potentials in the wearable devices and smart robots.

Soft Electronic and Optoelectronic Devices with Dynamic 3D Architectures Controlled by Heat-Responsive Polymers
Cheng Zhang and Jian Lin; The University of Missouri, Columbia, Missouri, United States.

Three-dimensional (3D) architectures qualitatively extend the functionalities of electronic and optoelectronic devices. Complex functional 3D structures have been fabricated by 3D printing, stress-controlled folding, and mechanically-guided assembly. However, the potential of 3D functional architectures built by previous methods is restrained by their static or human-intervention required dynamic structures. Herein, we demonstrate a soft 3D scaffold integrated with electronic and optoelectronic devices which can be dynamically tuned by responsive polymer substrates. The 2D films are selectively bonded onto the responsive substrates which can respond to heat simulation and actuate the assembly of the 2D films to 3D architectures. The assembled structures are dynamically controlled by the heat. The dynamic assembly is highly controllable by both experimental study and numerical simulation. Soft electronic and optoelectronic devices, i.e., a strain sensor array and a photodetector array, are integrated to the 2D films and also assembled to 3D structures. The strain sensors monitor the motion of the assembly. The photodetectors can measure both intensity and direction of incident light attributing to its 3D architecture. Moreover, the photodetector array has the capability of tracking lights incoming from all directions because its spatial configuration can be dynamically tuned by heat.

EP04.03.07

A MXene-Based Wearable Biosensor System for High-Performance In Vitro Perspiration Analysis
Yongjiu Lei; King Abdullah University of Science and Technology, Jeddah, Saudi Arabia.

Wearable electrochemical biosensors for sweat analysis (e.g., glucose, lactate) present a promising means for noninvasive biomarker monitoring. However, the sweat-based measurement of the developed devices still poses many challenges: easy degradation of enzymes and biomaterials upon regular testing; the corresponding poor shelf life of the all-in-one working electrodes patterned by traditional techniques (e.g., electrodeposition, screen printing); limited detection range and sensitivity of the enzyme-based biosensors caused from oxygen deficiency in sweat. Herein, we develop a wearable multifunctional biosensor incorporating MXene/Prussian blue (Ti₃C₂Tₓ/PB) composite for durable and sensitive detection of glucose and lactate in sweat. Due to the metallic conductivity and hydrophilic nature of the MXene, greatly improved electrochemical activity was observed on the Ti₃C₂Tₓ/PB composite in comparison to previously reported Graphene/PB and CNTs/PB composites. During in-vitro perspiration monitoring, the physiochemistry signals (glucose and lactate level) could be measured simultaneously, showing high sensitivity and acceptable repeatability. A unique modular architecture design enabled a simple exchange of the specific sensing electrode to tailor to the desired analytes. Furthermore, an implemented solid-liquid-air three-phase interface design led to superior sensor performance and stability, with typical electrochemical sensitivities of 35.3 μA mM⁻¹ cm² for glucose and 11.4 μA mM⁻¹ cm² for lactate using artificial sweat. Hence, this approach represents an essential step towards the realization of ultra-sensitive enzymatic wearable biosensors for early disease identification and personalized medical applications.

EP04.03.08

Electrochemically Stable and Adherent PEDOT Coatings for High Quality EMG Recording
Niccolò Rossetti, Ada Lee, Prabhjot Kaur Luthra, Côme Bodart and Fabio Cicoira; École Polytechnique de Montréal, Montréal, Quebec, Canada.

Conductive polymers coatings on metal electrodes are an efficient solution to improve neural signal recording and stimulation due to their mixed electronic-ionic conduction and biocompatibility [1]. However, only a few studies have been reported on conductive polymers coatings on metallic wire electrodes for muscle signal recording [2]. In this work, we developed mechanically and electrochemically stable invasive electrodes for muscle signal recording in small animals based on stainless steel multi-stranded wires coated with the conductive polymer PEDOT. PEDOT doped with LiClO₄ was galvanostatically electropolymerized on stainless steel wires using three different solvents: propylene carbonate (organic), acetonitrile (organic) and water (inorganic). The coatings adhesion to the metallic substrate was tested through ultrasonication and the electrochemical stability was evaluated through phosphate buffer solution soaking test and autoclave sterilization. The solvent played a key role on the adhesion of the PEDOT coating, with organic solvents giving the best mechanical stability. Electrodes prepared with these solvents possessed excellent electrochemical stability and survived sterilization and prolonged soaking without major changes in electrochemical properties. A solution for high quality invasive muscle signal recording in small animals based on conductive polymers has been demonstrated.

EP04.03.09

3D-Printed Hydrogel with Superior Stability for Energy Harvesting and Physiological Monitoring
Min Wu, Shengjie Gao, Yixiu Wang, Ruoxing Wang and Wenzhuo Wu; Purdue University, West Lafayette, Indiana, United States.

Hydrogels have attracted much attention recently as a promising class of biomaterials. Traditional hydrogel bioelectronics are limited in several aspects, including the poor ability of the hydrogel to retain water under cold or hot environment, complicated device fabrication procedure, and complex external power requirement to drive the device. Here we propose an approach to directly fabricate hydrogel by 3D printing method, and further prepare wearable devices for self-powered sensing applications. With the addition of glycerol, the hydrogel would be able to resist a water loss and can tolerate a temperature with a wide range from -20 °C to 60 °C. The 3D printed hydrogel is able to deliver a stable triboelectric output, which can be explored as self-powered sensors for physiological monitoring. The facile 3D printing method, coupled with the water loss prevention properties
Compared to other liquids (e.g. water, ionic liquids, organic liquids), liquid metals have outstanding thermal and electrical conductivity, as well as distinct optical properties (i.e. reflectivity). As a result, they are excellent components for stretchable and soft metallic components such as antennas, electrodes, and interconnects. Thus, there is great interest in facile methods to create and pattern these liquids into useful components. The large tension and low viscosity of liquid metals presents a challenge: the metal tends to adopt a spherical shape as it exits a nozzle. There are a number of strategies to address this challenge that require the metal to directly contact other solid or visco-elastic surfaces. Here we report a way to create wires by directly extruding the metal from a nozzle. To control the shape of the liquid metal, we used electrochemical control of surface oxidation because the formation of the surface oxide significantly lowers the interfacial tension and allows the metal to adopt shapes that overcome Rayleigh-Plateau instabilities (i.e. it does not bead up). To create these wires, we pump liquid metal into electrolyte (1M NaOH). As it emerges from the nozzle, the liquid metal forms large spherical drops to minimize the surface area. However, the droplet size diminishes with an increase of potential, which indicates a decrease in interfacial tension. At a critical potential, the interfacial tension drops significantly, and the liquid metal forms wires. At larger values of electric potential (>0.8V), the oxide layer gets thicker, causing the wire to deform and turn into unusual shapes. We successfully analyze each regime of EGA as a function of flow rate and electric potential to identify conditions that form wires. The ability to deposit or remove the oxide electrochemically enables unprecedented control over interfacial activity (well beyond what is possible using electrocapillarity), which provides a means to reconfigure and manipulate the shape and position of liquid metal. This method requires minimal energy and provides reversible control of interfacial tension over an enormous range compared to conventional molecular surfactants. By adjusting the electrical potential and flow rate, the configuration of liquid metal can be manipulated on demand, which offers the possibility to create actuators or soft and stretchable analogues of rigid conductors.

Extruded Liquid Metal Wires at Room Temperature via Electrochemical Oxidation

Mingyong Song and Michael Dickey; North Carolina State University, Raleigh, North Carolina, United States.

Electronic skin devices capable of monitoring physiological signals and displaying feedback information through closed-loop communication between the user and electronics are being considered for next-generation wearables and the ‘Internet of Things’. Such devices need to be ultra-thin to achieve seamless and conformal contact with the human body, to accommodate strains from repeated movement and to be comfortable to wear. Recently, self-healing chemistry has driven important advances in deformable and reconfigurable electronics, particularly with self-healable electrodes as the key enablers. Unlike polymer substrates with self-healable dynamic nature, the disrupted conducting network is unable to recover its stretchability after damage. Here, we report the observation of self-reconstruction of conducting nanostructures when in contact with a dynamically crosslinked polymer network. This, combined with the self-bonding property of self-healing polymer, allowed subsequent heterogeneous multi-component device integration of interconnects, sensors and light-emitting devices into a single multi-functional system. This first autonomous self-healable and stretchable multi-component electronic skin paves the way for future robust electronics.

Fast Self-Healing and Conductive Hydrogels as Soft Strain Sensor

Yujiie Chen, Hua Li and Hezhu Liu; Shanghai Jiao Tong University, Shanghai, China.

Remarkable process achieved for conductive hydrogels has been witnessed in recent years. However, hydrogels easily damaged during the course of use, which limits their applications as soft conductors. Here, two different methods are presented to obtain multi-functional hydrogels which have fast self-healing property, conductive capability and stain-sensitive performance. In the first method, the nanocomposite hydrogel (PVA-PDA-pRGo) is designed and synthesized from polyvinyl alcohol (PVA), polydopamine (PDA) and graphene oxide (GO). Dynamic diol-borate ester bonds built from polyvinyl alcohol (PVA) and borax mainly allow nanocomposite hydrogels to display decent self-healing behaviors in mechanical (restore 92.89% of original tensile strength within 60s), electrical (restore 96.7 ± 2% of original resistance within 4.2s) and rheological recovery experiments without any external stimuli. Graphene oxide (GO) is partially reduced under the oxidative self-polymerization of dopamine (DA), providing conductivity for nanocomposite hydrogels (2.7 mS cm⁻¹). In the second method, physically crosslinked oxidized sodium alginate (OSA)/poly(acrylic acid) hydrogel (OSA/PAA-Fe3+) are synthesized by one-pot free radical polymerization. Both hydroxyl and carboxyl groups on oxidized sodium alginate chains were involved in coordination with Fe3+, which endowed the hydrogel with double network structure. OSA/PAA-Fe3+ hydrogels have excellent mechanical properties, like tensile strength up to 0.1MPa and elongation up to 1500%. The self-healing experiment showed that the self-healing efficiency of OSA/PAA-Fe3+ hydrogels can reach about 90% within 4 hours at room temperature. Furthermore, all of the hydrogels prepared by these two ways demonstrate strain sensitivity in the designed LED bulb circuit. In view of no apparent anaphylaxis of nanocomposite hydrogels in human skins, the soft stain sensor prepared by designed hydrogel can be fabricated to detect human activities, such as bending and sitting. Our work offers an effective approach to synthesize a fast self-healing, conductive and strain-sensitive hydrogel applied as soft strain sensor for human movement monitoring.

Planting Carbon Nanotubes onto Supramolecular Polymer Matrixes for Waterproof Non-Contact Self-Healing

Bo Li and Ning Ma; College of Material Science and Chemical Engineering, Harbin Engineering University, Harbin, China.

Supramolecular polymers show unique and excellent properties due to the reversible and designable nature of the non-covalent interactions. Herein, ureido-pyrimidionone (UPy)-based supramolecular polymers were employed to fabricate the thermo-responsive composite materials with multi-walled carbon nanotubes (MWCNTs) by planting the MWCNTs onto the supramolecular polymer matrix via a simple surface spraying procedure. The MWCNTs coating on the surface of the supramolecular polymer matrix gave the composite film superhydrophobic and conductive properties, and it had a non-contact healable ability under water 808 nm near-infrared light (NIR) irradiation. Moreover, the UPy-based supramolecular polymer acted as thermo-responsive matrices to guarantee the self-healing properties at a relatively low temperature, such as body temperature (33 °C–34 °C). The supramolecular polymer/ MWCNTs composite materials exhibited excellent strain sensitivities and could be used to prepare human motion-monitoring devices. Meanwhile, non-contact IR or body temperature self-healing property will greatly extend the life of the device. It provides a promising possibility for the development of the next generation of health monitoring system applied in underwater environments. This line of research may find a promising practical application in healable wearable devices used in particular conditions. And we hope this scheme can provide a new avenue for the design and preparation of functional devices with supramolecular polymeric materials. Pressure-Sensitive Rectifier Array for High Resolution E-Skin Tactile Sensor

Insang You, Minsik Kong and Unyong Jeong; Pohang University of Science and Technology, Pohang, Korea (the Republic of).

E-skin tactile sensors mimicking human mechanoreceptors have been studied intensively and expected to be applied to various future electronics such as haptic device, robot tactile sensor, human-machine interface, prosthetic appliances and implantable electronic devices. To imitate the human cutaneous tactile sensors, E-skin is characterized by extreme mechanical flexibility or deformability and excellent recognition of force distribution. The mechanical flexibility of the E-skin has been successfully achieved using ultrathin substrates or stretchable interconnection between the rigid sensor units. Those device structures minimize the stress accumulated on the device units so that E-skin can operate under repeated stretches. The breakthroughs open the possibility of fabricating printed active matrix tactile sensors. In order for E-skin to sense the spatial distribution of mechanical stimulation, a large number of sensors must be integrated to provide enough spatial resolution. For this purpose, some advances have been made in the fabrications of transistor-operated tactile sensor arrays. Although the transistors could prevent electrical crosstalks between the pixels and greatly reduce the complexity of the transistor-based device is high. Active matrix structure is advantageous for individual pixel operation especially for highly integrated devices such as display or memory. However, in terms of E-skin tactile sensors, a passive device with a simple two-terminal structure would be more desirable to achieve high flexibility or deformability simultaneously with enough spatial resolution. Using a rectifying diode can be another approach to remove the electrical crosstalks. Someya and coworkers fabricated a pressure sensor matrix in which each cell was composed of a resistor-selector combination. They developed a mechanically robust organic diode and integrated a pressure sensitive elastomer resistor on top of the diode layer, which was the first demonstration using the rectifying diode for a flexible tactile sensor. This type of
In neuroscience, weakly electric fish are used to study how motor signals influence sensory processing [1-3]. Specifically, understanding how information is encoded in the precise timing of electrotactile spikes relative to sensory inputs will significantly contribute to behavioral studies. Previously, stimulating the electrotactile receptors of weakly electric mormyrid fish has been restricted to dipole current sources [4]. In this work, we present a dense flexible electrode array that conforms to the fish’s skin and is seamlessly integrated with a robust user interface. The electrode array consists of 96 square electrodes with a side length of 250 μm and diagonal spacing of 1 mm. The pattern was chosen to match the hexagonal pattern of the fish’s electrosensors. Gold electrodes were photolithographically patterned on parylene-covered spin-coated PDMS, as shown in multiple previous studies [5,6]. A second parylene layer was deposited and patterned to encapsulate the electrode traces and avoid crosstalk between electrodes. Chemical surface modification was completed to match the surface energy of the fish’s skin for several days. A multiplexer based circuit was used to individually select electrodes. A LabVIEW program allows a user to choose an electrode and synchronize the electrode’s information with neurophysiological data acquisition software. Local field potential was measured in the electrosensory lobe of the hindbrain while individually driving electrodes. Results demonstrate that this system is satisfactory for more complex neuroscience experiments.

Neuromorphic electronics is promising to process complex real-world problems such as visual information, speech recognition, and body movement control based on their compactness, fault tolerance, and high-energy efficiency. Artificial synapses are rapidly emerging for neuromorphic electronic devices that emulate biological nervous systems. Emulating learning and memory functions of the brain is the main focus in neuromorphic electronics, but mimicking the complicated biological sensory and motor nervous systems that operate sequential functions related to proprioception, signal processing, and a motor response is also a challenging issue especially to realize bio-inspired soft robotics and electronics. Herein, we demonstrate flexible and stretchable organic artificial synapses for sensory and motor nervous systems of bio-inspired electronics. Sensory and motor electronic nerves are demonstrated by integrating organic synapses with sensory and motor organs. The sensory organs detect stimuli and fire artificial neural signals which will be transmitted to organic synapses as presynaptic action potentials. The flexible and stretchable organic synapses which are favorable for soft robots generate a post-synaptic response which will stimulate motor neurons and muscles. Thus, we realize i) a hybrid reflex arc system composed of artificial pressure-sensory nerves and biological motor nerves in a detached insect leg, and ii) artificial sensorimotor nervous system composed of an artificial light-sensory receptor and electronic neuromuscular system with an artificial muscle fiber. In addition, we demonstrate that these neuromorphic systems are promising to develop human/machine interface by distinguishing braille characters and conducting wireless optical communication. We can reasonably derive that this system is satisfactory for more complex neuroscience experiments.
The adoption of a thin-film substrate is a key aspect for the development of skin-contact imperceptible devices, in the so-called cutaneous or epidermal electronics. Together with reducing the thickness, lowering the mismatch in the mechanical properties of the device, with respect to the skin’s own, plays a major role. These properties reflect in devices inherent bending stiffness, determining their ability to flex to small curvature radius, following the skin relief profile in conformal adhesion. Temporary Tattoo Electrodes (TTEs) were developed to meet these requirements. TTEs are all made by polymers and their overall thickness is < 1-2 μm. They are fabricated by inkjet printing of the conductive polymer PEDOT:PSS on top of commercially available temporary tattoo paper. Recently, ultraconformable TTEs have been adopted in the recording of many electrophysiological signals and compared with standard Ag/AgCl electrodes. Wet Ag/AgCl electrodes are routinely used in electrophysiology (EP) thanks to their high signal quality. On the other hand, these electrodes exhibited many disadvantages which impose severe restrictions in all EP applications. The major issues are related to their limited time stability, due to gel drying, and to their cumbersome nature. With TTEs we showed the recording of electrocardiography (ECG) and electromyography (EMG) demonstrating their outstanding capabilities in interfacing with human body (1,2).

Now, we investigated the recording of electroencephalography (EEG) signals, the most challenging scenario due to the weakest signal and the lowest frequency range in EP (typical 10 - 100μV signal amplitude, frequency components 0.5Hz - 100Hz), EEG monitoring was performed in a clinical environment with the aim to open for new perspectives in EEG. TTEs have been thus tested in different clinical conditions, to cover the most of EEG diagnostics. We firstly validated TTE with the recording of alpha waves, the most known and studied brain rhythm. TTEs were also compared with Ag/AgCl electrodes, through Power Spectral Density (PSD) assessment, showing a good match over the whole signal spectrum. TTEs were further evaluated in auditory evoked potentials (AEP) measurements, in comparison with the standard Ag/AgCl electrodes, exhibiting comparable at all results. Furthermore TTEs’ compatibility with magnetoencephalography (MEG) equipment have been performed. EEG/MEG are frequently used in combination and at the best of our knowledge this is the first time that a dry electrode exhibits complete compatibility with MEG. The successful evaluations of TTEs in the EEG field paves the way for future development of imperceptible alternatives to standard electrodes in clinical practice.

SESSION EP04.05.01

Hydrogels Sense and Heal Better with MXene Yizhou Zhang, Kanghyuck Lee and Husam N. Alsharief; King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

Conductive hydrogel-based strain sensors hold great promise for wearable electronics, point-of-use medical sensors, and soft robotics. However, their sensitivities are generally low and they suffer from signal hysteresis and fluctuation due to the viscoelastic property, which can compromise their sensing performance. In our recent work, we prepared MXene (Ti3C2Tx-based Poly (vinyl alcohol) (PVA) hydrogel (M-hydrogel) via a simple method [1]. The obtained M-hydrogel sensor exhibits high strain sensitivity with remarkable stretchability, instantaneous self-healing ability, excellent conformability, and adhesive prowess to various surfaces including the human skin.

More importantly, the M-hydrogel shows much higher sensitivity under compressive strains than tensile strains. This asymmetrical strain sensitivity coupled with viscous deformation (self-recoverable residual deformation) is for the first time proposed to add new dimensions to the sensing capability of hydrogels: both direction and speed of motions on the hydrogel surface can be detected conveniently. Based on this effect, the M-hydrogel shows superior sensing performance in advanced sensing applications such as recognition of signature and vocal signals. Thus the traditionally disadvantageous viscoelastic property of hydrogels is turned into an advantage for sensing, which reveals new prospects for hydrogel sensors.

Bioimpedance Spectroscopy with Conformal Polymer Electrodes and Its Application in Long-Term Health Monitoring Jae Joon Kim, Linden Allison and Trisha L. Andrew; Chemistry, University of Massachusetts Amherst, Amherst, Massachusetts, United States.

Conformal polymer electrodes can be vapor printed directly onto the surfaces of living organisms without damaging their health and self-sustenance. These polymer electrodes can then be used as contact pads for bioimpedance spectroscopy, which reveals detailed information about the health of the organism. Notably, polymer electrodes can be created directly on living plants, meaning that bioimpedance measurements can be performed on-demand, throughout the growth cycle of a plant. Vapor-printed polymer electrodes, unlike their adhesive thin-film counterparts, do not delaminate from microtextured living surfaces as the organism matures and do not observably attenuate the natural growth pattern and self-sustenance of the plants investigated herein. Deep tissue damage caused by dehydration and UVA exposure can be reliably detected throughout the life cycle of a plant. Long-term plant health monitoring will find strategic use in food farming, crop management, and biohazard signaling.

3D Designed Ion Selective Sensors Chao Bao and Woo Soo Kim; School of Mechatronic Systems Engineering, Simon Fraser University, Surrey, British Columbia, Canada.

Requirement of real-time health monitoring boosts the development of wearable electronics. Especially cutting-edge technologies of integrated circuit board have been successfully utilized to obtain flexible devices. Here we report development of 3D ion selective field sensors integrated by 3D printing as ion selective field effect transistors (ISFETs). Separately fabricated FETs and ion selective membranes are both verified before hybridization. Then, the combined ISFETs show high sensitivity to ammonium (NH4+), potassium (K+), and calcium (Ca2+) ions with linear responses depending on ion concentrations. Moreover, high selectivity of these ISFETs has also been proved during the interference tests, not only by the separate interference ions testing, but also by artificial saliva with multiple interference ion concentrations. Additionally, unique wireless protocols for the 3D printed ISFET has also been implemented. The AC output signal converted from DC input during this signal transmission process is identified as the ion concentration. This new wireless sensing protocols open the potential of the 3D printed ISFETs in the field of wireless health monitoring sensors.

Stretchable Conductive Nanocomposite for Implantable and Wearable Bioelectronics Dae-Hyeong Kim1, 2; 1Seoul National University, Seoul, Korea (the Republic of); 2Institute for Basic Science, Seoul, Korea (the Republic of).

Intrinsically stretchable conductors form a vital component of advanced soft bioelectronics. And novel nanocomposites based on conductive nanomaterials have been used in diverse applications of implantable and wearable bioelectronics. Among many nanomaterials for the composites, silver nanowires (Ag NWs) have been popular. However, achieving highly conductive and soft composite simultaneously is challenging. Furthermore, because bioelectronics is necessarily exposed to biofluids, preventing Ag NW oxidation and Ag ion leaching is a significant challenge. Here we have achieved a highly conductive, biocompatible, and soft nanocomposite by using silver chloride (Ag-Au) core-sheath NWs and polystyrene-butadiene-styrene (SBS) elastomer. We synthesized ultralong Ag NWs encapsulated with a smooth and uniform Au sheath and then mixed them with the polymer. Phase separation of Ag-Au NWs and SBS occurs, which forms microstructures in the composite, reduces Young’s modulus, and increase softness and conductivity of the composite. We used the nanocomposite to fabricate a customized multi-channel soft cardiac mesh for the diseased swine heart. The mesh could be also fabricated as a wearable device which monitored electrophysiological signals and applied electrical and thermal stimulations on the human skin.

Ionic Liquid Doping Enables High Transconductance and High Ion Sensitivity in Flexible, Stretchable Organic Electrochemical Transistors Xihu Wu, Abhijith Surendran, Jieun Ko and Wet Lin Leong; Nanyang Technological University, Singapore, Singapore.

Organic electrochemical transistors (OECTs) are highly attractive for applications ranging from circuit elements, neuromorphic devices to transducers for biological sensing and the archetypal channel material is poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate), PEDOT:PSS. The operation of OECTs involves the doping and de-doping of a conjugated polymer due to ion intercalation under the application of a gate voltage. However, the challenge is the trade-off in morphology for mixed conduction since good electronic charge transport requires a high degree of ordering among PEDOT chains, while efficient ion uptake and volumetric doping necessitates open and loose packing of the polymer chains. Here we demonstrate ionic liquid doped PEDOT:PSS that overcomes this limitation. Ionic liquid doped OECTs show high transconductance, fast transient response and high device stability over 3600 switching cycles.[1] The OECTs are further capable of having good ion-sensitivity and robust towards physical deformation. These findings pave the way for higher performance bioelectronics and flexible/wearable electronics.

SESSION EP04.06: Liquid-Material Embedded Soft Structures II

From Particles to Parts—Multi-Phase Metallic Particle Additives for Sensing and Tunable Materials Rebecca Kramer-Bottiglio; Yale University, New Haven, Connecticut, United States.

Particles made from liquid or low-melting-point alloys can be leveraged to create a new class of functional responsive composite materials. In this talk, I will present two types of metallic particles: eutectic gallium-indium particles and Field’s metal particles. Eutectic gallium-indium particles have been used to achieve printable, soft, and stretchable electronics. More recently, we have demonstrated the role of Field’s metal particles in enhancing the range of stiffness properties in a thermally responsive epoxy, and in creating variable elasticity and switchable anisotropy when embedded in silicone elastomer. These responsive material properties derived from metallic particle additives enable new capabilities for wearables, soft electronics, and soft robotics.

2:00 PM EP04.06.02
Electrical Control of Shape in Liquid Crystalline Elastomer Nanocomposites Tyler Guin1,2, Timothy White1 and Amit Naskar2; 1Air Force Research Laboratory, Wright Patterson AFB, Ohio, United States; 2Physical Sciences Directorate, Oak Ridge National Lab, Oak Ridge, Tennessee, United States; 3University of Colorado Boulder, Boulder, Colorado, United States.

Liquid crystal elastomers (LCEs) are soft, anisotropic materials that exhibit large, reversible shape changes in response to external stimuli. The director (average alignment) of an LCE can be localized into pixels via photoalignment. By rationally designing the director profile, out-of-plane shape transformations are possible when the material is activated. In this talk, single-wall carbon nanotube – LCE nanocomposites are presented, and their distinctive electromechanical actuation explored. When a DC electric field is applied through the material thickness, the composite waxes and wanes along the alignment direction. By localizing the orientation of the LCE and SWNT via photoalignment, complex 3-D shapes can be electrically triggered. Additionally, a brief explanation of the novel electrostrictive mechanism will be presented.

Mechanical Tunability of Core-Shell Liquid Metal Nanoparticles for Self-Healing Electronics Nicholas J. Morris1,2, Zachary J. Farrell1,2, Carl Thrasher1 and Christopher Tabor1; 1RXAS, Air Force Research Laboratory, Wright-Patterson AFB, Ohio, United States; 2URE, Inc., Dayton, Ohio, United States.

A vision for many potential applications of flexible and stretchable electronics has led to new and diverse research approaches in the previous decade, such as intrinsically stretchable organic electronics and strain relief geometries in otherwise non-compliant traditional materials. A third approach is to engineer materials to respond and adapt to strain by repairing themselves through self-healing mechanisms. In this work, we utilize the stimulus-responsive characteristics of a colloidal room temperature eutectic gallium-indium alloy (EGaIn) to achieve electronic self-healing triggered by strain and mechanical damage. Unlike organic conjugated systems, EGaIn possesses the high conductivity of a metal and while its fluidic properties allow it to flow and adapt to induced strain. We utilize EGaIn’s intrinsic ability to grow a native passivating viscoelastic oxide skin to produce liquid metal core-shell nanoparticles, serving as small reservoirs of the fluidic metal core, which upon rupture provide the potential to reconnect damaged electronic components and restore electrical connectivity. We report on our ability to modify the mechanical properties of the core-shell nanoparticles by correlating changes in stiffness, shell modulus, and ultimately the rupture force required to induce healing with various chemical treatments of the oxide shell (Farrell et al., Langmuir 2018). Flat-punch nanoindentation techniques with in situ electrical characterization were developed to experimentally characterize single particle stiffnesses and the critical buckling loads associated with particle rupture which would lead to electrical restoration. The modulus of the oxide shell was estimated using Reissner’s elastic thin plate theory, with estimated moduli between 0.37-1.38 GPa depending on functionalization. A fifty-fold increase in critical buckling load was measured across the various particle systems, providing a large range of engineering control and allowing application specific mechanical properties for implementation in self-healing coatings, stretchable conductors, and push-to-connect low temperature solders. In light of the standalone nature of the particle system, we anticipate their addition to existing electronics in a variety of ways, such as chemical binding through ligand anchoring, spray coating, or drop casting; imparting healing functionality and mechanical robustness to traditional electronic materials.

Emerging Self-Healing Material and System Platforms for Electronic Skins in Wearables and Robotics Benjamin C. Teso1,2,3; 1Materials Science and Engineering, National University of Singapore, Singapore, Singapore; 2Institute of Materials Research and Engineering, Singapore, Singapore; 3Biomedical Institute for Global Health Research and Technology, Singapore, Singapore.

The multi-disciplinary efforts in the last few decades have enabled mechanically softer and skin-like electronic devices1–5. These exciting progress opens multiple doors of opportunity to utilize innovative materials and devices intimately with epidermal surfaces, wearable technologies and robotics. In this talk, I will discuss some of the new material platforms we are developing for more robust human-machine interactions, such as self-healing stretchable optoelectronics devices. At the same time, I will also present our efforts
in developing new system architectures to scale the density and number of such devices for rapid environment perception. Such system architectures can be broadly applied in electronic skins, and has broad potential for continued applications in wearables, brain-machine interfaces, prosthetics and robotics.

4:00 PM EP04.07.02 Stretchable, Transparent and Breathable Epidermal Electrode for Health-Related Applications You Jun Fan, Lu Liu, Xin Li and Guang Zhu; Beijing Institute of Nanoenergy and Nanosystems, CAS, Beijing, China.

Recently emerged electronic skins with applications in on-body sensing and human–machine interfaces call for the development of high-performance skin-like electrodes. In this presentation, a family of recently developed stretchable, transparent, and breathable epidermal electrode will be introduced, which is composed of a nanofoils scaffold and a silver nanowires network.

Through techniques such as vacuum filtration or electro-spinning/electro-spraying, the silver nanowires are embedded into a scaffold made of polymer nanofibers. Optical transmittance of 84.9% at 550 nm wavelength is achieved at a significantly low sheet resistance of 8.2 Ωsq⁻¹. The resistance of the epidermal electrode only slightly increases by less than 0.1% after being bent for 3000 cycles at the maximum curvature of 300 m⁻¹ and by less than 1.5% after being dipped in saline solution for 2500 cycles. Attributed to silver nanowires with hierarchical dimensions, great robustness against tensile strain is achieved. The reinforcement from the nanofoil-based scaffold as a backbone maintains the connections among the Ag nanowires by undertaking most of the loaded stress. The epidermal can still maintain its conductivity when experience a strain of over 300%.

The epidermal electrode can form tight and conformal bonding skin through Van Dal Walls force. Because of the conformal contact as well as the high conductivity, the epidermal electrode shows a contact impedance 50% lower than commercial gel-based electrode. As a result, the epidermal electrode exhibits apparently higher noise resistance again body motions when measuring physiological signals such as ECG, making it promising to be used in ambulatory on-body monitoring for healthcare applications. Besides, the epidermal electrode allows the evaporation of perspiration, making it suitable for long-time use.

4:15 PM EP04.07.03 Fully Wirelessly-Operated Soft Actuators with Environmental-Sensing Capability Byungkook Oh, Young-Geun Park, Sangyoon Ji, Woon Hyung Cheong and Jing-Ling Park; Materials Science and Engineering, Yonsei University, Seoul, Korea (the Republic of). The most important function in soft robotics is to travel through harsh spaces and receive the real-time sensing signals wirelessly based on today’s smart technologies. However, to date, the reported soft robotics has the limitation of low degrees of freedom of movement because tethered systems should be connected to soft actuators to initiate the actuation. Although few research groups have demonstrated an untethered soft actuator, the reported untethered soft actuators only mimicked the movement of people or animals without any environmental-sensing capability. The key requirements for designing human-like soft robots with somatosensory systems are to operate the soft actuators without supporting equipment and to have wireless environmental-sensing capability. Fabricating fully wirelessly-operated soft actuators with environmental-sensing capability has advantages of improving degrees of freedom of movement and adapting them to various applications like biomedical fields. For the Internet of Things (IoT)-based smart wireless environment, providing wireless environmental-sensing systems has highlighted the need for using the electronic sensors and integrating them to a soft actuator body. However, the conventional electronic sensors are rigid, the integration of the electronic sensors to the soft actuator body has challenges for poor adhesion between electronic circuits and the soft actuator body and low reliability and stability of electronic sensors due to their rigid properties. Thus, improving the reliability of electronic sensors is essential for the advances in soft robotic fields. Herein, we report an unconventional approach for demonstrating fully wireless soft robotics with wireless tactile-sensing systems. The electrothermally-activated phase transition soft actuator is composed of the entirely soft and flexible body matrix so that the rate of initiating the actuation of the soft actuators increases. Soft actuators we designed are integrated to a pressure sensor and temperature sensor with improved stability and reliability due to conformal actuating properties, causing the actuation strain to distribute throughout the entire soft body actuated. However, it still has a problem of generating of electron-hole pairs (EHPs) in pressure sensors as the temperature of flexible heaters increases. The generation of EHPs results in the increase in the output current. Thermally excited charge carriers can affect the sensing signals of pressure sensors. Evading the generation of EHPs is an important feature for the sensory system to receive pressure sensing information exclusively. To that end, we designed the configuration of pressure sensor and temperature sensor above the heater film. By integrating them in parallel above the soft body frame, only tactile sensing signals can be received with calibration steps using sensing signals of the temperature sensor. It provides the pressure sensors are independent of the increasing temperature of heaters. Our soft actuators can be actuated wirelessly with remote temperature control systems interconnected to heaters. And, they can also receive real-time sensing feedback wirelessly by connecting the wireless pressure sensory module to electronic sensors. Our demonstration of wireless actuation of soft actuators with wireless environmental-sensing capability suggested that the soft actuator has an important feature for providing the capability of the use in the harsh spaces.

4:30 PM EP04.07.04 Liquid Crystal Elastomers for Soft and Stretchable Bioelectronics Jinn Maeng, Hyun Kim, Mahajbeen Javed and Taylor Ware; Bioengineering, The University of Texas at Dallas, Richardson, Texas, United States.

Achieving implantable devices that reside in human body with chronic stability has long been a goal of the bioelectronics community. A major challenge in achieving long-term stability lies in the difficulty in establishing reliable interconnection of the implantable devices to the outside world. For example, implantable neural devices in the periphery undergo significant strain due to repeated muscle flexion and extension. Furthermore, device encapsulation can be significantly weakened under such strain, causing infiltration of physiological fluids into devices that leads to chronic failure. Therefore, efforts toward developing implantable electronics based on high barrier and strain tolerant materials are needed.

Here, we present a liquid crystal elastomer (LCE)-based, soft, and stretchable electronics architecture for their potential as a platform for chronic implantable bioelectronics. The unique shape-morphing capability of LCE is leveraged to fabricate electronic devices in strain tolerant three-dimensional (3D) shapes. Specifically, we employ LCEs as substrates for electronic devices that are flat during processing but then morph to 3D shapes for use. A variety of thin-film electronic components, including conducting traces and metal-insulator-metal (MIM) capacitors, is fabricated on surface-aligned LCE substrates by using photolithographic microfabrication processes. These devices are shown to morph their shapes from 2D to 3D as programmed, upon the release of the LCE films from the carrier wafer. The 3D helical cable conductors and capacitors created by this method demonstrate strain tolerance up to 100% with less than a 5% change in resistance or capacitance. We will discuss the mechanical and electrical properties of these cables with various encapsulation coatings including parylene-C, AlOx/parylene-C bilayer, and LCE. Our preliminary results suggest that the LCE-based soft electronics technology proposed herein may open up a new avenue for developing chronic implantable bioelectronics and neural interfaces.

4:45 PM EP04.07.05 3D Printing Flexible Silicones, TPUs and Nylon Materials for Actuating Devices and Motors Rigoberto C. Advincula; Case Western Reserve University, Cleveland, Ohio, United States.

The application of silicones and thermoplastic polyurethanes (TPUs) in the number of electronic and flexible device applications has multiplied through the years with its excellent composition control and the ability to prepare various forms primarily through the injection molded and thermo-formed processing shapes. This means that their thermo-mechanical properties can be tuned towards more mechanically compatible properties to the human body including elastomeric properties. However, in a number of prosthetics devices including artificial body parts, sensors, implants, etc. 3D printing is emerging to be an alternative for additive manufacturing with its rapid-prototyping advantage and the ability to incorporated new polymer and nanocomposite in processing methods such as fused deposition modeling (FDM), stereolithographic apparatus (SLA) and viscous solution printing (VSP). It should be a viable method for the limited and specific production of flexible electronic devices that are fit even for personalized healthcare. This talk will highlight our work on 3D Printed Silicones, 3D printed TPU, etc. and 3D Printed nylons, to form basic material compositions flexible <span style="background-color:rgb(246, 213, 217);"—electronic nanocomposite materials containing graphene, carbon nanotubes, carbon black), etc. </span> Structure-property relationships correlated with the formation
of improved modulus and flexural strength with increasing amounts of electronic nanofiller components.

NIR Absorbing Ionic Dyes for Transparent Photo-Actuators Minsu Han, Lim Hanwhuy, Jongun Hwang and Eunyongu Kim; Chemical and Biomolecular Engineering, Yonsei University, Seoul, Korea (the Republic of).

Photothermal materials absorbing near infrared light have received strong attention for optical filters, sensors, energy harvesters, and photothermal theragnosis agents. In particular, NIR absorbing ionic dyes containing multi aromatic units have high transparency and optical selectivity, so that they are challenging materials as a transparent photothermal material. However, the researches on these materials are rather limited due to the multi-step synthetic process as well as difficulty in the characterization of molecules. Herein, we report synthesis and application potential of NIR absorbing ionic dyes as a photo-actuating electrode. NIR absorbing ionic dyes were synthesized through modification of aromatic amines over >80% yields, and characterized by spectroscopic methods. The ionic dyes showed strong absorption of NIR light at ~ 1000 nm region, while they were transparent in visible region (%T > 90) both in solution and film state (Fig. 1(a)). Thin film of the ionic dyes was applied to a photothermal actuator, which showed large temperature rise upon exposure to a NIR light (Fig. 1(b)). The temperature rise, transparency, and photo-actuation of the transparent actuator of the ionic dyes will be presented.

EP04.08.02
Thermally Self-Healing Electrochromic Film and Devices Derived from Reversible Diels–Alder Polymer Yi Wang and Chunyang Jia; School of Electronic Science and Engineering, Chengdu University, Chengdu, China.

The cracking of electrochromic materials due to aging or reiterative bending is a major problem which noticeably degrades the performances of electrochromic devices. In this research, a novel self-healing electrochromic polymer PPFMA was synthesized, which integrated the electrochromic triphenylamine and self-healing Diels-Alder groups. The PPFMA film showed all superior electrochromic properties, such as stable color changes (yellow to green to blue) with a maximum optical contrast of 42.7% at 1050 nm and high coloration efficiency of 108.3 cm2/mC. Meanwhile, the polymer PPFMA also showed excellent self-healing performance, cracks cut on the film surfaces (bleached or colored states) could be self-healed at 110 °C within 4 min, and the self-healing rate was about 80%. The results indicate that the polymer PPFMA has the mutual independent bifunction of electrochromic and self-healing, it is a promising material for prolonging the service life of electrochromic device.

Highly Robust, Transparent and Breathable Epidermal Electrode Yousun Fan; Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, Beijing, China.

Recently emerged electronic skins with applications in on-body sensing and human-machine interface call for the development of high-performance skin-like electrodes. In this work, we report a highly robust, transparent, and breathable epidermal electrode composed of a scaffold-reinforced conductive nano-network (SRCN). Solution-dispersed silver nanowires, through facile vacuum filtration, are embedded into a scaffold made of polyanime nanofibers. Optical transmittance of 84.9% at 550 nm wavelength is achieved at a significantly low sheet resistance of 8.2 Ω sq−1. The resistance of the SRCN only slightly increases by less than 0.1% after being bent for 3,000 cycles at the maximum curvature of 300 m−1 and by less than 1.5% after being dipped in saline solution for 2,500 cycles. The excellent robustness is attributed to the reinforcement from the nanofibers-based scaffold as a backbone that maintains the connections among the silver nanowires by undertaking most of the loaded stress. The SRCN not only forms tight and conformal bonding with target surface but also allows the evaporation of perspiration, making it suitable as an epidermal electrode for long-time use. Furthermore, fine and clean-cut circuit patterns with line width on the micrometer scale can be readily prepared, paving the basis for fabricating sophisticated functional electronic skins.

EP04.08.04
Patterned Transfer of Silver Nanowire Electrode by Using UV Curable Pressure Sensitive Adhesives KeumHwan Park1, Ye-seul Song1, Hee-Jin Lee1, Woongsik Jang2, Dong Hwan Wang2 and Youngmin Kim1; 1KETI, Sungnam-si, Korea (the Republic of); 2Chung-Ang University, Seoul, Korea (the Republic of).

Recently, studies on the fabrication of stretchable electrodes using AgNW have attracted much attention. Among the many methods, stamping transfer process is most considered as an advanced technology which can overcome the limitations of existing methods such as lithography, and wet coating. In this study, UV curable pressure sensitive adhesives (PSAs) consisting of acrylic adhesives and UV curable oligomers are prepared. The novel UV curable oligomers are synthesized through two steps. The anilinolysis of the cyclic carbonate with amine-capped polypropylene glycols (PPGs) afforded multifunctional alcohols in the first step. Next, the reaction between the alcohols and methacryloyl isocyanates produced multi-arm PPG methacrylates. These compounds were mixed with the acrylic adhesive to generate two kinds of UV curable PSAs. The peel strength of the two PSAs on th PC substrate was 1,113 g/in, and 991 g/in, respectively. Interestingly, the peel strength of the PSAs was reduced by two orders of magnitude after UV irradiation. The initial tack forces of the PSAs also were dramatically reduced. The reduced adhesion of the PSAs was attributed to the high storage moduli induced by UV treatment. The UV curing of PSAs was confirmed by monitoring the disappearance of an IR absorption band corresponding to H=C=C stretching by FTIR spectroscopy. Finally, AgNW and UV curable PSA were mixed and coated to make a film. The sample was irradiated with UV through a mask to produce a pattern in which only the exposed portion to lost its adhesion. The adhesive portion was transferred to the opposite substrate through the stamping transfer process, and the sheet resistance was measured as nearly same to that before the transfer. Stretching and bending tests were performed on the fabricated samples, which demonstrated that they are well suited for the production of stretching electrodes.

EP04.08.05
A Hybrid PVDF/PDMS Electronic Skin for Accurate Touch Localization Keith Behrman, Caroline Yu, Pedro Placenza, Johnny C. Li, Matei Ciocarlie and Ioannis Kymissis; Columbia University, New York, New York, United States.

Flexible tactile sensors that can precisely and rapidly detect touch and provide location are of great importance for e-skin development [1]. Piezoelectric sensors are a great candidate because of their high voltage response, speed and sensitivity [2]. Current implementations use dense taxel arrays to accurately detect touch with high precision [3,4]. However, these solutions suffer from complex designs, slow response rates, expensive detection equipment or large wire arrays required to address individual sensors. The work presented here improves on current work by achieving high spatial resolution with a simple fabrication scheme and a minimal number of sensing elements. The sensing circuitry for the device utilizes a single charge-amplifier and a multiplexer controlled by a microcontroller to achieve high-speed measurements at a low cost.

Yu et al., have shown that multiple sensing modalities can be combined within a single PVDF sensor and utilizing compressible compliant layers, such as foam, can improve device sensitivity [5]. Here we iterate on this design by stacking two layers of PVDF with patterned electrodes to create a dense sensing area encapsulated and sandwiched by PDMS layers. The deformable nature of the PDMS offers increased sensitivity by acting as a compliant layer. PDMS can be used in a release mold to create a flexible skin that can be attached to existing grasping fingers, or the PDMS can be directly bonded to custom finger architectures to improve adhesion to the substrate while being fully integrated into the finger.

PVDF pre-coated on both sides with sputtered Cr/Au (40/250nm) was lithographically patterned and wet-etched utilizing backside alignment techniques to form electrode arrays
on a 15x15mm active area. The electrode arrays were electrically connected with heat-seal connectors before being stacked and encapsulated in PDMS. This sensor consists of two PVDF arrays with 16 electrode pairs to create a grid pattern. The electrodes were individually addressed with a multiplexer as seen in Geng et al., to simplify the circuit by using only one charge amplifier while maintaining a high sampling frequency [5].

The sensor was characterized with a robotic indenter by collecting individual sensor readings across a dense grid of indentation locations to train a kernel ridge regressor to predict locations against a test set of randomized locations. The prediction accuracy improves at deeper indentation depths and has a minimized prediction error of 0.78 mm with a standard deviation of 0.61 mm. Compared to a 15x15 array of individual taxels, this design achieves comparable spatial resolution with 14x fewer sensing elements. The sensor can also be implemented as a tri-modal sensor to capacitively sense object proximity, measure pressure by implementing strain gauges along with localization data from the grid. This rich information set can be used to augment robotic grasping applications.

EP04.08.06
Single-Crack-Activated Ultrasensitive Flexible Impedance Strain Sensor Iljong Ye; Mechanical Engineering, Tsinghua University, Beijing, China.

A development of single-crack-activated impedance strain sensors with unprecedented sensitivity is demonstrated first. The gauge factor of the device is beyond 10^6 in 10^4 strain range in comparison with the reported highest gauge factor 1.5 x 10^4 within 60% strain range, and the displacement sensitivity is 1.6 MΩ nm^-1. The extremely high sensitivity is attributed to the transition region which has never been studied before. Multiple crack-based sensors, however, cannot work in the transition region due to complicated interaction among cracks, which essentially limits their sensitivity. Additionally, studying a precisely controllable single crack rather than multiple cracks is favorable for excluding other factors such as crack spacing, difference among cracks, and interaction among cracks, simplifying the model and facilitating better understanding of the underlying mechanism of the device. The device can satisfy requirements of mechanical flexibility, durability, and repeatability. In addition, the device developed is capable of measuring displacement in nanometers range or force in tens of nanonewton range, and has the potential to be applied in various fields, such as specific biomolecular recognition.

EP04.08.07
Highly Stretchable Strain Sensors Comprising Double Network Hydrogels and Conducting Polymers Prepared by Microfluidic System Dowan Kim1, Jin-woo Oh2, Soo Hyung Kim2 and Jinhwan Yoon1; 1Graduate Department of Chemical Materials, Pusan National University, Busan, Korea (the Republic of); 2Department of Nanoenergy Engineering, Pusan National University, Busan, Korea (the Republic of).

Strain sensors with high sensitivity and stretchability are highly required for the application of wearable or implantable sensor to detect the human motion. In this study, we have prepared a highly stretchable double network (DN) of soft polyacrylamide and brittle calcium-alginate microfibers containing poly(3,4-ethylenedioxythiphene)-poly(styrene sulfonate) (PEDOT:PSS) by using microfluidic devices. The resistance changes in response to the stretching of the microfiber due to the connection/disconnection of the PEDOT:PSS domain can be observed up to 400% of elongation with the resolution of 0.1%. Furthermore, these changes are fully reversible and repeatable over more than 10,000 cycles at 300% elongation. On the basis of these mechanical and electronic properties, the DN microfibers are envisioned to use stretchable strain sensor, demonstrating the detection of the human motion including bending of the finger and walking and running in real time. We also demonstrated that the developed sensor can be stably used in outdoor by measuring the growth of the bamboo planted in the garden.

EP04.08.08
Fabrication, Characterization and Dielectric Spectroscopy of BaTiO3 Styrene Butadiene Styrene Stretchable Thin-Film Nanocomposites for Flexible Electronics Suporna Paul, Benard Kavey and Gabriel Caruntu; Central Michigan University, Mount Pleasant, Michigan, United States.

Polymer ceramic nanocomposites exhibit performance characteristics superior to those of the parent materials as they harness the electrical properties of the polymer and the dielectric properties of the ceramic. However, the rational design of flexible high-k dielectric nanocomposites with high filler loading is still challenging as the increase of the ceramic content deteriorates the mechanical properties of the nanocomposites. In this work, we investigated the fabrication of flexibleelectronics by dispersing BaTiO3 (BTO) colloidal nanocrystals with various sizes (10-20 nm) into the styrene butadiene styrene (SBS) matrix. The resulting SBS-BTO nanocomposite films contain up to 50% (weight) BaTiO3 nanocubes fillers and possess high energy density values along with excellent mechanical properties. It has been observed that the nanocomposite films can easily be peeled off from any type of substrate which is an indication of good flexibility and strength of these free standing films. We observed a linear increase in the dielectric constant with respect to fillers content, ranging from 6.1 to 24.1 for 0% to 40% respectively. The alternate current (AC) conductivity of the polymer remained below 10^-8, which shows the polymer is insulative and can be used in flexible capacitor applications. Also, with scanning electron microscope, we observed that, the BTO colloidal nanocrystals are uniformly distributed in the polymer matrix which can explain the reason behind of good flexible property of the film. The experimental results show that these nanocomposite thin films exhibit superior properties which make them attractive for implementation in high-performance capacitive storage devices, wearable technology and nanoelectronics.

EP04.08.09
Transformable Crystalline Silicic Photovoltaics Inchan Hwang and Kwanyong Seo; UNIST, Ulsan, Korea (the Republic of).

Transformable photovoltaics (TPVs) have been attracting much attention because of the limitation of the PV’s installation and a continuous power source for the portable and wearable electronic devices. At present, TPVs have been developed based on the perovskite and organic photovoltaics. However, these PVs have problems of the low efficiency and instability. In contrast, crystalline silicon (c-Si) PVs exhibit high efficiency and stability, but they are not able to be transformable because they tend to be fragile when an external force is applied. Therefore, a new strategy for the TPVs technology based on the crystalline silicon is required to realize the high efficiency and stable c-Si TPVs. In this research, we developed the c-Si TPVs through the interdigitated back contact (IBC) structured c-Si module and introduction of a stretchable electrode. Because all electrodes (positive and negative contact) of the IBC PVs are positioned on the rear side, we can easily fabricate the TPVs module using the stretchable electrode. The stretchable electrode is consisting of the combination of the carbon materials and elastic polymer. The stretchable carbon filler/ polymer composite is found to effectively retain its electrical conductivity, even when under the high strain of ≥200%. Due to the outstanding electrical conductivity and highly stretchable property of the carbon filler/ polymer composites, the fabricated IBC PVs can be transformable without the efficiency degradation. Thus, we expect that the proposed c-Si TPVs are possible to overcome the PV’s installation limitation and integrate with flexible or wearable electronic devices for the continuous power source.

EP04.08.10
Effective Processing Strategies to Integrate Ag NWs with Polymer Semiconductors for High Performance Stretchable Field Effect Transistors Rujiao Song1, Shanshan Yao1, Zheng Cui1, Jingyan Dong2, Yong Zhu1 and Brendan T. O’Connor1; 1Mechanical & Aerospace Engineering, North Carolina State University, Raleigh, North Carolina, United States; 2Industrial & Systems Engineering, North Carolina State University, Raleigh, North Carolina, United States.

Intrinsically stretchable transistors are a critical building block for an array of stretchable electronic applications. They also represent a model system where conductors, semiconductors, and insulators must all be stretchable and effectively integrated. Here, we present an intrinsically stretchable organic field effect transistor that incorporates Ag nanowires (NWs) as the source, drain, and gate electrode with a stretchable PDMS gate dielectric and stretchable DPP-4T polymer semiconductor. The Ag NWs provide a significant improvement in electrical conductivity compared to other candidate stretchable electrode materials such as carbon nanotubes and PEDOT:PSS. However, there are several challenges associated with roughness and patterning that can limit their application. Here, we demonstrate an effective processing strategy of embedding the Ag NWs in a PDMS elastomer allowing for high stretchability and high conductivity. This high conductivity enables the electrical leads and electrodes to be composed of the same material. The NWs are patterned using direct electrophyssohydrodynamic jet printing, and through drop casting followed by laser ablation. While the NWs are embedded in the elastomer, we show that the surface of the NW network is able to effectively contact the semiconductor for low contact resistance transistor performance. Through this processing strategy we are able to demonstrate a stretchable transistor with a saturated field effect mobility that remains largely unchanged when under an applied strain of 40%, and remains functional under cyclic loading. As part of this work, the morphology of each active component is studied in detail along with detailed device characterization.
Flexible and Multi-Functional Energy Storage Devices with High Safety

Yang Zhao, Ye Zhang, Yifan Xu, Hao Sun and Huisheng Peng; Fudan University, Shanghai, China.

Flexible energy storage devices are critical for the next-generation electronics and have attracted extensive attention. With the fast-growing requirements of portable and wearable electronic equipment, great efforts have been made to develop flexible batteries and supercapacitors. However, the energy densities of these devices are still urgent to be further increased. Furthermore, most of the reported flexible batteries and supercapacitors employ either strong acid/base or toxic flammable organic solutions as electrolytes, which poses potential safety issue for being worn by humans or implanted into the bodies. Therefore, the energy density, safety concerns and compatibility of the flexible energy storage devices are still urgent to be improved to meet the practical application requirements.

Herein, we have developed a new family of flexible energy storage devices including fiber-shaped aluminum-air battery with superior energy density, self-healing and multi-functional aqueous batteries with high safety, and a novel sticky-note supercapacitor with high compatibility. 1. The all-solid-state fiber-shaped aluminum-air batteries showed a specific capacity of 935 mAh/g and an energy density of 1168 Wh/kg. They are also flexible and stretchable and can be further woven into a variety of textiles. 2. After breaking, the flexible self-healing batteries can be healed to recover the normal functionality by simply contacting the two breaking parts for seconds. The electrochemical performance of these batteries can be well maintained after repeated cutting and self-healing. 3. The flexible aqueous sodium-ion batteries exhibit high volumetric energy/power density and high flexibility. When the normal saline or cell culture medium is used as electrolyte, these batteries can still work well, indicating an application prospect in implantable electronic devices. 4. The sticky-note supercapacitor demonstrated high compatibility and can be easily and repeatedly attached onto various substrates including cloth, glass, paper, plastic and metal with the electrochemical performance well maintained. These flexible and multi-functional energy storage devices can be woven into lightweight and flexible electronic textiles to effectively meet the requirement of the modern electronics including portable and wearable products.

Bioinspired Multi-Responsive Soft Actuators Controlled by Laser Induced Graphene

Heng Deng, Cheng Zhang, Jhong-Wun Su, Yunchao Xie, Chi Zhang and Jian Lin; University of Missouri, Columbia, Missouri, United States.

By exploiting aligned cellulose fibrils as geometrically constraining structures, plants can achieve a complex programmable shape change in response to environmental stimuli. Inspired by this natural prototype, a series of manmade materials with aligned structures have been developed and employed in self-morphing materials. However, in these cases, the constraining materials are fabricated and aligned in separate processes. In botanic systems, a more efficient way is adopted, in which the aligned microstructures are simultaneously synthesized and aligned in one bottom-up process. Herein, we report a bioinspired bottom-up approach to fabricate laser induced graphene (LIG) structures which resemble the aligned microstructures of the cellulose fibrils in plants. Such LIG structures serve as geometrically constraining structures to precisely control the shape-changing behaviors of soft actuators made from polymer and LIG layers. Meanwhile, the LIG structures also serve as functional materials to absorb photo and electrical energy to stimulate motions of the soft actuators. Taking advantage of the geometrically constraining effect from the aligned LIG structures, a series of programmable actuations stimulated by electricity, light, organic vapor, and moisture were demonstrated. Furthermore, the soft actuators also act as soft grippers and walking robots upon different stimuli, indicating their potential applications in soft robotics, electronics, microelectromechanical systems, and others.

Robust and Stretchable Polymer Semiconducting Networks—From Film Microstructure to Macroscopic Device Performance

Guoyan Zhang and Elsa Reichmanis; Georgia Institute of Technology, Atlanta, Georgia, United States.

Although stretchable polymer-based devices with promising electrical performance have been produced through the polymer blend strategy, the interplay between the blend film microstructure and macroscopic device performance under deformation has yet to be unambiguously articulated. Here, we will discuss the formation of robust semiconducting networks in blended films from a thermodynamic perspective. Thermodynamic behavior along with the linear absorption and photoluminescence measurements predict the competition between polymer phase separation and semiconductor crystallization processes during film formation. Semiconducting films comprised of different pi-conjugated semiconductors were prepared and shown to have similar mechanical and electronic properties to films comprised of a model P3HT and PDMS blend. These results suggest that a film’s microstructure and therefore robustness can be refined by controlling the phase separation and crystallization behavior during film solidification. Fine-tuning a film’s electrical, mechanical, and optical properties during fabrication will allow for an advanced next-generation of optoelectronic devices.

Stretchable/Flexible Transparent Conductors for Emerging Optoelectronic Devices and Epidermal Transducers

Bin Hu; Huazhong Univ of Science and Technology, Wuhan, China.

Compared with continuous transparent conductive films, such as metal oxides that cannot effectively release the strain during bending or stretching, percolated network composed by conductive nanowires like silver nanowires (AgNWs) can be a ductile form, which also possesses excellent electro-optical performance and solution-processed manufacturing. However, this unique metal percolated structure also has issues, such as the binding strength with polymers and poor patterning performance. Therefore, the design of network and development of compatible techniques become important for practical applications in stretchable/flexible optoelectronic devices.

In our study, we firstly use finite element simulation to explore the electrical, optical and mechanical properties of the network, which guides us to optimize the fabrication of stretchable polymer-based devices with promising electrical performance. 1. The all-solid-state fiber-shaped aluminum-air batteries showed a specific capacity of 935 mAh/g and an energy density of 1168 Wh/kg. They are also flexible and stretchable and can be further woven into a variety of textiles. 2. After breaking, the flexible self-healing batteries can be healed to recover the normal functionality by simply contacting the two breaking parts for seconds. The electrochemical performance of these batteries can be well maintained after repeated cutting and self-healing. 3. The flexible aqueous sodium-ion batteries exhibit high volumetric energy/power density and high flexibility. When the normal saline or cell culture medium is used as electrolyte, these batteries can still work well, indicating an application prospect in implantable electronic devices. 4. The sticky-note supercapacitor demonstrated high compatibility and can be easily and repeatedly attached onto various substrates including cloth, glass, paper, plastic and metal with the electrochemical performance well maintained. These flexible and multi-functional energy storage devices can be woven into lightweight and flexible electronic textiles to effectively meet the requirement of the modern electronics including portable and wearable products.

Fully Printed Carbon Nanotube Network Thin-Film Transistor Based Gas Sensors on Flexible Substrates

Diego Vaca, Jiakuo Chen, Woonhong Yoo and Satish Kumar; School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 3Petit Institute for Bioengineering & Bioscience, Georgia Institute of Technology, Atlanta, Georgia, United States; 4W. W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 5Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Aerosol jet printing (AJP) has been proven to be capable of printing microelectronic devices and relevant circuits with relatively high precision, repeatability, and scalability using a wide range of materials because it can handle inks viscosities in the range of 1-1000 Cp. In this work, fully-printed thin film transistors (TFTs) have been fabricated on flexible films microstructure and therefore robustness can be refined by controlling the phase separation and crystallization behavior during film solidification. Fine-tuning a film’s electrical, mechanical, and optical properties during fabrication will allow for an advanced next-generation of optoelectronic devices.
substrates. Metallic, semiconducting, and dielectric materials such as silver, single walled carbon nanotubes (SWCNTs), and xdi-dcs, have been printed successively with high quality using APJ. In this fabrication process, CNT network is printed in the channel region of TFTs as a semiconducting CNT solution. Highly uniform CNT network film is achieved by performing a multiple layer-by-layer deposition method. The printing of thin layer of xdi-dcs as gate-dielectric is realized by diluting with n-butanol solvent and plasma treatment for better surface wetting during printing. Fully printed CNT-TFTs showed a very stable performance with on/off current ratio as high as ~10^8, mobility around 5 cm^2V^{-1}s^{-1}, negligible hysteresis, and good uniformity. More importantly, this device can be operated using bias voltages as small as 5V, which is much smaller than the previously reported values because of the improvement in both CNT network and dielectric layer (thicker). CNT-TFTs were used as gas sensors to detect NO_2 and NH_3 and their performance was compared with two-electrode CNT gas sensors. Our printing method has potential to further reduce the bias voltages for operation. This improvement is key for the application of printed microelectronics and CNT-TFTs based circuits on flexible substrates because of the relatively lower voltage operation and power dissipation.

EP04.08.17
Water Permeable Sticky Patch with Serpentine Patterns for Detection of Electrophysiological Signals
Hyeokju Chae, Sunkook Kim, Srinivas Gandla and Muhammad Naqvi; Advanced Material and science, Sungkyunkwan University, Suwon, Korea (the Republic of).

Skin patch based stretchable sensors for Physiological monitoring have drawn great attention due to their significant finding in many human-machine interaction applications. As of now, stretchable serpentine structures supported by biocompatible elastomeric substrates have been widely examined for conformable and strain relief stretchable electrophysiological sensors. However, the substrates are not breathable, which is crucial for next-generation wearable electronics. Additionally, the fabrication of these sensors mostly relies on conventional lithographic techniques followed by etching processes that are complex, expensive and entail multiple steps, which greatly impede the realization of low-cost and scalable manufacture electronics. The development of flexible stretchable materials and novel processing techniques can enable a viable solution for these electronics.

In this, we present a novel low-cost and rapid “cut and transfer” method to fabricate electrophysiological sensor using a benchtop programmable mechanical cutter plotter. Furthermore, the stretchable sensor performances have been achieved by introducing a water permeable patch possessing filamentary serpentine patterns that are stretchable, sticky, and conformable. Moreover, the sensors maintain the sensing performances irrespective to the deformations that are imposed. Overall, the fabrication method offers the chance of developing a new format of stretchable and flexible electronics.
communication through a recyclable on-board computation unit. Such advances in the synthesis of biodegradable, mechanically tough and stable ionico-and hydrogels may bring bionic soft systems a step closer to nature.

Programmed Mechanically-Triggered Ultrafast Soft Robots for Implantations Beyond Human

Soft robots have been designed and developed to fulfill the demands of better deformability and adaptability to changing environment [1-2]. These soft robots could be made of various stimuli responsive materials that can be actuated by magnetic field [3], light [4], temperature [5], electric fields [6], chemicals [7], pressure [8], etc. In contrast to other actuation mechanisms, magnetic fields are appealing for numerous application scenarios (e.g. environmental, biological, medical), where the benefits stem from their long-range penetration, easy accessibility, and controllability of magnetically triggered millimetre- and centimetre- scaled soft robots performing multimodal locomotion [9] and complex 3D actions [10]. However, their thick and bulky bodies [9-10] challenge themselves to reveal better performances for specific implantations which require more, for instant action speed, and reversible large-scale actuation amplitude by a rather low magnetic field.

Here, we present an ultrathin (7-100 μm) and lightweight (1.2-2.4 g/cm3) soft robot that can be actuated in a tiny magnetic field of 0.2 mT reaching full action amplitude with a reaction time of 10 ms only. By programming the foils into different geometries, these soft robots are readily used for multifunctional nature-mimicking motion with a magnetic coil or a permanent magnet, such as a quick fly gripping and releasing, complex fast human cross-clapping mimicking, etc.

Organic Haptics
Darren J. Liponi1; University of California, San Diego, La Jolla, California, United States.

The goal of this project is to create a class of electronic materials that can measure signals and interface with the nervous system for two-way communication with biological systems. The project is exploring three classes of materials. (1) Semiconducting polymers with properties inspired by biological tissue. The goal of organic bioelectronics is to detect and treat disease by using signal transducers based on organic conductors and semiconductors in wearable and implantable devices. Except for the carbon framework of these otherwise versatile materials, they have essentially no properties in common with biological tissue: electronic polymers are typically stiff and brittle, and do not degrade under physiological conditions. Such properties can be realized in a single-component polymer by incorporating biocompatible subunits. We have synthesized a new type of stretchable, biodegradable polymeric semiconductor whose electronic performance is unaffected by the biodegradable components. Such materials have applications in wearable and implantable sensors. (2) Metallic nanoislands on single-layer graphene for cellular biomechanics and wearable sensors. We have used these materials to measure the forces under physiological conditions. Such properties can be realized in a single-component polymer by incorporating biocompatible subunits. We have synthesized a new type of stretchable, biodegradable polymeric semiconductor whose electronic performance is unaffected by the biodegradable components. Such materials have applications in wearable and implantable sensors. (3) Ionically conductive organogels for haptic feedback. Medical and implantable sensors. (2) Metallic nanoislands on single-layer graphene for cellular biomechanics and wearable sensors. We have used these materials to measure the forces under physiological conditions. Such properties can be realized in a single-component polymer by incorporating biocompatible subunits. We have synthesized a new type of stretchable, biodegradable polymeric semiconductor whose electronic performance is unaffected by the biodegradable components. Such materials have applications in wearable and implantable sensors.

Tattoo-Like Electronic Systems for on Body Measurements
Andrea Spanu1, Danilo Pani2, Andrea Achilli2, Fabrizio Viola2, Annalisa Bonfiglio3, and Piero Possad4; 1MST-Microsystems Technology CMM-Center for Materials & Microsystems, FBK-Bruno Kessler Foundation, Trento, Italy; 2Università Degli Studi di Cagliari, Cagliari, Italy; 3Istituto Italiano di Tecnologia, Milano, Italy.

The recent rise of the so-called “tattoo electronics” has pushed further the innovation on flexible and ultra-conformable electronic devices that can be transferred onto the skin, being this unprecedented possibility of obtaining a seamless skin/electronics interface particularly interesting for biomedical imaging. In fact, these systems can be specifically engineered in order to adhere to the skin and they could include several kinds of electronic devices, such as sensors, light-emitting diodes, photodetectors or electrodes for biopotentials acquisition. In this work, we have developed a very simple approach for the realization of ultra-conformable electronic systems, such as electrodes and sensors that can be employed for the recording of biopotentials and/or different physiological parameters.

The proposed approach is based on the employment of a nanometric film of Parylene C. The process starts from a plastic substrate on which we spin coat a sacrificial layer which can be dissolved in either polar or non-polar solvents. After that, a submicrometer film of parylene C is deposited, such nano-films acting as the actual substrate where electrodes for biopotential acquisition and OTFT-based sensors can be fabricated using standard techniques (such as, for example, photolithography, micro-contact printing, and inkjet printing). Once the fabrication process is completed, the sacrificial layer can be dissolved allowing the electrodes/sensors to be easily transferred onto a different substrate, as for instance onto the skin.

In this work we report about the employment of such tattoo electrodes for the recording of both electrocardiographic (ECG) and electromyographic (EMG) signals, which can be performed standard commercial pre-gerellated electrodes in terms of signal-to-noise-ratio and movement artifacts suppression. Moreover, a particular kind of organic transistor sensor called organic charge-modulated field-effect transistor (OCMFET) has been fabricated onto such nanometric thin films and coupled to a solution processable and printable piezoelectric/pyroelectric polymer, namely PVDF-TrFE, in order to obtain ultra-thin multimodal force and temperature sensors. Such devices can detect very small pressure (below 300 Pa) in both the static and the dynamic regime, being in fact able to detect stimuli at a frequency enough to 500 Hz. Moreover, thanks to the pyroelectric properties of PVDF-TrFE, temperature variations ranging from 10 °C up to 45 °C can be also detected. Interestingly enough, we will show that with the proposed approach it is also possible to employ the same device and the very same active layer for the fabrication of multimodal tactile sensing systems. The highly flexibility of the developed structure and the simple fabrication process make this solution a very interesting candidate for the development of ultra-sensitive, multimodal, and mechanically compliant electronic systems that can be employed in many different scenarios, ranging from biomedical applications to robotics and prosthetics.

Electro-Active Soft Photonic Devices for the Simultaneous Generation of Color and Sound
Do Yoon Kim1, Sunglok Choi2 and Jeong-Yun Sun1; 1Seoul National University, Seoul, Korea (the Republic of); 2Electronics and Telecommunications Research Institute, Daejeon, Korea (the Republic of).

For the satisfactory fulfillment of the two primary human senses (i.e., vision and hearing), every contemporary media platform employs an independent speaker and display, as display panel technology currently disallows tunable audio-frequency vibration. However, mechatronic systems that feature amenability towards color tuning based on structural deformation have an inherent potential for the generation of mechanical vibration; all the same, most systems are constrained to demonstrations in low-frequency regimes (< 1 Hz) as color change events necessitate large strains, which has until now precluded the possibility for simultaneous high-frequency vibrations. It is well known that overcoming sluggish strain response rates that are characteristic of stretchable viscoelastic material systems is extremely challenging. Hence, most mechatronic systems have thus far only aimed at satisfying visual perception and have overlooked the possibility of a merger of sound and display modules, despite their disparate inherent mechanical vibration modes. Here, we target both senses, especially under single input control by actuating a single mechatronic platform built from an organogel skin composed of close-
packed photonic lattices with an organogel matrix. Exploiting a dielectric elastomer actuator, the skin features large areal strains at low frequencies of actuation, which allows the reversible tuning of the photonic stop-band. Notably, the skin remains incompressible and exhibits negligible strain when actuated at higher frequencies (e.g., audio frequencies), thereby making it amenable for sound modulation in this regime. Remarkably, a pseudo-synthetic event with color and sound can be orchestrated with a single actuation mode; that is the simultaneous generation of the large strain (for color) with the high-frequency vibration (for sound) by taking advantage of the soft and highly responsive photonic organogel skin. This strategy will be widely helpful to eliminate the need for the independent construction of modules for color and sound, as required in all current commercial implementations. The evolution of flexible electronics has enabled the appearance of revolutionary concepts like electronic skins (e-skins) [1-3], wearable electronics and smart implants, among others. E-skins have the potential to seamlessly integrate with the human body owing to their mechanically imperceptible and compliant nature. Due to these characteristics, they provide a much more natural way of interacting with electronic devices by eliminating the need for bulky or stiff parts interfering with human perception. Furthermore, conventional flexible interactive electronics typically use tactile stimuli like pressure or temperature [4,5], limited to direct contact detection. To progress beyond tactile approaches, we have recently demonstrated magnetosensitive skins [7-12] as a touchless alternative for interactivity. These skins can utilize a plethora of magnetic stimuli like permanent magnets [7-10], the geomagnetic field [11] and even submicrotesla fields [12], to reconstruct and digitize spatial interactions. Here, we present the technologies at the core of these interactive magnetosensitive skins and showcase some of the applications stemming from them [10-12]. These technologies utilize different configurations of magnetoresistive (MR) and planar Hall-effect sensor elements, based on metallic thin films fabricated on 6-µm-thick polymeric foils. The combination of this broad spectrum of sensors allows multiple magnetic range detection possibilities for these magnetosensitive skins. Besides, by introducing geometrical conditioning like barber poles [13] or measurement schemes like zero-offset anomalous Hall magnetometry [14,15], the output sensitivity and offset can be tuned to increase the overall performance. We anticipate that this novel kind of magnetic skins could be used to track and digitize fine motion in an ultra-thin and lightweight format. This feat could ease the integration of usually rigid magnetic detection systems into on-skin, textile-based or Internet of Things (IoT) applications. A successful implementation could lead to a new class of virtual or augmented reality systems and interactive input devices which extract information from their surroundings through magnetic signals.

SESSION EP04.10: Soft and Stretchable Systems and Applications II
Session Chairs: Roozbeh Ghaffari and Cunjiang Yu

Soft and Ultra-Conformable Electronic Circuits on Thin Metallic Foil Séverine C. de Mulatier1,2, David Coulon2, Sylvain Blayac1, Roger Delattre1 and Marc Ramuz1; 1Department of Flexible Electronics, Ecole Supérieure des Mines de Saint-Etienne, Centre Microélectronique de Provence, Gardanne, France; 2@-HEALTH, Aix-en-Provence, France.

Fabrication of complex circuitry for ultra-conformable and imperceptible devices is a key challenge for tomorrow-wearable technologies. As a matter of facts, the only way today to perform complex computational operations, such as data processing and transmission, is by using standard rigid silicone-based systems. The mismatch in mechanical properties between conformable substrates and rigid components induces specific reliability issues, especially for wearable systems, as they are subjected to wearing and washing.

In this work, we focus on different solutions to create thin and ultra-conformable electronic circuit, using a customized stack of thin metallic foil on a polymer film. We consider and study the aforementioned aspects of imperceptibility (wearability) through conformability, and robustness through specifically designed bending and washing tests. This study investigates the optimization of electrical connection between ultra-soft substrates and rigid components, and the influence of the stack composition in multilayer electronic systems on the overall reliability of the device.

The combination of optimized stack layout and compliant interconnections allow the fabrication of robust and ultra-conformable, imperceptible devices.

2:00 PM EP04.10.02
Flexible and Wearable Electronics Based on 2D Materials Jong-Hyun Ahn; Electrical and Electronic Engineering, Yonsei University, Seoul, Korea (the Republic of).

With the emergence of unusual format electronics such as flexible and wearable devices, an effort has been made to integrate devices with various functions in smart clothing and human body for providing enhanced convenience for the users. However, it is difficult to accomplish such emerging electronics with conventional rigid inorganic materials. Two-dimensional (2D) materials such as graphene and transition metal chalcogenides have superb electronic properties that make them a promising host for device applications and they are increasingly studied for the next generation electronics.

In this talk, we focus on the development of flexible electronics using two-dimensional materials such as graphene and transition metal chalcogenides for applications in energy harvesting and biomedical devices. The design and fabrication of graphene and transition metal chalcogenides-based devices are discussed with their potential applications.

2:15 PM *EP04.10.03
Climbing-Inspired Twining Electrodes Using Shape Memory for Peripheral Nerves Stimulation and Recording Xue Feng and Yinji Ma; Department of Engineering Mechanics, Tsinghua University, Beijing, China.

Peripheral neuromodulation has been widely used throughout clinical practices and basic neuroscience researches. However, the mechanical and geometrical mismatch in the current electrode-nerve interfaces, and the complicated surgical implantation often induce irreversible neural damages such as the axonal degradation. Here, compatible with the traditional 2D planar processing, we propose a 3D twisting electrode by integrating stretchable mesh-serpentine wires onto flexible shape memory substrate, which possesses shape re-configurability (from 2D to 3D), distinct elastic modulus controllability (from ~100MPa to ~300kPa) and shape memory recoverability at body temperature (~37°C). Similar to the climbing process of twining plants, the temporarily flattened 2D stiff twisting electrode can naturally self-crimp onto nerves driven by 37°C normal saline, and forming 3D flexible neural interfaces with minimal restraint on the deforming nerves. In vivo animal experiments including the right vagus nerve stimulation for the heart failure therapy and the action potential recording of the sciatic nerve for the neuroprosthetics demonstrate the potential clinical utility.

SESSION EP04.11: Wearable Sensors and Devices
Session Chairs: Roozbeh Ghaffari and Cunjiang Yu
Thursday Afternoon, April 25, 2019
PCC North, 200 Level, Room 222 A

3:15 PM *EP04.11.01
Flexible and Wearable Electronics Based on 2D Materials Jong-Hyun Ahn; Electrical and Electronic Engineering, Yonsei University, Seoul, Korea (the Republic of).

With the emergence of unusual format electronics such as flexible and wearable devices, an effort has been made to integrate devices with various functions in smart clothing and human body for providing enhanced convenience for the users. However, it is difficult to accomplish such emerging electronics with conventional rigid inorganic materials. Two-dimensional (2D) materials such as graphene and transition metal chalcogenides have superb electronic properties that make them a promising host for device applications and they have a good mechanical property, offering a great opportunity to flexible and wearable electronics that should maintain a stable operation under a high strain. In this talk, I will present various flexible and wearable electronic applications for including touch and self-powered communication devices, and biosensors.

3:45 PM EP04.11.02

The extraneous thermal regulation of the human body has a wide array of applications ranging from assisting with medical conditions such as Multiple Sclerosis (MS) to being an essential component in the design of protective suits used for maneuvering extreme environments. Out of the plethora of thermoregulatory garment designs that are available commercially or have been proposed in the literature, liquid-cooled garments provide one of the highest heat removal capacities along with sustained and nearly-environment independent performance. In addition to the thermal regulation of the human body, these liquid-cooled garments show potential to meet the rising demand to dissipate the heat produced by wearable electronics and high power robotics while maintaining the sought after flexibility. However, in these thermoregulatory liquid cooled garments the tubing
material often used is rigid PVC which has a very low thermal conductivity, of around 0.2 Wm⁻¹K⁻¹; a value far too low to effectively deal with the amount of heat that will inevitably be generated by future wearable electronics. A low thermal conductivity contributes to magnifying the total thermal resistance which results in an excessive amount of tubing being networked around the human body or electronic device to effectively regulate its temperature. This excessive amount of tubing in turn has to be carried around by the wearer.

In this work, we explore how tubing made of soft, thermal conductive elastomers composites can improve on the performance of these liquid-cooled jackets (LCJ). In doing so, we study the effect of filler material on the tube-wall thermal resistance in combination with the interfacial thermal resistance. The interfacial resistance depends on mechanical properties of the materials in contact, thus, a microscale composition of the filler particles and matrix elastomer that provides a balance between thermal and mechanical properties of the composite must be achieved for optimal performance of the cooling device. To explore this relationship, we develop a closed-form thermomechanical model that predicts thermal performance of a composite silicone LCJ as a function of metallic filler content. To validate the model, we fabricate a set of liquid-cooled jackets out of silicone-aluminum composites. We relate the cooling ability of these devices with composition as well as thermal and mechanical properties of the composite materials. Based on these results, we develop LCJ architectures with material properties tuned via composition adjustment at each device level to achieve optimal device performance for personal (skin substrate) and robotic (metal substrate) cooling.

4:00 PM EP04.11.03
Point-of-Use Flexible Sensors for Health and Environmental Applications—Assessment of Motor Skills and Chemical Exposure Moran Amit1, Sarah Hacker2,3, Trent Simmons2,3, Rupesh K. Mishra1, Quyen Hoang1, Aida Martin Galan1, Leanne Chukoskie2,3, Joseph Wang1 and Tse Ng Ng1,2,3,4,5,6; Department of Electrical and Computer Engineering, University of California, San Diego, La Jolla, California, United States; Institute for Neural Computation, University of California, San Diego, La Jolla, California, United States; Research on Autism and Development Laboratory (RAD Lab), University of California, San Diego, La Jolla, California, United States; Department of Nanoengineering, University of California San Diego, La Jolla, California, United States.

Rapid, on-site assessment is highly desirable in the fields of both medical treatment and novel robotics. To achieve this goal, our research aims to develop low-cost, flexible, large-area sensor devices for different health and environmental applications. In this presentation, we discuss case studies using touch and pressure sensors for two different point-of-use applications:

I) Autism spectrum disorder (ASD) motor skills characterization. There is no objective metric for evaluating motor skill training progress in autistic children, and current assessments rely on qualitative surveys. A common method used is a finger tapping task that requires videotaping and unreliable, time-consuming manual analysis, with large room for errors, even with computer vision analysis algorithms. We have fabricated an instrumented glove with touch sensors on textile for straightforward finger tapping patterns characterization. The results provide immediate objective feedback not only on the tapping counts, but on the temporal data (such as tapping duration and variation in duration) as well, which was not collected before. For the index finger tapping test, children with ASD perform less counts per minute compare to typically developing (TD) children. In addition, children with ASD tap their finger for an average longer duration, with larger variation between tap durations. In a 4-fingers tapping test children with ASD tend to have more irregular patterns and skip fingers compared to TD children. This glove could find future use for characterizing motor skills of people suffering from Parkinson’s disease, epilepsy seizures, and other neurological motor disorders.

II) Robotic sensors for simultaneous pressure and organophosphate (OP) pesticide detection. There is an urgent need of sensor technologies to monitor hazardous materials for security and environmental applications, in particular, the occurrence of OP pesticide residues in agricultural products that poses a serious concern in the food and agriculture industries. Hence, rapid on-site detection of OPs through remote robotic sampling is highly desired to avoid placing people at exposure to the OPs risks. To handle sample collection, the robotic manipulator requires tactile feedback, in order to ensure no damage will be done to either the robot or the other object in contact due to excessive force. To provide tactile feedback, pressure sensors based on capacitive mechanism were chosen. The sensitivity of the capacitive pressure sensors was tuned by adjusting the dielectric compressibility. Particularly, the sensitivity was increased by choosing softer materials, i.e. elastomers with low elastic modulus and porous structure that further lower elastic moduli of the foam dielectrics compared to solid films of the same material. We have combined low-cost chemical and pressure sensors together on disposable gloves, and demonstrated successful simultaneous tactile sensing and OP pesticide detection in a point-of-use platform that is scalable and economical.

4:15 PM EP04.11.04
All Stretchable Aqueous Rechargeable Batteries for Wearable Devices Woo-jin Song and Soonjip Park; Chemistry, Pohang University of Science and Technology, Pohang, Korea (the Republic of).

There is currently a great deal of interest in stretchable electronics for widespread applications such as wearable devices, smart sensors, healthcare devices, electronic skins, and soft robotics. The stretchable electronic devices that consist of soft and deformable components can stably maintain their functions under the complex physical deformations such as bending, twisting, folding, and stretching. To achieve independent and reliable stretchable electronics, a key challenge is the development of stretchable energy-storage devices that could power such devices. Among them, Li-ion batteries (LiIBs) is a representative power source for the portable electronics owing to their advantages such as high working voltages, stable cycle life, and high energy density. However, LiIBs are based on a volatile and flammable non-aqueous electrolyte, which make them a high risk of explosion owing to the internal short circuit during extremely mechanical deformations. For this reason, typical LiIBs are not suitable for energy storage-devices system in stretchable electronic devices. Compared with LiIBs, aqueous rechargeable batteries hold great potential for a power supply in stretchable electronics because of the aqueous electrolyte having inherent safety features and high ionic conductivity. Herein, we successfully replaced rigid components of typical batteries including, electrodes1 and a separator membrane2, with stretchable materials using straightforward and scalable fabrication strategies. First, we fabricated a conductive polymer composite composed of bio-inspired Jabuticaba-like hybrid carbon/polymer (HCP) composite as a stretchable current collector, which effectively maintained its electrical percolation network even under 200% uniaxial strain. To further understand the behavior of carbon fillers in the polymer matrix under strain. And then, a poly(styrene-b-butadiene-b-styrene) (SBS) block copolymer-based stretchable separator membrane was fabricated by the nonsolvent-induced phase separation (NIPS). The diversity of mechanical properties and porous structures can be obtained by using different polymer concentration and tuning the affinity among major components of NIPS. The stretchable separator membrane showed a high stretchable feature (~270% uniaxial strain) and porous structure (~61% porosity). Using as-prepared the stretchable electrode and the stretchable separator membrane, we assembled stretchable aqueous Li-ion batteries as a power source for use in stretchable electronic devices. As a result, our all stretchable aqueous batteries manifested good cycling performance and stable capacity retention even under 100% uniaxial strain, without failing the battery performance.

Addressable Organic Light-Emitting Diode Fabrics Toward Fully-Functional Wearable Displays Young Jin Song, Jae-Won Kim, Ha-Eun Cho and Sung-Min Lee; Kookmin University, Seoul, Korea (the Republic of).

To expand the application area, unconventional forms of displays have been actively emerging beyond the flexible displays. The wearable display is conceded as one of the promising forms of such unusual emerging displays due to its remarkable functions such as real-time communication and superior portability. The wearable cloth-type displays are particularly imperative in the commercial fields because of their notable contribution to offering a high degree of freedom in terms of design and functions. There have been successful demonstrations of the so-called ‘on-cloth’ displays, where textiles (i.e. woven fabrics) were instead used as substrates of the devices. Without technical issues in defining a two-dimensional pixel matrix and making their interconnections, the reported systems of the on-cloth displays could work as fully-operating display panels. On the other hand, current technology for the ‘on-cloth’ displays that comprise emitting fibers is limited to a level of the lightings rather than the information displays, as there has been a hurdle to form a two-dimensional interconnection network with one-dimensionally configured fibers, and hence no route to perform the matrix addressing for driving designated pixels. In this regard, here we present a highly feasible approach to achieve the on-cloth class of matrix-addressable displays by weaving assembly with perpendicularly arranged organic light-emitting diode (OLED) fibers and conducting fibers. To create the OLED fibers that behave as scan lines of the matrix addressing, periodically patterned phosphorescent OLED pixels are thermally deposited on polyethylene terephthalate (PET) fibers coated with indium tin oxide (ITO) common electrodes, where complete passivation of the deposited organic constituents and subsequent formation of contact pads connected to the top electrodes of each OLED pixels are implemented to prevent the mechanical damage to the pixels as well as the water/oxygen permeation. The contact pads of OLED pixels on the OLED fibers can be electrically linked to the other perpendicular conducting fibers of data addressing lines by simply tailoring cross spots of layout design, which allows the successful operation of the resulting woven OLED fabric displays by the matrix addressing scheme. Details of fabrication strategy to enhance the reliability of matrix-addressable OLED fabric displays can provide technically compelling solution options for

**Emerging Designs for Polymer-Based Infrared Photodetectors**

Zhenghui Wu¹, Weichuan Yao¹, Hyunwoong Kim¹, Yichen Zhai², Jason Azoulay² and Tse Nga Ng¹;¹University of California, San Diego, La Jolla, California, United States; ²University of Southern Mississippi, Hattiesburg, Mississippi, United States.

The shortwave infrared spectral region (SWIR: 1-3 um) is particularly powerful for health monitoring and medical diagnostics, because biological tissues show low absorbance and minimal SWIR auto-fluorescence, enabling greater penetration depth and improved resolution in comparison to visible light. However, current SWIR photodetection technologies are largely based on epitaxially grown inorganic semiconductors which are costly, require complex processing and impose cooling requirements incompatible with wearable electronics. Organic semiconductors offer numerous advantages including large-area and conformal coverage, temperature insensitivity, biocompatibility, and low-cost integration for enabling ubiquitous SWIR optoelectronics. This talk will discuss organic SWIR devices and discuss the main bottlenecks associated with charge recombination and trapping, which are more challenging to address in narrow bandgap photodetectors in comparison to devices employing wider bandgap materials that operate in the visible.

As progress is made towards overcoming challenges associated with losses due to recombination and increasing noise at progressively narrow bandgaps, the performance of organic SWIR photodetectors is rising with detection exceeding 10⁻¹¹ Jones, comparable to commercial germanium photodiodes. The organic photodetectors are easily integrated within a wide range of portable systems spanning wearable physiological monitors to SWIR spectroscopic imagers that enable compositional analysis for food, water quality monitoring, and medical and biological studies. There are exciting opportunities for low-cost organic SWIR technologies to be as widely deployable and serve as an empowering tool for users to discover information in the SWIR to inspire new use cases and applications.

**8:30 AM EP04.12.02**

**Mechanically Tunable Nonlinear Dielectrics**

Deng Li Ko¹, Jie Jiang², Yu-Hong Lai¹, Pu-Wei Wu¹ and Ying-Hao Chu¹;¹Department of Materials Science and Engineering, National Chiao Tung University, Hsinchu, Taiwan; ²Key Laboratory of Low Dimensional Materials and Application Technology of Ministry of Education, Hunan, China.

In the past decade, strain engineering has been used to markedly manipulate characteristics of functional materials such as increasing tunability. However, the ways to apply strain reversibly into materials such as hydrostatic pressure, strong magnetic, electric and lattice mismatch are difficult to achieve in general environment and our daily life. In this study, in order to surmount this obstacle, we adopt flexible muscovite mica substrate to fabricate epitaxial (Ba₀.₅Sr₀.₅) TiO (BSTO) thin films with high and tunable dielectric constant via van der Waals epitaxy. The combination of X-ray diffraction and high-resolution transmission electron microscopy was conducted to reveal the heteroepitaxy of the BSTO/muscovite system. Due to the mechanical flexibility of muscovite sheet, the tunability of dielectric constant were highlighted by the capacitance-voltage measurement under various bending measurement which is ranging from 5–15 mm radius of curvature including tensile and compressive strain. In the bending measurement, the dielectric constant of BSTO thin films with different thicknesses was altered nonlinearly and reversibly from -77 % to 36 % compared to the unbent state. Such a system composed of flexible BSTO/muscovite heteroepitaxy delivers a new path way to apply mechanical strain on thin film system with tunable dielectric feature.

**From Chemistry to Mechanically-Adaptive Assemblies—Designs for Soft Thin-Film Electronics**

Stephanie Lacour and Jennifer MacRoy; Campus Biotech LSB1, Ecole Polytechnique Federale de Lausanne, Geneva, Switzerland.

Softness describes the ability of being easily shaped, conformal or folded. Stiff electronic materials may be engineered in thin, sub-micron thick, structures with 3D geometries to form electronic circuits with new form factors and reversible deformability. To increase further the circuits’ softness, a new class of materials, namely hydrogels, is emerging as a soft carrier for electronic devices. The versatility of hydrogel chemistry combined with their biomimetic properties inspires numerous applications in soft robotics, wearable and implantable electronics. However, their long-term integration within a functional electronic thin film assembly remains a challenge. In air, hydrogels dry progressively, leading to massive shrinkage of the organic network. Kept in water, they can swell up to more than ten times their initial volume thereby resulting in important mechanical stress at the interface with the electronic structure. In both cases, this significant volume change is not compatible with the cohesion of a multilayer system and has irreversible impact on the electronic properties.

This talk will report on our recent efforts to mitigate this mechanical and structural mismatch. We integrate a low-swelling type of hydrogel, the poly(2-hydroxyethyl methacrylate) [PHEMA] with thin-film electronics on polymer substrate. Because of a good balance between its hydrophilic and hydrophobic properties, we imagined a hydrogel-elastomer micrometric bilayer with a stable interface that can sustain multiple swelling-drying cycles. We will discuss the dynamic modifications of the mechanical properties of the bilayer from its initial dry state (stiff mechanical properties) to its soft and swollen state at equilibrium in wet environment. Combined with thin-film electronics technologies, this mechanically-adaptive hydrogel-elastomer assembly offers an exciting avenue for soft electronic circuits and neural devices.

**Acoustic Assembly of Electrically Conductive Particle Structures in Flexible Printable Composites**

Drew S. Melcher¹, Tyler Ray¹, Rachel R. Collino¹, Leanne Friedrich¹, Neil Dolinski¹, Matthew Begley¹ and Daniel S. Gianola¹;¹University of California, Santa Barbara, Santa Barbara, California, United States; ²Northwestern University, Evanston, Illinois, United States; ³Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Developments in 3D-printing of flexible and integrated electronic interconnects will enable advances in the design of soft robots and other emerging flexible electronics technologies. Printing flexible interconnects with high conductivity (>10⁵ S/m) faces challenges like post-process sintering steps, resolution limitations, viscosity requirements, and substrate incompatibility that limit production speed, scalability, and cost-effectiveness. One way to overcome these challenges is to print architected composite materials with microstructures engineered for high electrical conductivity at low particle loading. We demonstrate a novel approach to accomplishing this by employing a structure-assembly technique called acoustic focusing, in which microparticles suspended in a fluid are manipulated with pressure fields generated within a microfluidic printing channel coupled to piezoelectric actuators. This technique produces composites with embedded structures that have high electrical conductivity at low particle loading in the ink (as low as 0.5% by volume). These composites are 3D-printable, have good strain tolerance, and can be modulated on-the-fly during printing to have either anisotropic conductive, nearly-isotropic conductive, or insulating behavior.

Electrically conductive filler particles (here, carbon fibers and silver-coated fibers) are aligned and compacted into dense bundles 10-200 μm in diameter, which serve as electrically conductive networks integrated within the host material. Assembly control parameters (i.e. focusing driving frequency and amplitude) and ink properties (filler fiber length and volume fraction) are modulated to adjust the composite microstructure, and thereby material properties. We demonstrate that we can form composites with anisotropic electrical conductivity (on the order of 10⁵ S/m in the printing direction within assembled bundles which are insulated from each other in the perpendicular directions), nearly-isotropic conductivity, or fully insulating behavior all using the same precursor ink. Furthermore, assembly control parameters can be modulated mid-print, so that one can switch between printing anisotropic conductive, isotropic conductive, and insulating material within the same printed line of material.

Microstructural characterization of the resulting composites reveals that the anisotropic conductive composites consist of “wires” of compacted particles insulated from each other within the material, enabling each structure to be individually addressed. These materials have sufficient conductivity to carry currents of >100 mA without heat accumulation. Furthermore, we assemble these networks in elastomeric photopolymers to form flexible conductive composites that can withstand deformation to bending strains of >20% with...
9:30 AM EP04.12.05
High-Performance Stretchable Conductive Adhesives for Bio-Compatible Stretchable Electronics Youngpyo Ko1,2, Miju Jung1, Kyung Tae Park1, Jinwoo Oh1, Soo Jin Kim1, Jung Ah Lim1, Sang-Soo Lee1,2, Wansoo Huh1 and Heesuk Kim1; 1Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2KU-KIST Graduate School of Converging Science and Technology, Korea University, Seoul, Korea (the Republic of); 3Soongsil University, Seoul, Korea (the Republic of).

Stretchable conductive adhesives are one of the key elements in medical and wearable devices. Most interconnections of components in electronic devices have been made using Sn/Pb based solders or epoxy-based conductive adhesives. However, Sn/Pb based solders and epoxy-based conductive adhesives are not flexible and stretchable, thus leading to limitation their uses in various flexible and stretchable devices. Herein, we have demonstrated the silicone based conductive adhesive (SCA) that exhibits remarkably low resistivity of 1.5×10−4Ω cm. It maintains the electrical resistivity even when it is stretched by 2.2-fold increase in length. In addition, it shows the resistivity change of less than 3% after 3000 stretching cycles. The SCA shows excellent adhesion to various substrates such as polydimethylsiloxane (PDMS), thus enabling it to be used on various stretchable electronic devices. In order to demonstrate its versatility, the SCA has been applied to LED device as a stretchable interconnection material and electrode. Furthermore, the SCA has been used as an electrocardiogram electrode. These results indicate that the SCA with excellent adhesion to various substrates has great potential as stretchable interconnection materials and electrodes in stretchable and wearable electronics.

9:45 AM EP04.12.06
Flexible Conjugation-Break Spacers for Intrinsically Stretchable Polymer Semiconductors Jaewan Mun and Zhenan Bao; Stanford University, Stanford, California, United States.

Since the first discovery of semiconducting organic materials, tremendous effort has been made to improve their electrical properties. Their mobility exceeds that of amorphous silicon (>1 cm2 V−1 s−1), which makes them potential alternatives to inorganic electronic materials. Thanks to this significant improvement of electrical properties, research interest has now moved from mobility-oriented study to low-cost soft electronics. Along with the need for stretchable semiconductors for soft electronics, the development of intrinsically stretchable polymer semiconductors has gained much interest. However, the brittleness of conjugated polymers is a direct result of their semi-crystalline nature and rigid backbone structure. Furthermore, electrical performance and mechanical compliance of semiconducting polymers are usually inversely correlated. Thus, it is both important and challenging to develop stretchable semiconductors without sacrificing mobility. This presentation will focus specifically on using flexible conjugation breakers for stretchable polymer semiconductors. Non-conjugated spacers have been mainly utilized to enhance the solution processability of polymer semiconductors.[1-3] Reduced backbone rigidity arising from conjugation breakers can improve solution processability of semiconducting polymers. Several studies reported that these conjugation breakers can also tune mechanical properties of polymeric semiconductors.[2-3] Specifically, some non-conjugated spacers resulted in the improvement of ductility of semiconducting polymers; however, they accompanied significant compromise of electrical performance. Herein, we investigate the effect of flexible non-conjugated spacers on electrical and mechanical of semiconducting polymers.[4] Various conjugation breakers with different flexibility are synthesized and incorporated into diketopyrrolopyrrole (DPP)-based semiconductors. We show that more flexible spacers resulted in greater stretchability of semiconducting polymers without any noticeable decrease in mobility. Specifically, a dodecyl spacer exhibits both high crack onset strain of 100% and high mobility of >1.00 cm2 V−1 s−1. Furthermore, the polymer semiconductor containing the dodecyl spacer maintained much higher level of mobility than the fully conjugated counterpart under strain. Finally, fully stretchable transistors are demonstrated as a potential application of stretchable semiconducting polymers for wearable electronics. Such results show great potential for exploring conjugation-break spacers as a method of optimizing the performance of polymer semiconductors for soft electronics.

SESSION EP04.13: Soft Electronics—Manufacturing and Design I

Friday Morning, April 26, 2019
PCC North, 200 Level, Room 222 A

10:30 AM EP04.13.01
Controlled Component Positioning in 3D Thermofomed Electronics Andrés Vásquez Quintero, Herbert De Smet and Jan Vanfleteren; CMST, imec Ghent University, Gent-Zwijnaarde, Belgium.

There is a growing interest in integration of sensors and electronic circuits on irregularly shaped surfaces. These 2.5D circuits can be dynamically deformable (e.g. elastic) and adopt many shapes when no other forces than gravity act on it. They can also take a predetermined fixed shape without the action of external forces. In the latter case they can either still be deformable under external forces (e.g. a smart soft lens or shoe insole) or they can be rigid and non-deformable under moderate external forces (e.g. a car dashboard with integrated electronics). In any case, for the fixed shape circuits it is desirable that the production process allows for a precise control of the components positions on the 2.5D circuit surface. In order to achieve this, the circuit can be produced on a pre-shaped 3D carrier followed by assembly of the components on the 3D circuit. This approach is e.g. used in the 3D-MID technology. However, production of circuits and assembly of components on 3D carriers is time consuming, expensive and non-standard in industrial circuit production, where all processing steps, even for flexible circuits, are carried out on flat 2D substrates. In order to comply with these standard production technology the only way is to produce the circuit on a 2D flat carrier and as a final step deform it (e.g. by a thermofoming step) from flat to its final 2.5D shape. In this case, methods should be found to precisely predict and control the component position on the 2.5D surface, starting from their positions on the 2D surface, and taking into account the effects of different parameters in the thermofoming process. In this contribution, we will describe our approach to fabricate 3D thermofomed circuits and ways to control component positions. We have found that structuring the thermoplastic polymer in which the circuit is embedded before thermofoming, provides possibilities for this components position control. We have demonstrated this approach in smart lens applications where a thin-film circuit with assembled components (chip, antenna) is deformed from flat to a spherical shape.

11:00 AM EP04.13.02
Soft Electronic and Energy Devices Based-On Laser-Induced Porous Graphene Zheng Yan; Biomedical, Biological & Chemical Engineering, University of Missouri, Columbia, Missouri, United States.

Recent research reveals that transient CO2 laser heating can convert various polymer films into porous graphene (LIG) with continuous structures under ambient atmospheres. The process is rapid and automatic, and the motorized laser beam can write the computer-designed layouts of porous graphene on polymer substrates with precisely controlled patterns. Moreover, LIG has low sheet resistance (~ 10 Ohm per square) and large surface areas (~ 150 m2/g), which is therefore a promising conducting material for a broad range of electronic and energy devices. In this talk, I will introduce our recent research in exploring soft electronic and energy devices with unusual attributes using laser-induced porous graphene. First, we have successfully made porous, multifunctional on-skin sensors, consisting of LIG as device components and PDMS sponges as substrates. The device examples include electrophysiological sensors, hydration sensors, temperature sensors, and joule-heating elements. The porous geometries of the devices could facilitate perspiration transport and evaporation, and minimize discomfort and inflammation risks, thereby improving their long-term feasibility. Second, we have achieved the construction of various 3D hierarchical structures of LIG using mechanically-guided, 3D assembly approach. The well-designed, 3D hierarchical structures of LIG exhibit outstanding electromechanical properties. Mechanical loading, such as bending, stretching and compressing, has negligible effects on their electrical performances. The device examples
include highly-stretchable LED arrays and 3D supercapacitors with solid-state electrolytes.

11:15 AM EP04.13.03
Driving Crystallization on the Way to Polymer-Based, Heterogeneous Semiconducting and Electroactive Materials
Adam Kiersnowski1, Dorota Chlebosa2 and Krzysztof Janus2
1 Wroclaw University of Science and Technology, Wroclaw, Poland; 2 Mechanics and Composite Materials, Leibniz Institute for Polymer Research, Dresden, Germany

Most ionic conductors, such as polymer electrolytes, hydrogels and ionogels, are fully transparent over visible spectrum, intrinsically deformable and biocompatible. Such transmitters or modulate electron's behavior through electrical double layer (EDL), leading to novel functions which are impossible to realize within solid-state electronics.

Electroactive and semiconducting polymer materials attract attention because of their potential applications in e.g. sensors, actuators or energy harvesting, which are crucial in development of the wearable electronic devices. In order to take advantage of such materials it is necessary to control the charge generation and charge carrier transport through their volume. The crystal phases play key roles here: crystallinity and crystal sizes as well as polymorphism and crystal orientation have crucial influence on electric properties of electronic devices. Control over the materials performance can be achieved by controlling crystallization from the length scales characteristic of crystal unit cells up to microdomain morphology.1,2

In this work we showcase the crystallization in hybrid blends based on two semicyrstalline polymers: poly(3-hexylthiophene) (P3HT): the p-type semiconductor, and poly(vinylidene fluoride) (PVDF) with remarkable piezo- and ferroelectricity. Despite dissimilar in terms of the architecture of their main chains, these polymers have an important thing in common: crystallinity-driven electrical properties. Typically, PVDF and P3HT are used in the form of films or fibers being active parts of the devices. Polymorphism and orientation of crystals in such films can be controlled during their fabrication. In the case of the solution-based processing of pure polymers, the crystallinity can be controlled by tuning polymer-solvent interactions, aggregation of macromolecules in solution, and solvent evaporation rate.2 In the case of melt-processing, the crystallinity depends mainly on the cooling regime whereas the orientation of crystals is controlled by machine-induced shearing forces or mechanical deformation after the processing.3

Blending of either PVDF or P3HT with other materials typically leads to heterogeneous systems, where the crystallinity is additionally driven by interfacial phenomena like heterogeneous nucleation or epitaxy. These together with the aforementioned effects are particularly important in nucleating the preferred polymorphs. In PVDF the ferro- or piezoelectricity are observed only for polar crystal polymorphs, i.e. the crystal forms where the unit cells are non-centrosymmetric, as in the case of Form I or Form III resulting from e.g. nucleation by e.g. silver nanoparticles. In addition, nanoparticles with high aspect ratios such as nanoplatelets of organoclay have an ability to “direct” the diffusion of the polymer chains towards the crystal growth zones, which allows formation of the oriented PVDF crystals.4 Formation of the oriented crystals of P3HT can also be driven by anisotropic nanoparticles, such as needle-like nanocrystals of perylene diimides or graphene nanoribbons.5 In the case of P3HT, however, the formation of oriented crystals results from the specific interactions between the nanofibers and the polymer.6

The orientation of the polymer crystals can be further enhanced by thermally stimulated diffusion of polymer macromolecules to the crystal growth zones, which can be achieved by e.g. local laser heating. For this purpose we have developed Laser-Assisted Zone Crystallization technique (LAZEC) enabling solution crystallization of the polymers and other organic materials under controlled thermal conditions. Application of the LAZEC in crystallization of the blends with finely tuned composition enables a large-scale formation of continuous films with controlled polymorphism and spatial orientation of polymer crystals.

Inkjet-Printed Iontronics Based Conformable Transparent Touch Sensors for Human Machine Interface
Dace Gao1, Jiangxin Wang1, Kaixuan Ai1, Jiaqing Xiong1, Meng-fang Lin2,3 and Pooi See Lee2; 1School of Materials Science and Engineering, Nanyang Technological University, Singapore, Singapore; 2Enhanced Composites and Structures Centre, Cranfield University, Cranfield, United Kingdom

Iontronics is an interdisciplinary research topic which bridges ionics and electronics. In a hybrid iontronic system, the spatial and temporal distribution of ion species can either transmit signal or modulate electron's behavior through electrical double layer (EDL), leading to novel functions which are impossible to realize within solid-state electronics. Most ionic conductors, such as polymer electrolytes, hydrogels and ionogels, are fully transparent over visible spectrum, intrinsically deformable and biocompatible. Such remarkable optical and mechanical properties make them promising to serve as soft electrodes in applications where extreme optical transmittance or biological compatibility is stringently required. The strategy of incorporating ion conductive materials into electronic systems has enabled diverse iontronic devices spanning from artificial muscles, wearable sensors, energy harvesters, luminescent light emitters to biologically matched interfaces.

Emerging touch panels integrated in next generation wearable devices require the electrode material to be both skin-conformable and highly transparent, yet fatigue failure and sharp resistance increase are bottlenecks in stretchable and transparent electronic conductors. In this work, we demonstrated an inkjet printing-assisted iontronic touch panel with epidermal conformability and over 95% device-level light transmittance. Ionic electrolyte was directly “written” onto elastomer substrates as column and row electrodes to form a continuous films with controlled polymorphism and spatial orientation of polymer crystals.

Turning of the polymer crystals can be further enhanced by thermally stimulated diffusion of polymer macromolecules to the crystal growth zones, which can be achieved by e.g. local laser heating. For this purpose we have developed Laser-Assisted Zone Crystallization technique (LAZEC) enabling solution crystallization of the polymers and other organic materials under controlled thermal conditions. Application of the LAZEC in crystallization of the blends with finely tuned composition enables a large-scale formation of continuous films with controlled polymorphism and spatial orientation of polymer crystals.

Determining the Thermomechanical Properties of Polymer Semiconductors Supported on Elastomers
Runqiao Song1, Harry Schrick2, Nrup Balar, Salma Siddika and Brendan T. O’Connor; 1 Mechanical & Aerospace Engineering, North Carolina State University, Raleigh, North Carolina, United States

Polymer semiconductors are promising materials for stretchable electronics owing to the opportunity to tune mechanical behavior. For stretchable applications, the mechanical loading on these films is quite demanding, yet many important mechanical properties of these films related to their ability to operate over large strains has not been characterized in detail. This is due in part to the challenge of materials formulation, when forming ultrathin films, and the difficulty in measuring the mechanical properties of these films. While a large number of tools have been developed to probe ultrathin films, they all have limitations that inhibit a complete view of the film behavior. For example, the mechanical behavior of films under in-plane compression has not been captured well, which is a key part of a stretchable device that undergoes large cyclic strain. In this work, we demonstrated a novel mechanical testing technique is employed that is able to measure a broad array of mechanical properties of polymer thin films that include incompressive properties. The proposed approach consists of a polymer thin film laminated on a thin elastomer support that is then mounted in a dynamic mechanical analyzer (DMA). The elastomer provides support for the semiconductor film, but is thin enough that the properties of the polymer of interest are accurately captured. The elastomer support also provides a restoring force under large strain so that the film’s properties under compression can be obtained. By using a conventional DMA, variation in the load frequency, strain rate, and environment temperature can be used to extract detailed thermomechanical properties. In this presentation, we show the array of properties that this method can obtain from stress-strain curves under cyclic loading, to glass transitions, to stress relaxation master curves. Through this testing method, new insights into film behavior that lead to effective stretchable polymer semiconductors will be highlighted.
This presentation will describe our research efforts in developing materials for flexible and intrinsically stretchable electronic devices. A polymer composite comprising surface-embedded silver nanowires with high transparency, high surface conductivity, and low surface roughness is explored as a transparent electrode essential to the fabrication of deformable LEDs. Several electroluminescent materials are employed, including OLED, LEC, perovskite-polymer nanoocomposites.

High degrees of mechanical deformability in organic electronics (i.e., stretchability) have enabled a range of applications in energy and healthcare. These applications include large-area organic solar cells (via roll-to-roll solution printing), and wearable and implantable sensors (to allow intimate contact with biological tissues). But, polymers which have a high electronic performance and are mechanically compliant, biosafe, and easily processable remain difficult to obtain. Typically, the highest performing organic electronics are hard and undergo brittle fracture at low strains. Some of the strategies that have been reported to enhance the stretchability of conducting and semiconducting polymers include composites, blending with plasticizers, deposition on elastomers, formation of fibers and gels, and side chain engineering. While effective, each of these methods can have drawbacks in terms of biocompatibility, toxicity, ease of processing in solution, and electronic sensitivity to strain. Instead, we have investigated the use of block copolymers to obtain stretchable organic electronics. First, we reported the use of water-soluble poly(styrene sulfonate) block copolymers with poly(polyethylene glycol methyl ether acrylate) (PSS-b-PPEGMEA) as a scaffold for the conductive polymer poly(3,4-ethylenedioxythiophene) (PEDOT). The resulting conducting polyelectrolyte PEDOT:PSS-b-PPEGMEA has a toughness up to 10.1 MJ m⁻³ and can withstand elongations up to 128%. Second, we developed stretchable and degradable semiconducting block copolymers. By combining blocks of semiconducting diketopyrrolopyrrole (DPP) with insulating and flexible aliphatic poly(ethylene glycol) (PEG) blocks, we obtained materials that can be stretched >100%. Remarkably, the field-effect mobility of these block copolymers remains the same as the pure semiconductor.

In this talk, I will describe a new form of electronics with skin-like softness and stretchability, which is built upon a new class of intrinsically stretchable polymer materials and a new set of fabrication technology. As the core material basis, intrinsically stretchable polymer semiconductors have been developed through the physical engineering of polymer chain dynamics and crystallization based on the nanofluctuation effect. This fundamentally-new and universally-applicable methodology enables conjugated polymers to possess both high electrical-performance and extraordinary stretchability.[1] Then, proceeding towards building electronics with this new class of polymer materials, the first polymer-applicable fabrication platform has been designed for large-scale intrinsically stretchable transistor arrays.[2] As a whole, these renovations in the material basis and technology foundation have led to the realization of circuit-level functionalities for the processing of biological signals, with unprecedented mechanical deformability and skin conformability. Equipping electronics with human-compatible form-factors has opened a new paradigm for wearable and implantable bio-electronic tools for biological studies, personal healthcare, medical diagnosis and therapeutics.[3]

References

Upon designing high performance polymer semiconductors, degree of polymerization or molecular weight is an important polymer property that greatly affect the resulting polymer physical properties. The polymer chain length can directly influence on the morphology, packing and degree of crystallinity based on the polymer conformation and the dominating thermodynamics driving force (enthalpic vs entropic). The packing structures, especially p-p stacking distance, crystalline domain size and distribution have significant impact on not only charge transport but also thin film mechanical properties, such as modulus, ductility and deformability. Until now, it is very difficult to realize a fully conjugated rigid backbone with significant repeat units for study of the relationship between electronic performance, mechanical endurance, and molecular weight in the research community. Here we present the successful synthesis of diketopyrrolopyrrole (DPP)-based semiconducting polymers with controllable molecular weight over a wide range from approximately 20 to 100 kDa, realizing both high molecular weight and high solubility at the same time. The effects of strain on polymer thin film microstructures (alignment of polymer chains, change in crystalline domain size, degree of crystallinity and orientation), moreover, is investigated and a charge carrier mobility over up to 2 cm²V⁻¹s⁻¹ is achieved. Thanks to the relatively high molecular weight in our new polymer system, large-area biaxially stretched polymer thin film is firstly developed with superior electrical performance in stretchable devices.
Soft, noninvasive and multifunctional epidermal electronics (a.k.a. electronic tattoos or e-tattoos) have demonstrated many applications in mobile health, athletic training, human-machine interaction (HMI) and so on. However, e-tattoos are only practically useful when they are low cost and wireless. Previously, our group has invented a dry and digital manufacturing approach called the “cut-and-paste” method for the rapid prototyping of e-tattoo sensors using a paper/vinyl cutter plotter. The cut-and-pasted e-tattoos are low-cost and can be used to measure a variety of physiological signals such as electrocardiogram (ECG), skin hydration, skin temperature and so on. To make the e-tattoos go wireless, we now report the “cut-solder-paste” process to incorporate integrated circuits (ICs) such as chips for near field communication (NFC) or Bluetooth Low Energy (BLE). The key is to come up with a temporary adhesive that can survive solder-reflow temperature up to 240 degree C. To overcome the limited patterning resolution of mechanical cutter plotters and to recycle the IC chips, we propose a modular concept in which the communication layer, the readout circuit layer, and the sensor/electrode layer are fabricated individually and stacked up as the final step of fabrication. The thickness of a fully assembled multilayer e-tattoo (excluding IC chips) is less than 200 um and the overall stretchability is still beyond 20%. In addition to already mentioned capabilities, such wireless e-tattoos can also track motion, mechano-acoustic heart signals, and oxygen saturation (SpO2). The NFC-enabled e-tattoos can be wireless charged so no battery is needed but the sampling rate is limited to 25 Hz and the wireless communication distance is limited to 5 cm. The BLE-enabled e-tattoos require on-tattoo batteries but the sampling rate can be up to 4 kHz and the wireless communication range can be up to 10 m. We demonstrate that the different layers can be disassembled and reassembled multiple times. After disassembly, the communication and readout circuit layers are reusable and can be reassembled with different sensor/electrode layers. The wireless and reconfigurable capabilities and the low-cost, rapid prototyping method together represent exciting advancement towards practically useful e-tattoos.

3D Designed Sensor Systems with Complex Form Factors
Woo Soo Kim; School of Mechatronic Systems Engineering, Simon Fraser University, Surrey, British Columbia, Canada.

This talk will summarize recent research activities on 3D printed soft electronics in the Additive Manufacturing laboratory, Simon Fraser University. Design, fabrication and characterization of 3D printed soft sensor systems including ion selective electro-chemical sensors, 3D printed circuit boards for portable electro-chemical sensing applications will be discussed. 3D printing enables custom design of smart 3D form factors that enable electronics to be integrated into unique places. Different electro-chemical sensor platforms such as ion-selective field effect transistor and disposable wireless RF circuits have been developed for the portable electronic applications. It is shown that 3D design integration can significantly accelerate the hybridization with the fabrication process of conventional electronics, and merge its capability into portable sensor applications.

4:30 PM  EP04.15.03
Fiber Assembly-Based Concurrent Multimodal and Multifunctional Sensors for e-Textiles
Ashish Kapoor1, Michael McKnight2, Kony Chatterjee1, Talha Agcayazi1, Hannah Kausche2, Alper Bozkurt2 and Tushar K. Ghosh1; 1Department of Textile Engineering, Chemistry and Science, North Carolina State University, Raleigh, North Carolina, United States; 2Electrical and Computer Engineering, North Carolina State University, Raleigh, North Carolina, United States.

Soft polymer-based sensors as an integral part of textile structures have attracted considerable scientific and commercial interest recently because of their potential use in healthcare applications, security, structural health monitoring, and other applications where flexible, conformable sensors are required. While electronic sensing functionalities can be integrated into textile structures at any one or more of the hierarchical levels of molecules, fibers, yarns, or fabrics, arguably a more practical and inconspicuous means to introduce the desired electrical characteristics is at the fiber level, using processes that are compatible to textiles. Fiber-based sensors have been developed using a variety of materials such as polyethylene glycol (PEG), Kevlar, and polydimethylsiloxane (PDMS) which are doped with conductive particles such as silver, platinum, and carbon particles. A variety of techniques such as fiber extrusion, conductive coating of fibers, and 3D printing have been used to develop these sensors. Here, we report a prototype fiber-based sensor capable of multimodal and multifunctional sensing, formed within a typical woven textile structure. This is achieved by developing bicomponent fibers with ordered electrically insulating and conducting domains, composed of PDMS composites. The multifunctional characteristics of these sensors are successfully demonstrated by measuring their response to tactile, tensile, and shear deformations, as well as by their capability to detect wetness and report biopotential response. While the unobtrusive integration of sensing capabilities offers possibilities to preserve all desirable textile qualities such as comfort, flexibility, and conformability, this scaled-up fiber-based approach demonstrates the potential for scalable and facile manufacturability of practical e-textile products using extrusion-based processing of flexible sensor systems, and can be remarkably effective in advancing the field of electronic textiles (e-textiles).
bionestistic microvascular networks within mesoscale hydrogels. Our group has also pioneered bottom-up approaches to generate tissues by the assembly of shape-controlled cell-laden microgels (i.e. tissue building blocks), that resemble functional tissue units. In this approach, microgels were fabricated and seeded with different cell types and induced to self-assemble to generate 3D tissue structures with controlled microarchitecture and cell-cell interactions.

11:00 AM EP05.01.02 Fabrication of Neurobiological Circuits Liang Guo; The Ohio State University, Columbus, Ohio, United States.

Building new capabilities for the control of biological systems using embedded controllers made of biological parts to program system-level behavior holds tremendous promise to address a wide scope of both civilian and military needs. However, to date, the creation of artificial neuronal circuits that aim to perform specific functions has been proceeding at a rather slow pace due to a number of technical challenges. In order to hack the biological intelligence for behavioral and metabolic control, this work discusses the rational paths to move this field forward. Specifically, circuit design, simulation, and fabrication need to complement with new theory development to provide rational designs with optimal performance. We embody this approach through forward-engineering of simple analogs to innate neural circuits. As a first attempt, we choose to hack the Aplysia’s gill-withdrawal reflex circuit, a well-elucidated one composed of easily identifiable large neurons, so that the technical hurdles are minimized and we can focus on revealing the engineering principles and developing the engineering capability. Specifically, we identify and harvest these big neurons and reconstruct the circuit on a microelectrode array (MEA) by precisely placing and wiring the neurons according to their innate anatomical map in a photo-patterned biomaterial scaffold. The MEA is used to program long-term sensitization into this circuit and monitor its internal states. Ultimately, the advances in fundamental understanding and capabilities resulting from this project will create new opportunities for harnessing this promise of engineered biological systems for human use. The success and extension of this platform technology can have broad impacts on the advancement of medical devices, bio-robots, and human augmentation.

11:15 AM *EP05.01.03 Engineered Disease Models with Aged Tissue Microenvironments Pinar Zorlutuna; University of Notre Dame, Notre Dame, Indiana, United States.

The fact that the most significant life-threatening diseases of our times such as Cardiovascular Diseases (CVD) or Cancer remains the number one killer for over a century suggests that, despite the advancements in science and medicine over the years, there is a huge gap in translating these scientific findings to clinical setting. One of the major reasons for this gap is pre-clinical research’s heavy dependence on young animal models despite the fact that aging is the biggest risk factor for these diseases. For example, the average age for first heart attack is 65.3 years for males and 71.8 years for females, and most breast cancers develop in a postmenopausal, aged mammary gland tissue microenvironment at age of 62. Yet, due to the logistical limitations, current pre-clinical research predominately relies on experimental animals with a human-equivalent age of less than 35 years, which does not faithfully replicate the clinically prevailing aged tissue microenvironment. With increasing appreciation of the role of the tissue microenvironment in regulating disease progression and the response to therapeutics, there is an urgent need to develop, optimize and validate a novel 3D culture systems that fully recapitulates the aged tissue microenvironment in order to reproducibly model natural disease progression.

Here we present the first human induced pluripotent stem cell (hiPSC)-derived cardiomyocyte (iCM)-based, in vitro aged myocardial tissue model as an alternative research platform. Within 4 months, iCMs go through accelerated senescence and show cellular characteristics of aging. Furthermore, the model tissues fabricated using these aged iCMs, with stiffness resembling that of aged human heart, show functional and pharmacological deterioration specific to aged myocardium. We characterized hiPSC-derived cardiomyocytes (iCMs) over a prolonged culture period and determined that maturation process reaches a limit around 55 days in culture and is followed by a functional deterioration at late stages of culture (after 100 days). We show, for the first time, an in vitro aged, human-origin cardiac tissue model that is both physiologically and pathologically relevant for studying CVD such as MI. We achieved this by incorporating iCMs at the late stages into matrices with aged human heart stiffness. We show that late iCMs at cellular level and the respective tissue models at tissue level behave similar to aged human hearts, showing age-related responses, including altered gene expression and proliferative properties, impaired functional properties and stress response, decreased sensitivity to therapeutics and lower long-term viability. Our novel tissue model with age-appropriate physiology and pathology presents a promising new platform for investigating CVD or other age-related diseases.

11:45 AM EP05.01.04 Forward Design, Fabrication and Programming of Multi-Cellular Biomachines Using Neurons and Muscles Rashid Bashir; Department of Bioengineering, Carle Illinois College of Medicine, Micro and Nanotechnology Laboratory, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

The integration of living cells with 3D printed soft scaffolds can enable the realization of biomachines for soft robotics and hyper-tissue engineering. Here, we will present our group’s recent efforts towards increasing force in miniature biological robots, and efforts towards integrating neural control in these biological machines. We have developed biological locomotive systems that show millinewton forces capable of driving locomotion at speeds above 0.5 mm s⁻¹. The high force was achieved by combining a ring and strip muscle design to result tissues with increased muscle cell alignment, redesign of the scaffolds, and optimized processes for cell differentiation. We also present approaches for creating neural tissue from mouse embryonic stem cell derived motor neurons that could be created within a scaffold and then integrated with these biological robots towards neuronal control. We also study neuronal plasticity in these in-vitro networks by taking advantage of optogenetic mouse embryonic stem cells, in order to start stimulation as soon as the neural progenitor stage of differentiation. We also characterized the effects of stimulation during neural differentiation, by showing morphological changes in network formation and we were also able to show that the modulations in network function could be traced back to alterations to gene expression in response to such stimulation. Such complex cellular systems will be a major challenge for the next decade and beyond, requiring knowledge from tissue engineering, synthetic biology, micro-fabrication and nanotechnology, systems biology, and developmental biology. As these “biological machines” increase in capabilities, exhibit emergent behavior, and potentially reveal the ability for self-assembly and self-repair, questions can arise about the ethical implications of this work. These devices could have potential applications in drug delivery, power generation, and other biomimetic systems.

SESSION EP05.02: Multicellular Systems and Technologies II
Session Chairs: Rashid Bashir and Liang Guo
Tuesday Afternoon, April 23, 2019
PCC North, 200 Level, Room 226 B

1:30 PM *EP05.02.01 Emergence of Hierarchy and Functions from Cell Clusters In Vitro Taher Safi1, 2, Orn Aydin1 and Umnia Doha1; 1University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 3Bioengineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Most biological systems evolve through multiple stages of hierarchical multiplication. Individual components at a given hierarchy interact with one another to arrive at the next hierarchy with increased complexity and functionality. For example, organs and their functions emerge through interactions and cross-talk between individual cells and extracellular matrix. The rules of interactions between living biological components at various hierarchies and spatio-temporal scales are only partially understood at best. Here, we first address the question: is there a critical distance between cells necessary for the crosstalk? We address the question by considering two cell types, fibroblasts and muscle cells (C2C12) independently. We mix fibroblasts and collagen-1 and form free-discs. We find, consistent with literature, that the discs contract due to cell-ECM-cell interactions. However, compaction initiates only when the cell density exceeds a critical threshold value. We find a similar critical density for compaction in case of C2C12 cells. We differentiate the compacted C2C12-ECM tissue to myotubes when they generate force, both static and dynamic. We then plate a cluster of stem cell derived neurons in the vicinity of the muscle strip. These neurons interact with one another and form a neural network which fires in synchronous bursts. Some of these neurons are motor neurons. They innervate the muscle tissues and stimulate them in a synchronous fashion. The approach of the motor neurons towards muscle is also guided by the interactions between them possibly mediated by
soluble factors. Thus, interactions between muscle cells led to myotubes, and interactions between neurons resulted in a neural network, each arriving at a hierarchy and functionality distinct from their individual components. Finally, cross-talk between myotubes and neural network resulted in a neuro-muscular unit with complex functionality involving both sensing and actuation. Such a unit is applied to develop a living swimmer at low Reynolds number.

2:00 PM *EP05.02.02
On-Chip Interrogation of Neural Activity in Complete Nervous Systems Jacob T. Robinson; Rice University, Houston, Texas, United States.

Observing the activity of the entire nervous system as an animal responds to chemical and physical queues could reveal the fundamental principles of sensory information processing in dynamic networks of spiking neurons. Conveniently, millimeter-sized transparent organisms like C. elegans and Hydra can be manipulated on-chip using microfluidic technologies raising the prospect of high-throughput interrogation of the entire animal brain in well controlled environmental conditions. Here we describe how electrical, optical, and chemical interrogation capabilities can be integrated into scalable microfluidic devices that allow us to investigate neural information processing at the whole-brain level in living organisms. Experiments that exploit the on-chip technologies described can help reveal how adaptive networks of neurons provide robust control of animal behavior.

2:30 PM BREAK

3:00 PM *EP05.02.03
Organ-on-a-chip—Self-Rolling 3D Biosensors for Electrical Interrogations of Engineered μtissues Anna Kalmykov1, Sahil Rastogi1, Changjin Huang2, Arif M. Abdullah3, Jacqueline Billey1, Daniel Shiwarski1, K Jimmy Hsia1, Adam Feinberg1 and Tzahi Cohen-Karni1; 1Carnegie Mellon University, Pittsburgh, Pennsylvania, United States; 2Nanyang Technological University, Singapore, Singapore.

Since Hodgkin and Huxley’s seminal work (1952) on the electrical activity of giant squid neurons, studies of electroactive cells and tissue have been carried out using a variety of recording techniques, including glass micropipette patch-clamp electrodes, voltage-sensitive dyes, multielectrode arrays (MEAs), and planar field-effect transistors (FETs). However, multisite, simultaneous, three-dimensional (3D), and long-term electrophysiological investigation of an engineered tissue has not been possible using these technologies. Specifically, (1) voltage/ion sensitive dyes are toxic to the cells and limited in volume (3D) measurements, (2) patch clamp technique is limited by its recording sites, (3) both patch clamp and voltage sensitive dyes are limited to few minutes to hours, thus do not allow long term electrophysiological investigation of the tissue state, (4) planar FETs and MEA use established microfabrication methods to allow multiplexed detection on a scale not possible with micropipette technology, both exhibit relatively large detection areas confined to 2D substrates that render both cellular and subcellular and 3D electrical recording immensely challenging. We report a self-rolling 3D biosensors array for multiplex, simultaneous electrical measurements from excitable tissues in 3D with subcellular spatial resolution and μsec temporal resolution. Our approach directly monitors the electrical activity of microscale tissues (μtissues, ca. 300μm) engineered from induced pluripotent stem cell (iPSC) derived cardiomyocytes.

3:30 PM EP05.02.04
Microfiber-Guided Fabrication of Accurately Wired Neural Circuits Yu Wu, Meijian Wang, Huiran Yang, Hao Qi, Benjamin Seicol, Jordan Prox and Liang Guo; The Ohio State University, Columbus, Ohio, United States.

Functional biological devices made from living cells have the advantage of much less foreign body responses than non-biological implants. To engineer such neurobiological circuits, research to date still stays on the level of random neural patterning without knowing the function of each neuron, whereas neurons are precisely wired and functionalized in intact animals. As a result, the missing recognition of both components’ functions and connections becomes a major obstacle for rational design of neurobiological circuits. Based on the finding that neurite growth can be guided by microfibers, we developed a patterning technique enabling alysia neurons to be precisely wired with each other without cross-communication. We implement a microfiber scaffold using photolithographically fabricated SU-8 microfibers combined with selective surface coating of poly-l-lysine. Our results show that axons of alysia neurons adhere to the side walls of microfibers and grow along to reach to adjacent target neurons. This simple and effective technique enables rational design and functional fabrication of neurobiological circuits as potential living neural implants.

3:45 PM *EP05.03.05
Bottom-Up Approaches for Controlling Cell Behavior—Interfacing Synthetic Biology and Biomaterials Tara L. Deans; Department of Biomedical Engineering, The University of Utah, Salt Lake City, Utah, United States.

All tissues are composed of lineage committed cells and an extracellular matrix (ECM) that is secreted and maintained by the surrounding cells. Stem cells are an important cell population for tissue maintenance, regeneration, and repair because they have the ability to replenish their own population, and to differentiate into a number of cell types to restore tissue function. Both intrinsic as well as extrinsic mechanisms have been shown to be involved with the regulation of stem cell self-renewal and differentiation, and this interplay between intrinsic and extrinsic cues has made it difficult to direct an entire population of stem cells toward a desired lineage. This talk will describe approaches for interfacing synthetic biology and materials science to engineer genetically interactive biomaterials and programmed ECMs to control intrinsic and extrinsic cellular events to control cell behavior. Altogether, these novel approaches can be used to improve cell fate outcomes, in addition to reprogramming terminally differentiated cells to function as novel therapeutic diagnostic and delivery vehicles.

8:30 AM *EP05.03.01
Acoustic Biomolecules for Non-Invasive Ultrasonic Imaging and Control of Cellular Function Mikhail Shapiro; California Institute of Technology, Pasadena, California, United States.

The study of biological function in intact organisms and the development of targeted cellular therapeutics necessitate methods to image and control cellular function in vivo. Technologies such as fluorescent proteins and optogenetics serve this purpose in small specimens or surgically accessed tissues, but are limited by the poor penetration of light. In contrast, most non-invasive techniques such as ultrasound and magnetic resonance imaging – while based on energy forms that penetrate tissue effectively – are not effectively coupled to cellular function. Our work attempts to bridge this gap by engineering biomolecules with the appropriate physical properties to interact with magnetic fields and sound waves. In this talk, I will describe our recent development of biomolecular reporters and actuators for ultrasound. The reporters are based on a unique class of gas-filled protein nanostructures from buoyant photosynthetic microbes. These proteins produce nonlinear scattering of sound waves, enabling their detection with ultrasound. I will describe our recent progress in understanding the biophysical and acoustic properties of these biomolecules, engineering their mechanics and targeting at the genetic level and expressing them heterologously as acoustic reporter genes. Our actuators are based on temperature-dependent transcriptional repressors, which provide switch-like control of bacterial gene expression in response to small changes in temperature. This allows us to use focused ultrasound to remote-control engineered bacteria in vivo. Finally, I will describe how we have used ultrasound in combination with viral vectors and engineered receptors to provide spatially and cell-type specific non-invasive control over neural activity.

9:00 AM *EP05.03.02
Microfluidics Synthesis of Gene Silencing Cubosomes Hojun Kim and Cecilia Leal; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

The design of nanoscale reservoirs for efficient delivery of drugs and nucleic acids to cells is an enduring challenge in materials for medicine. Drug-loaded liposomes have enabled numerous FDA approved systems for several diseases. However, many of the applications of molecular materials are often discontinued. This is because they fail to deliver cargo
Multiple Mechanisms of Short-Term Presynaptic Plasticity Realized in Peptide-Doped Biomembranes

Joseph S. Naijen1,2, Patrick Collier1 and Stephen A. Sarles2; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2The University of Tennessee, Knoxville, Knoxville, United States.

It is through modifications of synaptic transmission (i.e., synaptic plasticity) between neurons that the brain is capable of adapting, learning, and modifying its functions in response to stimuli. Synaptic transmission can be either enhanced or depressed by brain activity, and these changes can last from milliseconds to a lifetime. They can occur in the form of short-term plasticity, which we demonstrated that insulative lipid membranes formed at the adjoining interface of lipid-coated aqueous droplets in oil exhibit memory capacitance stemming from voltage-driven modulation in the area and thickness of the hydrophobic core of the membrane. We show how introducing spontaneous, pore-forming, gramicidin peptides into the insulating lipid membrane creates conductive pathways—transforming the inherently memcapacitive device into a memristor that exhibits a pinched hysteretic current-voltage relationship. Experiments are performed to characterize the sensitivities and dynamics of membrane geometry changes and channel forming kinetics in response to voltage. Further, we developed a mathematical model that describes the physical states (membrane area, thickness, and channel kinetics) of the system involved in the memristive response. From both, we learn that the kinetics of channel formation by gramicidin peptides are extremely fast in comparison to the rates of dynamic modulations in bilayer area and thickness—suggesting that hysteresis and memory are dominated by the rates of change in membrane geometry. Our modular peptide doped bio-membrane also exhibits short-term synaptic-like facilitation and depression, emulating mechanisms of short-term plasticity exhibited by ion channels in pre- and post-synaptic neurons. Thus, our findings forecast an alternative paradigm of smart hardware using soft materials with simple composition and fabrication yet capable of providing inherent synaptic properties.
While it is clear that bacteria in the gut can impact brain function, many fundamental questions about the information processing along the brain-gut-axis remain. We developed a unique model for probing the earliest in-vivo brain-body interface, using Xenopus laevis (frog) developmental model, revealing that the nascent brain, even before being fully formed, contains and sends instructive information for morphogenesis of remote tissues. This brain-body information interchange is mediated by ancient bioelectrical mechanisms, suggesting the possibility of a well-conserved computational code that could be shared by the microbiome. Our latest results demonstrated communication between brain and pathogenic bacteria, showing that the brain is involved in regulation of innate immune response to infection. Transcriptome data indicate pathways and sub-networks involved in brain-dependent and brain-independent regulation of the infection, proposing several novel targets for top-down control of information processing across different scales of biological organization. We are thus undertaking a computational analysis of the information content of the cross-talk between bacteria and neurons in vitro. Using techniques from neuroscience, biophysics, molecular biology, synthetic bioengineering, and information theory, we are developing and fabricating the first integrated electrical-optical brain-bacteria interface (BBI), a multi-site stimulation and recording platform specifically suited to extract information in real-time across highly diverse biological entities. The BBI is a microfluidic, optogenetic, and electrophysiological platform consisting of i) a cultured vertebrate brain or brain organoid, ii) a bacterial biofilm, and iii) a closed-loop software-controlled actuation and sensing system which extracts bioelectrical measurements from the brain and the bacteria under a series of real-time perturbation and uses mutual information analysis to determine how much each side knows about what is happening to the other. Currently, we are validating the health of the two biological components (long-term co-culture of neurons and bacteria), verifying that we can read and write information into the system. We are monitoring information transfer both optically, through fluorescent genetically-encoded ion reporters, and electrically, through the design and constructing of customized micro-electrode-array on microfluidic chambers. Chemical stimuli (drug screening) are provided via microfluidics. Next steps will characterize the communication channel and generate a quantitative model of cross-level communication. Finally, we will manipulate and re-write active communication between components to test and refine specific hypotheses. The extraction of informational content from signaling between prokaryote and metazoan systems will produce exciting new knowledge of both basic and applied (biomedical) impact, bridge a capabilities gap that establishes a new direction for synthetic bioengineering, and serve as an enabling technology and proof-of-principle analysis that many other labs will be able to use to addressing major challenges from different perspectives (from cellular/biological or synthetic constructs to multicellularity and evolution).

**Will We See Gigahertz Organic Transistors?**

Hagen Klauk; Max Planck Institute for Solid State Research, Stuttgart, Germany.

Despite all efforts to advance the performance of organic transistors, their transit frequencies remain far below 1 GHz. The reason is that previous efforts have focused mainly on parameters that have little or no impact on the high-frequency performance. By analyzing the fundamental equations for the transit frequency, the requirements for gigahertz performance are derived. Not surprisingly, the critical parameter in this quest is not the charge-carrier mobility, but the contact resistance.

11:00 AM *EP06.01.02*

**Understanding Tunnel Currents in Organic Transistors—From New Theoretical Models to New Devices**

Shiyi Liu1, Akram Al-Shadeedi2, Max Tietze2, Chang-Min Keum3 and Bjorn Lüssem1; 1Kent State University, Kent, Ohio, United States; 2Center for Surface Chemistry and Catalysis, University of Leuven, Leuven, Belgium; 3School of Physics & Astronomy, University of St Andrews, St Andrews, United Kingdom.

A thorough understanding of tunnel currents in disordered organic semiconductors is essential to understand charge transport and injection into disordered organic semiconductors1–3. Furthermore, tunnel currents provide an additional parameter space to design novel devices, e.g. organic Zener-Diodes4,5, AC-driven OLEDs6, or inversion type OFETs7–9. In this presentation, we introduce a generic model to describe HOMO to LUMO tunneling in organic Zener diodes is presented. It is shown that the particular shape of the density of states in the organic layer determines the breakdown voltage in these diodes. Furthermore, the ideality factor of the diodes is shown to be limited by the width of the density of states and the roughness of the organic layer.

Based on this model, approaches to widen the design space of organic field-effect transistors are discussed. It is shown how HOMO to LUMO tunneling can be used to facilitate ambipolar injection and generation of minority charge carriers in organic field-effect transistors. Furthermore, the design and performance of Organic Field-Effect Transistors is presented and ways to improve their performance are discussed.

Flexible FET-Type Sensors Based on Nanoscopically Engineered Organic Semiconducting Materials

Enrique D. Gomez; The Pennsylvania State University, State College, Pennsylvania, United States.

We have recently demonstrated approaches that tune the molecular structure to suppress energetic disorder at interfaces and suppress coherent lattice vibrations in small molecule semiconductors to enhance charge mobilities. We control chain conformations within high-k fluorinated polymers, minimize energetic disorder at the dielectric—semiconductor interface, and enhance charge mobilities in rubrene single-crystal devices. Copolymerization of vinylidene fluoride and bromotrifluoroethylene (VDF-BTFE) monomers yields photopatternable, high-k fluoropolymer poly(vinylidene fluoride-bromotrifluoroethylene), (PVDF-BTFE). BTFE moieties allow crosslinking through thermal- or photocuring, and crosslinking of polymer chains perturbs the chain conformations within the polymer films. Devices incorporating hot-pressed, crosslinked (P(VDF-BTFE) as the dielectric and rubrene single crystals as the active layer exhibit lower interfacial trap densities compared to SiO2 and other polymer dielectrics, as well as charge mobilities exceeding 10 cm²/Vs. These charge mobilities are more than an order of magnitude higher than mobilities of rubrene single-crystal OFETs comprising poly(vinylidene fluoride-tetrafluoroethylene) (PVDF-TrFE) copolymers as gate insulator layers, and are the highest charge mobilities reported to date for devices incorporating high-k (k > 3) polymer dielectrics. Furthermore, we show that alkyl side chains can disrupt key modes of lattice vibrations that limit transport. We explore a model series based on [1]benzothieno[3,2-b][1]-benzothiophene (BTBT) derivatives where we systematically add one or two octyl side chains. Single crystal field-effect transistors made from these materials show an enhancement in hole mobilities by nearly three orders of magnitude upon addition of alkyl side chains in active layer materials. Quantum calculations based on the static structure cannot predict this large variation in charge mobilities. Instead, melastatic neutron scattering spectra (of deuterated BTBT derivatives) show that the addition of alkyl side chains suppresses picosecond intermolecular lattice vibrations, thereby enhancing charge mobilities in devices. Thus, although a trade-off has been hypothesized between disrupting charge transport and enhancing solubility due to the addition of alkyl side chains, we instead show that the addition of alkyl side chains can enhance charge mobilities by multiple orders of magnitude.

Organic electronics is a valuable technology for the development of novel applications in different fields, ranging from bioelectronics to smart packaging and displays. Transparency and compliance are often fundamental features for an effective device functionality and integration into complex systems. Several examples of organic devices, including diodes and Organic Field-Effect Transistors (OFETs) on transparent and ultra-flexible substrates, have been reported in literature. In the case of OFETs, however, the fulfillment of these characteristics is often related to the employment of small area, small throughput techniques which are not suited for the final development of complex applications and possibly up-scaleable for production. Moreover, low voltage operation is complex to be obtained with cost-effective, large area techniques, in particular when organic materials are employed in order to improve transparency of devices. As a matter of fact, low voltage transparent OFETs fabricated using cost-effective, large area techniques with enhanced transparency and conformability are absent in literature. Nevertheless, filling such a gap is fundamental in order to obtain fully functional systems that can be effectively employed in bioelectronics and electronics applications.

Here, an original approach for the fabrication of transparent, low voltage, all-organic FETs by means of large area techniques is presented. Two cost-effective, large-area techniques easily up-scaleable to an industrial size, namely inkjet printing and chemical vapor deposition, were employed for device fabrication. In particular, inkjet printing was used for patterning transistor electrodes using a PEDOT:PSS-based commercial ink, and for the deposition of the p-type, organic semiconductor, namely TIPS pentacene, from a custom-made solution. Chemical Vapor Deposition was used for the deposition of the organic insulator, namely Parylene C, in a uniform, 200-nm thick film allowing the low voltage operation. The overall transistor structure is perfectly transparent, as demonstrated by absorbance characterization in the range of visible light. More than 50 devices have been successfully fabricated over 175um-thick polyethylene terephtalate (PET) substrates: electrical characterization carried out before and after transferring on the skin demonstrated that the device functionality is perfectly maintained. Moreover, the ultra-thin OFETs were employed for the fabrication of basic electronics circuits, such as pseudo-CMOS inverters, which were successfully tested on skin. These results pave the way for the development of transparent organic electronics for different kind of applications, including bioelectronics and tattoo-like electronics.

Achieving Ultra-Low Turn-On Voltages in Organic Thin-Film Transistors—Investigating Fluoroalkyl-Phosphonic Acid Self-Assembled Monolayer Hybrid Gate Dielectrics

Rachana Acharya; 1 Boyu Peng; 1 Paddy K. L. Chan; 2 Guido Schnitz; 2 and Hagen Klauck 1; Max Planck Institute for Solid State Research, Stuttgart, Germany; 2 Institute of Materials Science, University of Stuttgart, Stuttgart, Germany; 1 Department of Mechanical Engineering, University of Hong Kong, Hong Kong, Hong Kong.

The optimization of organic thin-film transistors (TFTs) to address specific analog and digital circuit design requirements depends heavily on the choice of the materials employed, particularly the organic semiconductor and the gate dielectric. For a particular organic semiconductor, the performance must be reviewed with different combinations of substrate material, fabrication conditions and the choice of the gate dielectric material in order to achieve the optimum TFT characteristics for particular device and circuit needs. We have fabricated and characterized organic TFTs using the small-molecule organic semiconductor 2,7-diphenyl[1]benzothieno[3,2-b][1]-benzothiophene (DPh-BTB) [1] in combination with a hybrid gate dielectric composed of aluminum oxide and a fluoroalkyl-phosphonic acid self-assembled monolayer. We find that the optimum substrate temperature during the vacuum deposition of the DPh-BTBT layer depends on the type of substrate on which the organic TFTs are fabricated. For vacuum-deposited DPh-BTB to form a clear layer with the highest possible charge-carrier mobility, the semiconductor deposition should be carried out with the substrate held at a temperature of 100°C on silicon substrates...
and without substrate heating on flexible plastic substrates. XRD measurements indicate different orientations of the DPh-BTBT molecules under different fabrication conditions, which can be correlated to the TFT performance. Furthermore, fluoroalkyl-phosphonic acids with fluoroalkyl chain lengths ranging from 6 to 14 carbon atoms have been used to vary the thickness of the self-assembled monolayer in the gate dielectric, and its influence on the TFT characteristics has been studied. The fluoroalkyl terminal groups facilitate a shift of the TFTs turn-on voltage [2] in a deterministic manner, e.g., to exactly 0 V, if so desired from a circuit-design perspective, while taking advantage of the possibility to optimize the other TFT parameters by selecting the optimum fluoroalkyl chain length. We find that a medium fluoroalkyl chain length (10 carbon atoms in the fluoroalkyl chain) leads to the highest charge-carrier mobility (0.4 cm²/Vs on flexible plastic substrates, 1 cm²/Vs on silicon substrates) and the largest on/off current ratio (above 10⁶). Designing Solution-Processed Photonic Light- and Heat-Management Structures for Optoelectronic Devices
Natalie Stingelin; Georgia Institute of Technology, Atlanta, Georgia, United States.

An ever increasing interest in the development and application of innovative optical and optoelectronic devices places greater emphasis for the advancement of new smart and functional materials that are readily processable. Significant progress has already been realised in the fields of organic light-emitting diodes (OLEDs) and photovoltaic cells (OPVs) through development of novel semiconducting materials. Here we discuss developments and advancements in materials design towards photonic structures that aid and improve light management in organic and inorganic/organic hybrid devices. Here, we cover systems targeted for use in light input/output-coupling structures, anti-reflection coatings, waveguides, and beyond. Extension to architectures for heat management, important e.g. for a broad range of photovoltaic device platforms, will also be presented.

3:00 PM BREAK

3:30 PM *EP06.02.05
Large-Area Organic Single-Crystal Semicconductors for Integrated Circuits
Jun Takeya; University of Tokyo, Kashiwa, Japan.

In field-effect transistors, charge is accumulated in only a few-nanometer-thick surface of semiconductors interfacing gate-insulating layers, so structurally well-defined molecular-layer single-crystal films of organic semiconductors are highly beneficial in saving the material. We recently succeeded in growing highly homogeneous organic semiconductor films of ultrathin single crystals, so that high values of charge-carrier mobility exceeding 10 cm²/Vs is achieved everywhere in the dimensions of 10 cm x 10 cm substrates. Named as “organic single-crystal wafers” the multilayer films are ready to be fabricated to CMOS integrated circuits. P- and n-type organic semiconductor materials are newly synthesized for high-mobility carrier transport based on strategies of minimizing effective masses and phonon scattering rates. Both layers are formed by solution from continuous crystallization at the edge of coating blades. With recent development of key processing technologies for printed LSIs, low-cost platforms for RFID tags, AD converters, data processors, and sensing circuitries will be displayed. In particular, developing simple integrated devices based on CMOS using the p-type and n-type printed organic FETs, successful rectification and identification are demonstrated at 13.56 MHz with printed organic CMOS circuits.

4:00 PM EP06.02.06
Stability of Printed Organic Thin-Film Transistors Composed of Ultrafine Silver Electrodes by SuPR-NaP Technique
György Kitahara1, Takamasa Hamai2, Satoshi Matsuoka1, Shunto Arai3 and Tatsuaki Hasegawa1,2; 1The University of Tokyo, Tokyo, Japan; 2AIST, Tsukuba, Japan.

Solution-based productions of both metal and semiconductor patterned layers are the essential components for printed electronics technologies that have made considerable progress in recent years. Next important challenge is to combine and integrate the respective printing techniques, for realizing high-performance, highly-stable, and all-printed organic thin-film transistors (OTFTs). Here we demonstrate that stable operations become possible in solution-processed OTFTs, when they are composed of ultrafine silver electrodes that are produced by the “surface photo-reactive nanometal printing (SuPR-NaP)” technique [1]. The SuPR-NaP technique is based on a silver-nanoparticle chemisorption effect on photo-activated patterned perfluoropolymer surfaces, which allows easy, high-speed, and large-area manufacturing of ultrafine metal wiring. In the fabrication of bottom-gate, bottom-contact-type OTFTs, we used spin-coated layer of perfluoropolymer, Cytop (Asahi Glass Co., Ltd.), that functions as a base layer for producing patterned photo-activated surface in the SuPR-NaP technique for producing source/drain electrodes but also as a gate dielectric layer (combined with base silica/Si substrates) [2]. As the surface of Cytop layer is extremely hydrophobic, we used unique “push-coating” technique to produce uniform polymer semiconductor channel layer on the Cytop layer with source/drain electrodes [3]. For reference, we also prepared OTFTs without Cytop layer on silica/Si substrates, where source/drain electrodes were fabricated by vacuum deposition of Au. We found that the OTFTs with hydrophobic Cytop layer exhibit much higher carrier mobility (more than 10 times larger) than that of the devices without Cytop layer on silica/Si substrates. Additionally, the performance of the former devices is featured by negligible hysteresis and small threshold voltage around 0 V, where threshold voltage shift due to gate bias stress is effectively suppressed, as compared to the large hysteresis of about 3 V in the latter devices. We discuss the origin of stable and highly-efficient operations of the printed OTFTs, in terms of the elimination of carrier traps in the high-quality gate dielectric/semiconductor interface realized with Cytop in the SuPR-NaP technique [4,5].

4:15 PM EP06.02.07
Electronic, Optical and Electrical Properties of Single Crystal Dinaphtho-Thieno-Thiophene (DNTT) Sunita Pookpannang1, Emily Bittle2, Christina Hacker3, Andrei Kolmakov1, Steven Robey1, Erika Giangrisostomi1 and Ruslan Ovsyannikov2; 1National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 2Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany.

Organic semiconductors can be integrated onto device structures in different physical forms such as single crystals, polycrystalline thin-films, or amorphous thin-films. There are many studies which have shown that by altering molecular orientation or packing, the extrinsic properties of an electronic device properties can be impacted. The structural order of the molecular solid profoundly influences the electronic properties, that in turn controls important properties, such as the transport gap and energetic level of the highest occupied molecular orbital (HOMO). While there are numerous photoemission spectroscopic measurements of organic semiconductors in thin-film structures, far fewer attempts have been made to determine the “fundamental” electronic properties for pristine organic single crystals. We present results of photoemission measurements for single crystalline (SC) dinaphthothieno-thiophene (DNTT). DNTT is a small molecule-based thienoacene and has demonstrated carrier mobilities approaching 10 cm²/Vs [1], is air-stable [2] and durable against accelerated temperatures and humidity conditions. Electronic “band” structure measurements using a novel angle-resolved time-of-flight electron spectrometer is performed on SC-DNTT, and multiple highest occupied molecular orbitals are resolved of varying widths. Modest dispersion of the frontier HOMO is observed. Using polarized Raman spectroscopy, the orientation of the crystal unit cell can be identified. The electronic structure results will be discussed in context of the electronic structure calculations and charge carrier behavior of DNTT reported in the literature.

Mimicking Associative Learning Using Synapse-Like Non-Volatile Organic Electrochemical Transistor
Xudong Ji, Gary K. K. Chik and Paddy K. L. Chan; University of Hong Kong, Hong Kong, Hong Kong.

Since the last decade, the synaptic electronics has attracted much more attention due to its computational parallelism, fault tolerance as well as energy efficiency. These excellent
Polymer Light-Emitting Diodes with an Emitting Layer Based on a Nano-Confined Semiconducting Polymer Blend

Anielen Ribeiro, Paul Blom and Jasper Michels; Max Planck Institute, Mainz, Germany.

Blending a visible light-emitting organic semiconductor with an insulator alleviates the trap-limited nature of the electron current. Organic light emitting diodes (OLEDs) comprising such a blend as emissive layer exhibit a two-fold increase in luminous efficiency with only 10% semiconductor. Due to this low content of semiconductor, polymer-LEDs are more attractive than small molecule-based devices. However, polymers impose the difficulty of an inherently low miscibility. In a plain blend macro-phase separation can be avoided if the molecular weight is kept low, which, in case of the semiconductor, is a disadvantage as it suppresses charge carrier mobility. An alternative strategy is to impose a nano-confinement. We prepare aqueous nanodispersions of red (PPV) and blue (polyfluorene) emitting polymers, blended with polystyrene as an insulator. We seem to fully suppress macro-phase separation in both cases. For the latter, the combination of nano-confinement and blending influences the phase morphology of the semiconductor in an unprecedented way. Fabricating OLEDs with an emitting layer consisting of nanoparticles poses a considerable challenge due to high operational current densities. We now succeed in fabricating such devices in a reproducible way at very decent efficiencies.

Physical and Electronic Properties of COF-5 Films with Intercalated Metal Ions

Michael S. Bible, Emma F. Dohnmeier, Lindsey R. Guthrie, Justin Hendrix, Joseph R. Hunt and Michael S. Lowry; U.S. Department of the Navy, Dahlgren, Virginia, United States.

The ability to tailor the geometric arrangement and electronic structure of materials is appealing for a broad range of applications including energy storage, micro-electronics and electromagnetic shielding. This project aims to develop and study a series of new materials to gain insight into methods for controlling the electromagnetic properties of two-dimensional covalent organic frameworks (2D-COFs). 2D-COFs are porous, semi-planar and stackable macromolecular structures, which can serve as a scaffold for additive materials to yield novel performance. The experimental work reported herein focuses on the synthesis of a 2D-COF and the development of methods for incorporating ionic compounds and examining resultant changes in electronic structure. In-situ and ex-situ methods of intercalation have been explored/optimized, and advanced structural and property characterization techniques have been employed on these new materials. Preliminary findings have already shown induced changes in the physical and electronic properties of perhaps the most common 2D-COF. The results of these studies show promising trends that will be expanded upon by future investigations.

Influence of Trapping Effects on Organic Memory Devices

Ulli von Goscinski, Kavita Singh Ghotra, Maxim Kempf and Klaus Meerholz; Chemistry, University of Cologne, Cologne, Germany.

The ability to tailor the geometric arrangement and electronic structure of materials is appealing for a broad range of applications including energy storage, micro-electronics and electromagnetic shielding. This project aims to develop and study a series of new materials to gain insight into methods for controlling the electromagnetic properties of two-dimensional covalent organic frameworks (2D-COFs). 2D-COFs are porous, semi-planar and stackable macromolecular structures, which can serve as a scaffold for additive materials to yield novel performance. The experimental work reported herein focuses on the synthesis of a 2D-COF and the development of methods for incorporating ionic compounds and examining resultant changes in electronic structure. In-situ and ex-situ methods of intercalation have been explored/optimized, and advanced structural and property characterization techniques have been employed on these new materials. Preliminary findings have already shown induced changes in the physical and electronic properties of perhaps the most common 2D-COF. The results of these studies show promising trends that will be expanded upon by future investigations.
Organic memory devices (OMEs) are realized by integrating a layer of the crosslinkable dithienylethene XDTE in a solution-based multilayer OLED stack. The photochromic XDTE molecule can be switched reversibly by a photo- and/or electrically induced ring-opening/-closing reaction to two thermally stable states featuring different physical properties. The change in the energy level positions, which is responsible for controlling the hole injection by shifting the hole injection barrier, enables a high ON/OFF ratio approaching 10^4. For future application as data storage element, electrically induced switching is of great importance, but the charge trapping landscape is affected by this switching mechanism. By incremental switching via current densities pulses, intermediate switching states are accessible. The current-response is analysed as a function of the fraction of closed isomers obtained via in-situ reflectance absorption spectroscopy. In combination with impedance spectroscopy measurements, we study the role of trapping effects in this energetically anisiotropic switching process.

EP06.03.04 All-Room-Temperature Solution-Processed New Noncopolymers Based Hole Transport Layer from Synthesis to Film Formation for High-Performance Organic Solar Cells Towards Ultimate Energy-Efficient Fabrication Zhanheng Huang1, Jiaqi Chen1, Xingang Ren1, Jiaqi Zhang1, Vellaayassis A. Roy1, Jeffrey M. Burkhartmeyer2, Kam S. Wong2 and Wallace C. Choy; 1The University of Hong Kong, Hong Kong, Hong Kong; 2Department of Physics, The Hong Kong University of Science and Technology, Hong Kong, Hong Kong; 3City University of Hong Kong, Hong Kong, Hong Kong.

The ultimate goal of energy-efficient fabrication of photovoltaic devices requires low energy consumption processes covering both synthesis of material and fabrication of device. Regarding to charge transport layer, it is worthwhile to synthesize nanomaterials and deposit films all at room temperature while still have good electrical properties. In our work, we propose and demonstrate a new nanocomposites of maghemite and iron hydroxide through a low energy consumption approach which is all room-temperature solution process of the syntheses from the nanocomposites to the formation of high quality hole transport layer (HTL). Strategically adjustment of acidity for the conversion of prepared precipitation is demonstrated to achieve a component controllable maghemite and iron hydroxide nanocomposites which contributes to in-situ tunable work function of the nanocomposites HTL from 4.70 eV to 5.16 eV. Simultaneously, since the nanocomposites synthesized in this approach has the features of ultra-small size of 6–10nm and surfactant-free, high quality and efficient HTL films can be formed at room temperature. For organic solar cells using nanocomposite as HTL, the power conversion efficiency can be significantly improved by as much as 80% compared with the optimized devices without HTL. Besides, both the efficiency and stability of the nanocomposite based organic solar cells are better than that of devices using poly (3,4-ethylenedioxythiophene):poly(styrene-sulfonate) (PEDOT:PSS). Consequently, the work contributes to the fabrication of simple, low-cost, and stable optoelectronics promoting green photovoltaics and flexible electronics.

EP06.03.05 Dual-Conformation Fluorescent Emitters—From Stimuli-Responsive Materials to Highly Efficient Organic Light-Emitting Diodes Shi-Jian Su; South China University of Technology, Guangzhou, China.

One typical strategy for designing fluorescent emitters is to combine an electron donor (D) unit and an electron acceptor (A) unit via a π conjugation link. A large spatial separation of the frontier orbitals can be achieved by a large twisting angle between the D and A units to give a small singlet-triplet splitting energy (ΔE_{ST}) and thus thermally activated delayed fluorescence (TADE). On the contrary, a small twisting angle will generally enlarge the HOMO-LUMO orbital overlap due to a weak intramolecular charge transfer (ICT) to give a conventional fluorescence emitter. We found that some D-A molecules have dual conformations and thus dual fluorescence emissions, where one emission involves weak ICT excited states and the other comes from strong ICT excited states with a large Stokes shift. Such dual fluorescence emissions can be exploited for stimuli-responsive fluorescence materials, achieving white-light emission combining blue conventional fluorescence and yellow TADF from a single compound in various states due to controllable conformational distribution. In addition, dual fluorescence emissions can also be suppressed by improving molecular rigidity to give TADF-dominated emission with efficient reversed intersystem crossing from triplet state to singlet state. Corresponding organic light-emitting diodes (OLEDs) also achieved high efficiencies and reduced efficiency roll-off.

EP06.03.06 Utilization of Divinyl Sulfone as a TADF Acceptor Core Joshua T. Keubeck1, Allison Lim2 and Alan Sellienger1, 2, 3; 1Chemistry, Colorado School of Mines, Golden, Colorado, United States; 2Material Science Program, Colorado School of Mines, Golden, Colorado, United States; 3National Renewable Energy Laboratory, Golden, Colorado, United States.

A comparative study of thermally activated delayed fluorescence (TADF) properties of sulfone analogues are reported. Synthesis of multiple divinyl sulfones (DVSs) and their sulfone analogues have been explored via computational and experimental methods to determine the effects on the TADF properties. Utilization of DVS as the acceptor imparts several beneficial properties to the emitters: 1) increased separation between the donor and acceptor groups; 2) enhanced separation of the frontier orbitals; and 3) decrease in crystallinity. These properties lead to a smaller single-triplet energy gap thereby potentially improving TADF emission, and film imperfections caused by crystallization. Synthesis of selected compounds have been achieved via palladium catalyzed couplings followed by nucleophilic aromatic substitution using aromatic amine donors. Air versus argon solution photoluminescence, solution photoluminescent quantum yield, single-triplet state energy gap, density functional theory, thermal properties, and initial OLED results will be presented.

EP06.03.07 Work Function Modification of Indium-Tin Oxide by a Combination of Charge-Based Through-Space Interaction and Surface Interaction Da Soel Yum1, David Bilby1, Kyeongwoon Chung1, Jill K. Wendorf1, 2, Jacob Jordahl1, Bo Hyun Kim1, Joerg Lahnn1, Peter F. Green1 and Jinsang Kim1; 1University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 2Northwestern University, Evanston, Illinois, United States; 3Korea Institute of Industrial Technology, Cheonan, Korea (the Republic of); 4National Renewable Energy Laboratory, Golden, Colorado, United States.

Organic electronic devices rely upon the work function of their electrodes for control over charge injection and built in electric fields. However, an explanation of the origin of work function modification remains unclear. With a representative polyelectrolyte set, we studied how the work function of electrodes can be modified by a combination of charge-based through-space interaction and surface interaction. The formation of a surface dipole due to a through-space interaction between the modifying layer and substrate can be achieved by a large twisting angle between the D and A units to give a small singlet-triplet splitting energy (ΔE_{ST}) and thus thermally activated delayed fluorescence (TADE). On the contrary, a small twisting angle will generally enlarge the HOMO-LUMO orbital overlap due to a weak intramolecular charge transfer (ICT) to give a conventional fluorescence emitter. We found that some D-A molecules have dual conformations and thus dual fluorescence emissions, where one emission involves weak ICT excited states and the other comes from strong ICT excited states with a large Stokes shift. Such dual fluorescence emissions can be exploited for stimuli-responsive fluorescence materials, achieving white-light emission combining blue conventional fluorescence and yellow TADF from a single compound in various states due to controllable conformational distribution. In addition, dual fluorescence emissions can also be suppressed by improving molecular rigidity to give TADF-dominated emission with efficient reversed intersystem crossing from triplet state to singlet state. Corresponding organic light-emitting diodes (OLEDs) also achieved high efficiencies and reduced efficiency roll-off.

EP06.03.08 Charge Transport and Self-Assembly Tuning by Rational Molecular Design David Wisman1, 2, Tobias Morris1, Christopher Tempas1, Seyong Kim1, Dongwhan Lee1 and Steven Tait1; 1Chemistry, Indiana University, Bloomington, Indiana, United States; 2Materials Analysis, NAVSEA Crane, Crane, Indiana, United States; 3Chemistry, Seoul National University, Seoul, Korea (the Democratic People's Republic of).

Recent trends in the electronics industry have shown that organic semiconductors have the potential to replace silicon in some electronic devices due to their less stringent production environments and ability to offer new functionalities, such as large area flexible and self-healing architectures. Organic semiconductor films have traditionally lagged behind silicon devices due to the difficulty in predicting and controlling the molecular structure, which leads to unpredictable charge transport properties. In traditional organic film materials, the molecules lay flat in the first few molecular layers before transitioning to less favorable geometries for charge transport. Our collaboration has studied a molecular platform, tris(N-phenyltriazole)(TPT), that exhibits planar stacking through >20 molecular layers due to the π-π donor-acceptor intermolecular contacts between the electron-deficient tris(triazole) core and electron-rich molecular peripheral units. Here, we present recent investigations of derivative molecules of TPT, which have different electron distributions and structures, to examine connections between packing structure and charge transport functionality. Molecular-resolution scanning tunneling microscopy is used to compare the molecular packing of these derivative molecules in the monolayer and to investigate the effects the structural and electronic modifications have on the stacking in the multilayer. Conductivity measurements are also made using a 4-point van der Pauw technique to evaluate the charge transport properties of these different molecules compared to an industry standard, pentacene. These results suggest that the TPT molecule and its derivatives are more conductive than that of pentacene. These studies may lead to new organic semiconductor material designs that have well-controlled structure and more predictable charge transport properties, making them more competitive with traditional silicon devices.
Ultra-flat patterning on polymer surfaces on the order of nanometers is extremely important for advances in organic electronics and energy technologies due to improvement of light transmittance at the interface, fine circuit patterning. Nanoimprinting is an effective patterning technique for polymer surface, which has productivity advantages such as simple, low cost, large area. We have previously demonstrated atomic step-and-terrace pattern formed both on soda-lime-silicate glass and polymer sheets such as poly(methyl methacrylate) (PMMA) and polyimide (PI) by the thermal nanoimprint method. In addition this atomic scale morphology contributed to transparent conductive oxide films deposited on nanopatterned PI showed good surface flatness and films deposited on glass resulted in improved crystallinity and crystal orientation [1,2,3]. Meanwhile, we have also reported fabrication of highly oriented and crystallized UV-sensitive oxide semiconductor thin films by an excimer laser annealing at room temperature [4,5], that the technique could improve the crystallinity and orientation of the UV-sensitive semiconductor films on polymer sheets at a temperature lower than the glass transition point of the polymer. In this work we report room-temperature fabrication of UV-sensitive semiconductor thin films such as ZnO or Ga2O3 on the originally developed ultra-flat polymer sheets with 0.3 nm-high atomic step-and-terrace surfaces. Atomic scale surface patterning with a vertical resolution of 0.3 nm was performed on PMMA sheets by thermal nanoimprinting utilizing a mold sapphire (α-Al2O3 single crystal) with atomic step-and-terrace structure on its surface. Thin films of UV-sensitive semiconductors such as ZnO or Ga2O3 were then formed on the patterned PMMA substrates by pulsed laser deposition (PLD) at room temperature. The oriented film revealed flat surfaces reflecting the step-and-terrace morphology on PMMA, having smaller RMS roughness in comparison with the bare substrate.

In addition, XRD results indicated improvement of crystallinity and orientation. The influence of the film structure on the electrical and optical characteristics would also be reported.

Roll-to-Roll Deposition Process for Preparing Conjugated Polymer Thin Films 
Derek Ober and Darren J. Lipomi; NanoEngineering, UC San Diego, La Jolla, California, United States.

Conjugated polymers have a large range of applications, due to their characteristic electronic properties, and the variety of ways they can be processed. However, conjugated polymers with high mobility quickly degrade when processed in air. Therefore, a new roll-to-roll (R2R) processing technique is necessary in order to limit oxidation during polymer processing, while preserving the mechanical and electrical properties of the conjugated polymers.

In our proposed R2R design, polymer solution is slowly pumped onto the surface of a water-filled trough. When the polymer solution contacts the tub, the differing surface tension of the solvent and water causes the polymer solution to quickly spread and dry. The edge of the dry solution is pulled onto a substrate roller, freeing space on the water surface for more solution to spread and dry. This R2R method provides an efficient method for applying small amounts of polymer to large area substrates with minimal waste. Furthermore, the fact that the polymer film is dry when depositing means that it is possible to layer different polymer films onto the same substrate, including materials with non-orthogonal solvents. This is an advantage over other deposition methods, which cannot deposit “wet” solutions onto a dry film because the dry film will re-dissolve with the newly deposited polymer solution.

Crystal Growth Mechanism in Meniscus-Line-Guided Coating Method 
Ming Chen and Paddy K. L. Chan; University of Hong Kong, Hong Kong, Hong Kong.

The meniscus-line-guided coating technique has attracted a lot of attentions in field of organic electronics due to the low fabrication cost and the compatibility with large area processing. Different solution processing approaches such as blade coating, bar coating, zone casting and etc. have been proposed and anealorated to improve the molecular packing in the crystal. To control the crystallinity of the deposited organic semiconductors, the mechanisms behind crystal growth are actually very important. Here, we use blade coating method as a tool to systematically investigate effects of elementary factors on crystal growth rate or mass transfer rate with the semiconductor of 2,7-Dioctyl[1]benzothieno[2,7-b]fluorene BTBT. In the current study, we correlated four elementary parameters including shearing speed, concentration, solvent selection and deposition temperature. We have identified their roles in the meniscus-line-guiding coating process. Shearing speed showed an inverse proportion relationship with resulting thin film thickness, which could be used as thickness modulation parameter while the remained three factors are directly connected to growth rate. The experimental temperature range were set from 30°C to 100°C. By different combination of growth parameters, we achieve a crystal growth rate from 1x10⁻¹¹ to 5x10⁻⁸ cm/s. The equivalent thicknesses are well controlled below 40 nm by adjusting the shearing speed. These results could provide not only deep insight and guidance into crystal growth under meniscus-line-guided coating, but also reference for crystal growth analysis in other research fields.

Comparing Chemical Doping Methods for Preparing Micron-Thick Films of Semiconducting Polymers for Thermoelectric Applications 
Dane A. Stanfield, Matthew T. Fontana, D T. Scholes, Sarah H. Tolbert and Benjamin J. Schwartz; University of California, Los Angeles, California, United States.

Solution processable semiconducting polymers are of great interest because of their potential for use in a myriad of different device applications. Most recently, their promise for use as thermoelectric materials has come into focus as an area where they might hold significant advantages over their inorganic counterparts. The thermoelectric performance in these materials can be tuned by adjusting the doping level and as such, the molecular doping of conjugated polymer films has become an area of particular importance for these materials. To carry out the doping process, our group employs two different two-step sequential processing techniques, one based on solution processing and the other based on thermal evaporation. The purpose of this talk is to provide a detailed comparison between these two doping methods.

In the first step of the solution sequential processing method, a pristine polymer layer is formed via spin-coating a polymer solution. In the subsequent doping step, a semi-orthogonal solvent is chosen for the dopant that swells but does not dissolve the underlying polymer layer. The dopant is then driven homogeneously inside the swollen polymer film by spin-coating the dopant solution on top of the pre-formed polymer underlayer. Because this solution-based method relies on the polymer layer swelling in the presence of a semi-orthogonal solvent, dopant intercalation is largely independent of the polymer layer thickness, provided the solvent fully penetrates throughout the extent of the polymer layer. For the evaporation sequential doping method, thermal evaporation is used to place the dopant on top of the pre-existing polymer layer, where heating of the underlying polymer film is often used to help intercalate the dopant inside the polymer film from the gas phase. To date, most studies investigating doping by this process have been carried out on ultra-thin polymer films on the order of ~20 nm in thickness. For practical use, much thicker device architectures must be implemented and it has until now remained a mystery how this evaporative doping process would scale to multi-micron thick films for thermoelectric applications.

Here, we perform a systematic comparison between these two techniques by examining infiltration of the dopant 2,3,5,6-Tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ) inside increasingly thick polymer films of poly(3-hexylthiophene-2,5-diyl) (P3HT). Structural changes induced by the incorporation of the dopant species are evaluated using grazing-incidence wide-angle x-ray scattering (GIWAXS). In addition, changes in inter and intralayer ordering of the low-energy polaron absorption band are measured as a way of characterizing the degree of free charge carrier delocalization. Finally, conductivity measurements, coupled with measurements of the Seebeck coefficient, illuminate how the thermoelectric power factor changes as increasingly thick polymer films are used. We find, quite surprisingly, that the power factor obtained for these materials with the two different doping methods are largely indistinguishable, and even approach the same level within the error of the measurement at increasing film thicknesses. Thus, when thermal evaporation is undesirable due to constraints in cost or time, solution processing provides a suitable method of dopant intercalation for fabricating polymer-based thermoelectric devices.
Electrode ignorant substrates (EGTs) or electric double layer transistors (EDLTs) have attracted significant research attention as potential switching devices for wide variety of thin-film devices because of their solution processability, low-voltage operations, and excellent device performance. Many different types of organic and inorganic semiconductors have been applied for these high performance EGTs. In this work, organic/inorganic hybrid complimentary inverters operating at low voltages were successfully fabricated by transfer-stamping all the active components including organic p-type poly(3-hexylthiophene) (P3HT), inorganic n-type zinc oxide (ZnO), high capacitance solid electrolyte ion gel dielectric and conducting polymer. A semicrystalline homopolymer-based gel electrolyte was transfer-stamped on the semiconductors for low voltage EGT operation. For the ionogel stamping, the thermoreversible crystallization of network cross-links was utilized to control the physical contact between the gel and the semiconductors. The p-type P3HT EGTs showed high hole mobility of 2.14 cm²/Vs, whereas the n-type ZnO EGTs exhibited high electron mobility of 1.82 cm²/Vs. By combining these p- and n-type EGTs in series, organic/inorganic hybrid complimentary inverters were fabricated. The complementary inverter operated at low-voltages below 2 V with appropriate inversion characteristics including a high voltage gain of ~18.

EP06.03.14
Two-Dimensional Organic Single Crystals as Deposition Templates for High-Performance Field-Effect Transistors Zhiwen Zhou, Shien-Ping Feng and Paddy K. L. Chan; The University of Hong Kong, Hong Kong, Hong Kong.

In a bottom gate top contact organic field effect transistors (OFETs), the carrier transportation is happening in the first few monolayers of organic semiconductors closed to the dielectric/semiconductor interface. Great efforts have been devoted to modifying the physical properties of the dielectric-organic interface, including improvement of conductivity by doping and enhancement of crystallinity by optimizing the molecule packing and reducing grain-boundary defects. Here, we firstly fabricated a two-dimensional (2D) highly crystalline C_60-DNTT film with large-area uniformity by a quasi-steady ultra-slow shearing (USS) method where the heterogeneous nucleation is intentionally chosen with a significant reduction of the number of nuclei. The preferential molecular orientation during the process was observed and the behind formation mechanism was analyzed in the form of surface energy calculated by density functional theory (DFT). After having the 2D crystal being deposited, we further demonstrated the following thermally deposited C_60-DNTT ultra-thin film can pack in a particular form by using the 2D crystalline monolayer as a template. The sequentially deposited films showed an excellent crystallinity with a followed crystal orientation of templating crystals through a vertical quasi-epitaxial growth mode. Being benefited from the solution shearing layer, the OFETs with hybrid-deposited organic semiconducting films exhibited an improved carrier mobility of 19.7 cm²/Vs compared with 2.5 cm²/Vs achieved by solely thermal-evaporated thin-film devices. In turn, the overlying films act as a passivation layer and help to gain a better long-term stability over one year with only 5-10% drop of carrier mobility. This work provides a simple and easy approach for fabricating high-performance and low-cost electronics on a large scale by seeded growth templates.

EP06.03.15
Liquid Crystal- Organic Field Effect Transistor with Elastomeric Gate Dielectric Reshma Ravendran,1,2, Mamatha Nagaraj1 and Manoj A. Namboothiry1; 1School of Physics, Indian Institute of Science Education and Research-Thiruvananthapuram, Thiruvananthapuram, India; 2School of Physics and Astronomy, University of Leeds, Leeds, United Kingdom.

The basic attraction of organic electronic devices is their flexibility. Among the widely used flexible materials, the polymer elastomer, poly(dimethylsiloxane) PDMS has an important position due to its additional features like optical transparency and insulating properties. In our recent work, the effective application of PDMS as a gate dielectric in solution-processed organic field effect transistors (OFETs) was investigated.1 In the present work, we discuss the fabrication of OFETs using a solution-processed liquid crystal (LC) semiconductor, 2-decyldodecyl-4,7-(phenyl-1-[benzozeno[3,2-b][1]benzothiophene (Ph- BTBT-10) with PDMS as the gate dielectric. The organic semiconductors exhibiting liquid crystalline phase have attracted high attention due to their capability to self-organize into large area thin films by solution processing methods and their high charge transport properties.2–3 Ph- BTBT-10 exhibiting smectic phases is attractive due to its solution processability and its good thermal stability up to 250°C and high mobility of 13.9 cm²/Vs.2 Here, the high potential of Ph- BTBT-10 as an active organic material is utilized to fabricate LC-OFETs with PDMS as gate dielectric material. The devices showed high performance with an average field effect mobility > 5 cm²/Vs and current on/off ratio as high as 10⁶. These devices worked under very low threshold voltage (<5 V) which indicates the capability of elastomers for flexible OFET applications. The high device performance is attributed to the good crystallinity of the LC thin-film solution-casted on PDMS surface. Also, the LC material maintained its bilayer structure throughout the OFET operation.

Fabrication and Characterization of Nano Particle Colors for Electrophotoreic Display Sung Yong Nam; Gyeongsang National University, Jinju, Korea (the Republic of).

Electrophoretic display (EPD) technology is a technology which has lots of advantages such as easy manufacturing process, being made of flexible material, requiring ultra-low power consumption, low-cost manufacture and, most of all, easy and convenient to read. In this study nano-size color particles were studied for application to electrophoretic display. Color particles were prepared by Emulsion polymerization and Seed polymerization. Polymerization method were proposed for the synthesis of monodispersed poly(vinyl acetate-co-divinylbenzene) [poly(VA-co-DVB)] particles with different VAc/DVB feed ratios. Poly(Vinyl alcohol-co-divinylbenzene) [poly(VAc-co-DVB)] particles were obtained by the basic hydrolysis of poly(VAc-co-DVB) particles. The hydroxyl groups on poly(VA-co-DVB) particles have a suitable reactive functionality for surface covalent bond with reactive dye. So, Poly(VA-co-DVB) particles were reacted with reactive dye. Poly(VA-co-DVB) color nano particles were characterized by using SEM, IR, DSC, UV-vis.

EP06.03.17
Improved Hydrophobic Interface of Polyurethane Acrylate via Perfluoropolyether for Efficient Transfer Printing and Stable Operation of Conductive Polymer in Perovskite Photovoltaic Cells Min Ji Yi, Ji Hyun Lim, Min Seong Kim and Dongs Hwan Wang; Chung-Ang Univ, Seoul, Korea (the Republic of).

Recently, development trends of electronic devices and optoelectronic devices are related to simple and economic next generation printing processes based on organic and organic/inorganic hybrid nano materials. The transfer printing process, which is one of the next generation printing processes, is attracting attention because it is relatively dry, economical, and more stable by forming a reverse structure compared to the wet process. In this research, we investigated transfer printing process from enhanced hydrophobic interface of polyurethane acrylate (PUA) mold film via perfluoropolyether (PFPE)3. The energy release rate (G) of mold film has been successfully controlled for efficient transfer process, which was confirmed by contact angle measurement compared to the normal PUA. The transfer printed PEDOT:PSS layer exhibits comparable surface properties, and also induce favorable crystallinity of perovskite related to the spin-coated layer, which shows similar JSC and PCE (spin-coated vs. transfer printing: 12.85 VS. 12.33 %), and improved VOC. Furthermore, the stability of the device with transfer printed PEDOT:PSS layer was confirmed by the preserved crystallinity of perovskite, and the inhibition of the degradation of ITO from XRD and XPS analysis, respectively. As a result, the transfer-printed hole extraction layer through interface control between mold film and PEDOT:PSS using the improved hydrophobicity contributes to maintaining the surface morphologies and device electrical properties, which correlates with the stable operation of perovskite photovoltaics. This work suggests a encouraging process of organic inter-layer fabricated by the controllable material-customized transfer films.

Solution-processed active semiconductor doping would be a powerful strategy in order to improve CNTFETs performance in balanced charge transport. CNTs are promising material for high performance, large area printable and flexible thin film transistor. However, as synthesized single-walled carbon nanotubes (SWNTs) show non-uniform electrical properties due to the mixture of metallic and semiconducting SWNTs. Selective separation of semiconducting SWNTs (s-SWNTs) using conjugated polymers has been developed with the aim of utilizing their superior properties. We separated s-SWNTs with the high purity from as-grown mixed-type SWNTs using conjugated polymer with long alkyl side-chain length. Separated s-SWNTs were adapted for active layer of CNTFETs with or without dopant. Properties and doping effects of the CNTFETs active layer were revealed by UV-VIS spectroscopy, Raman Spectroscopy, low-temperature measurements and other experiments. We demonstrate that hole and electron charge carrier tuning can be easily achieved by simple spin coating in CNTFETs with s-SWNT/dopant bilayer structure. Furthermore, through this study, we implemented logic gates such as inverter and pass gate with simple solution processing.

Efficient Deep-Blue Organic Light-Emitting Diodes with Asymmetric Diphenylsulfone-Type Materials Used as TADF Emitter and Sensitizer

Hui Jae Choi, Ohyoung Kim, Seok-Ho Hwang, Chul Won Lee and Byung Doo Chin; Dankook Univ, Yongin, Korea (the Republic of).

The state-of-the-art commercial materials of organic light emitting diode (OLED), especially for a blue fluorescence, still need further improvement in terms of their efficiency. We have synthesized several diphenylsulfone-type thermally delayed activated fluorescence (TADF) host materials with diphenylsulfone (DPS) as acceptor unit, while carbazole (Cz), 3,6-di-tert-butyl-carbazole (tBCz), or 7,7-dimethyl-5,7-dihydroindeno[2,1-b]carbazole (DMICz) were utilized as donor units. The calculated S1/T1 energies of synthesized host materials, CzBrCz-DPS and CzDMICz-DPS (with the standard B3LYP/6-31G*) are 3.35/3.00 eV and 3.13/2.86 eV, respectively. Deep blue emitting TADF devices with a color coordinate of (0.16,0.09) and (0.15,0.09) were obtained for devices having CzBrCz-DPS and CzDMICz-DPS emitter with bis(2-(diphenylphosphino)phenyl) ether oxide (DEPEO) host. A molecular design of interlocking two phenyl units of DPS could help to reduce molecular motion, resulting in a shift of emission color to deep blue. Experimental values of electro-optical properties and time-resolved studies were investigated by the spectrometry on photoluminescence, UV-vis, and transient experiment to analyze a good overlap of the host emission to dopant absorption and delayed fluorescence. Therefore, those TADF devices demonstrated still limited efficiency, about 3.7% (DPEPO): CzBrCz-DPS (10%) and 5.7% (DPEPO): CzDMICz-DPS (10%). For a further improvement of TADF device efficiency, severe roll-off characteristics, and poor device stability, asymmetric DPS series compounds were applied for sensitizing host at TADF device architecture. The hyperfluorescence devices, with blue emitting layer composed of DPEPO: DPS-series-sensitizers (30%):fluorescent dopant (5,9-Diphenyl-5H,9H-[1,4]benzazaborinio [2,3,4-k]phenazaborine; DABNA-1; 1%), showed 12 to 14% external quantum efficiencies at a color coordinate about (0.14, 0.07) depending on the type of asymmetric DPS-series-sensitizers. Although more detailed investigation is required, it is expected that sensitizers with tBCz-donor group were found to be more efficient compared with DMICz-donor materials.

**EP06.03.20**
The Effects of Annealing on Doped P3HT Thin Films for Potential Electronic Applications

Fania C. Dowell, Harold O. Lee and Sam-Shajing Sun; Norfolk State University, Norfolk, Virginia, United States.

Polymer conjugated materials are convenient for developing future soft-material-based semiconductors, conductors, electronic and optoelectronic devices due to their inherent features. These features include being lightweight, flexible, cost efficient, malleable, and easily scaled. Similar to their inorganic counterparts, the addition of certain minority molecules, or dopants, to polymer conjugated materials can significantly alter the electronic and optoelectronic properties of the host conjugated polymers or composites. This allows for tunability of a variety of electronic and optoelectronic applications. One way to improve device performance is through the process of thermal annealing. Annealing allows for a polymer matrix to self-assemble into a lower energy state, which leads to an increase in crystallinity and higher charge mobility. Previous research does not explicitly define how dopants can affect this process. This study involves an evaluation of the affects of annealing with doped P3HT films to demonstrate changes in optoelectronic and electronic properties.

Device Physics of Non-Ideal Organic Thin-Film Transistors and Analysis of Current-Voltage Relations

Chuan Liu; School of Electronics and Information Technology, Sun Yat-sen University, Guangzhou, China.

Very high values of carrier mobility have been recently reported in newly developed materials for field-effect transistors (FETs) or thin-film transistors (TFTs). Concerning the precise characterizations of OTFTs or OFETs, we investigate the device physics of devices with non-ideal current-voltage relations:

(a) How to choose the analysis tool for contact resistance in OTFTs? Given the limitation of the transfer-line method in the difficulty in experiments and theoretical assumptions, we could perform analysis on a single device with transfer or output characteristics. These methods provide facile tools and whether their assumptions are valid are discussed.

(b) How much contact resistance a FET or TFT can tolerate allowing the conventional current-voltage equations? Mobility in transistors with resistive contact can be underestimated with the presence of the injection barrier, whereas mobility in transistors with gated Schottky contact can be overestimated by more than ten times. This is because the band bending and injection barrier experience a complicated evolution on account of electrostatic doping in the semiconducting layer.

(c) How to assess the capacitance in OTFTs or OFETs, we investigate the device physics of devices with non-ideal current-voltage relations: we could perform analysis on a single device with transfer or output characteristics. These methods provide facile tools and whether their assumptions are valid are discussed. Underestimated with the presence of the injection barrier, whereas mobility in transistors with gated Schottky contact can be overestimated by more than ten times. This is because the band bending and injection barrier experience a complicated evolution on account of electrostatic doping in the semiconducting layer.

(d) How to compare disorders of charge transport in various OSCs can be directly compared in the same map? The generalized Einstein relation can unify various theoretical models and predict charge transport in OSCs with various crystallinity, by altering the variance of the density of states and delocalization degree in a Gaussian-distributed density of states.

is typically employed in OPVs that is processed almost exclusively from toxic organic solvents, such as chloroform, chlorobenzene, and 1,2-dichlorobenzene. There is the need to move away from processing with chlorinated solvents and hence the development of eco-friendly processing technologies for solar cells is a recent target of the polymer solar cell community. Unfortunately, a reduction in solar cell performance often results when chlorinated solvents are eliminated, which is attributed to the non-optimal microstructure of the light absorbing layer. This seminar presents recent work on unravelling the material-morphology-performance relationships in eco-friendly processed polymer solar cell photoactive layers with the use of advanced synchrotron X-ray characterization techniques, STXM and NEXAFS. Here we explore the microstructure of green solvent cast BHI films and aqueous colloidal nanoparticle films for the poly[2,3-bis-(3-octyloxyphenyl)quinoxaline-5,8-diy-alt-thiophene-2,5-diyl] (TQ1) : phenyl-C61-butyric acid methyl ester (PC61BM) and poly(3-hexylthiophene) (P3HT) : PC61BM donor-acceptor material systems. With additive engineering and customizing nanoparticulate colloidal inks we are able to reduce the material domain size to approach the typical exciton diffusion length in these organic semiconductor systems, demonstrating that eco-friendly processing of large area OPV is a realistic goal for the near future.

Developing Atomic-Scale Models to Improve the Processing of Organic Semiconductors
Shi Li; Sean Ryno and Chad Risko; Chemistry, University of Kentucky, Lexington, Kentucky, United States.

To ensure optimal performance, the development of organic semiconducting materials from their molecular and/or polymer constituents requires precise processing controls to optimize the solid-state molecular packing arrangements. Temperature, solution deposition rates, and secondary solvents are among the tools that can be used to fine tune solid-state packings. However, many of these tools are used in an ad hoc fashion, and process discovery remains largely in the realm of trial-and-error approaches. We are developing all-atom molecular dynamics (MD) approaches to explore the solution processing of organic semiconductors. Here we will discuss recent advances in simulations that examine the free energies of mixing of solutions, and the influence of solution composition on molecular conformations and aggregation. For solvent and additive systems, diffusion parameters, solvation energies, and free energies of mixing are determined to provide insight into the solution environment. We then use these solvent systems to explore the solution behavior of complex donor-acceptor oligomers. The simulations reveal critical insight into the role of the secondary solvent additive during aggregation. These simulations are providing key atomic-scale insights as to how variations in processing solutions impact morphology development in organic semiconductors.

Formation and Device Implications of Microcrystalline Organic Semiconductor Films and Heterojunctions
Barry P. Rand; Princeton University, Princeton, New Jersey, United States.

We have recently been exploring organic semiconductor-based thin films that feature crystalline grains of up to 1 mm in extent, termed microcrystalline films. We will show our efforts to understand their formation, epitaxy, and transistors. Homoeptaxial studies uncover evidence of point and line defect formation in rubrene films, indicating that homoepitaxy is not at equilibrium or strain-free. Point defects that are resolved as screw dislocations can be eliminated under closer-to-equilibrium conditions, whereas we are not able to eliminate the formation of line defects. We are, however, able to eliminate these line defects by growing on a bulk single crystal of rubrene, indicating that the line defects are a result of strain built into the thin film template, indicating that, perhaps in general, organic crystalline thin films may not adopt the exact lattice of a bulk crystal.

In terms of optoelectronic behavior, we have found that charge transfer (CT) states incorporating these long-range-ordered films can be highly delocalized, contributing to noticeably lower energy losses. Also, we have discovered that relative energies of CT states with respect to singlet and triplet energy levels are critical when considering devices that exploit multiple exciton processes such as singlet fission and its complement, triplet-triplet annihilation (or triplet fusion). We will discuss these aspects and their implications for more efficient organic solar cell function.

Ionic Conduction as a Function of Side-Chain Chemistry of Polythiophene Derivatives
Christine Luscombe; University of Washington, Seattle, Washington, United States.

A new class of materials called mixed ionic/electronic conductors (MIECs) has the potential to be highly useful for many applications, ranging from biological sensors to battery electrode materials. The majority of current organic MIECs are created through the blending of two materials, where one component provides ionic conductivity, and the other electronic. This leads to a complex phase behavior that is still not fully understood. For rational design of MIECs, the connection between morphology and conduction must be better understood. To begin to answer these questions, guided by molecular dynamics simulations we synthesized two polythiophene derivatives bearing oligoethylene glycol side chains; one with an oxygen atom directly conjugated to the thiophene backbone, and one with a methylene spacer. Both polymers showed lithium uptake into crystalline domains, though lithium preferentially resided in the amorphous regions. By using a combination of electrochemical impedance spectroscopy and molecular dynamics simulations, we confirmed that ionic conduction occurs predominately in the amorphous regions. These polymers provide a valuable scaffold into investigating the interplay of morphology and ionic conduction.

Disregarded Channel Fringe Effect on Mobility Overestimation in Organic Thin-Film Transistors
Ke Pei and Paddy K. L. Chan; The University of Hong Kong, Hong Kong, Hong Kong.

Field-effect carrier mobility (m) is an important parameter to evaluate the performance of the organic field effect transistors (OFET). However, accurate measurement of this value is nontrivial. Apart from the recently discussed Schottky contacts induced mobility overestimation, the fringe effect resulting from the improper electrodes design is another disregarded source which would lead to mobility overestimation even the devices show good linearity in the transfer curves. We found that the OFET with unpatterned active layers or gate dielectric can have a mobility overestimation up to 210%. We systematically examine the fringe effect on mobility overestimation in the organic transistors with both vacuum-deposited and solution-processed semiconductor active layers. We introduce a correction-factor (C-factor) of the W/L defined by the source-drain electrodes to indicate the severity of the mobility overestimation caused by the fringe channel. By using electrodes with W/L ratio equals to one, the C-factor can reach 1.16 and 0.74 for vacuum-deposited and solution-processed OFETs, respectively. On the other hand, we also demonstrated the C-factor can be minimized to 0.1 when using properly designed electrodes (W/L ≥ 40 for vacuum-deposited and W/L ≥ 20 for solution-processed transistors). In the talk, we will also provide recommendations on the design of device geometry and channel dimension so that common pitfalls of fringe effect in the device fabrication can be avoided. With a detailed comparison table of the reported mobilities, the current work will help to provide a blueprint to the researchers about how the fringe effect would affect the reliability of reported mobility values. We believe the improvement on accurate evaluation of carrier mobility in relation to the fringe effect will ensure the development of novel OFET materials towards a correct direction, rather than keep on reporting inflated mobility values which are actually wrong.

In Situ Measurement of Evolving Exciton Dynamics During Organic Film Formation
Cathy Y. Wong; University of Oregon, Eugene, Oregon, United States.

The electronic structure and exciton dynamics of the molecules and polymers that form the active layer in organic electronic devices can change dramatically during solution deposition. As solvent vaporizes, molecules become electronically coupled as they aggregate to form a film, sometimes dramatically changing the exciton dynamics and thus the suitability for electronic devices. The dynamics of molecules in solution and in thin films of aggregates can be measured using transient absorption spectroscopy, but the exciton dynamics of intermediate aggregation states during thin film formation are typically unknown since measurements cannot be performed quickly enough to collect accurate
transient absorption spectra of these species. The exciton dynamics of evolving material systems can be measured by increasing the speed of data collection. A novel implementation of transient absorption spectroscopy is introduced that can measure transients with up to a 60 ps pump-probe time delay in one shot. The exciton dynamics measured during the solution deposition of a film is validated by comparing the initial exciton dynamics of the solution and the final exciton dynamics of the dry film to traditional transient absorption measurements. The exciton dynamics of intermediate aggregation states will be presented for the first time. The information gained using this technique can be used to modify environmental parameters during the film formation process to kinetically trap aggregates with exciton dynamics tailored for particular types of electronic devices.

The Impact of Energy Barriers at Grain Boundaries and Interfacial Traps on Charge Carrier Motion in a High-Mobility, sub 10 nm Thin, Organic Semiconductor
Thomas Weitz, LMU Munich, Munich, Germany.

Using high-surface tension solvents allowed us to grow 3–10 nm thick, highly-crystalline films of a N,N-di(5-tert-butylphenyl)-1,7(6)-dicyano-perylen-3,4,9,10-bis(carboximide) (PDI1MPCN2) at the liquid/air interface of a drying droplet [1]. We find, that charge carrier mobilities in these electron conductive films is as high as 4 cm^2/Vs even for an only 3 nm thin PDI1MPCN2 film. Changing the solvation composition used for crystallization of our organic semiconductor also has allowed us to systematically tune the crystallinity and consequently the grain boundary density in thin films. From the temperature-dependent charge carrier mobility, we have extracted the density of states and compared to it to kinetic Monte Carlo simulations [2]. This combined theoretical and experimental approach has allowed us to identify, that it is rather the energetic barriers at grain boundaries than the usually identified energetic traps that limit charge carrier motion below room temperature. We also have revealed that the dipole moment of the PDI1MPCN2 is the cause for the energetic disorder at grain boundaries serving as clear guideline for future design of organic semiconductors with potentially no energetic barriers present at the grain boundaries. We furthermore have investigated in detail the dependence between charge carrier mobility and density at various temperatures and find surprisingly that above room temperature the charge carrier mobility decreases upon increasing the charge carrier density [3]. While the true cause for this suppression is currently unclear, we present evidence that the squeezing of charges closer to the semiconductor/dielectric by the gate dielectric field a subsequent scattering at this interface might cause the drop in mobility. We anticipate that our combined observations will help to understand the still debated nature of charge transport in high-quality organic semiconductors.

Selective Poling the Ferroelectric Dielectric Layer in Organic Field-Effect Transistors for Improved Performance
Amrit Laudari, Alec M. Pickett and Suchismita Guha; Physics, University of Missouri, Columbia, Missouri, United States.

Polymer ferroelectrics are playing an increasingly active role in flexible memory application and wearable electronics. The relaxor ferroelectric dielectric, poly(vinylidene fluoride trifluoroethylene) (PVDF-TrFE), although vastly used in organic field-effect transistors (FETs), has issues with the gate leakage current especially when the film thickness is below 500 nm, and low carrier mobilities that arise due to its inherent polarization fluctuation. The poling condition of PVDF-TrFE in organic FETs plays a large role in dictating the transport properties. The subthreshold swing and other transistor parameters in organic FETs can be controlled in a reversible fashion by switching the polarization direction in the PVDF-TrFE layer [1]. By using solution processed small molecule semiconductors such as bis(dicarboximide) (PDI1MPCN2) at the liquid/air interface of a drying droplet [1]. We find, that charge carrier mobilities in these electron conductive films is as high as 4 cm^2/Vs even for an only 3 nm thin PDI1MPCN2 film. Changing the solvation composition used for crystallization of our organic semiconductor also has allowed us to systematically tune the crystallinity and consequently the grain boundary density in thin films. From the temperature-dependent charge carrier mobility, we have extracted the density of states and compared to it to kinetic Monte Carlo simulations [2]. This combined theoretical and experimental approach has allowed us to identify, that it is rather the energetic barriers at grain boundaries than the usually identified energetic traps that limit charge carrier motion below room temperature. We also have revealed that the dipole moment of the PDI1MPCN2 is the cause for the energetic disorder at grain boundaries serving as clear guideline for future design of organic semiconductors with potentially no energetic barriers present at the grain boundaries. We furthermore have investigated in detail the dependence between charge carrier mobility and density at various temperatures and find surprisingly that above room temperature the charge carrier mobility decreases upon increasing the charge carrier density [3]. While the true cause for this suppression is currently unclear, we present evidence that the squeezing of charges closer to the semiconductor/dielectric by the gate dielectric field a subsequent scattering at this interface might cause the drop in mobility. We anticipate that our combined observations will help to understand the still debated nature of charge transport in high-quality organic semiconductors.

Dynamic Mechanical Analysis of Polymer Semiconductors for Insights into Mechanical Stability
Nuppal Balar1, Masoud Ghasemi2, Harold Ade3 and Brendan T. O'Connor; 1Physics, North Carolina State University, Raleigh, North Carolina, United States; 2Mechanical and Aerospace Engineering, North Carolina State University, Raleigh, North Carolina, United States; 3North Carolina State University, Raleigh, North Carolina, United States.

One of the key advantages of polymer semiconductors over traditional inorganic semiconductors is their mechanical behavior. The polymers typically have lower stiffness, greater ductility and toughness than their inorganic counterpart enabling effective integration in ultraflexible and stretchable devices. To exploit the full potential of these materials for mechanically demanding applications, the fundamental thermomechanical behavior of these materials must be accurately determined, including how their viscoelastic properties translate to device stability. However, capturing the thermomechanical properties of these materials can be challenging. A common approach is to use differential scanning calorimetry (DSC). But, DSC often doesn’t have the sensitivity to capture the thermal transitions of polymer semiconductors. Dynamic mechanical analysis (DMA) on the other hand offers a very sensitive and versatile tool to probe the thermomechanical behavior of these materials. In this talk, we describe specimen preparation on probing both bulk and thin film thermomechanical properties of the polymers. We demonstrate DMA measurements that reveal thermal transitions including sub-glass transitions in a number of high performance polymer semiconductors, and how these transitions relate to the film mechanical behavior such as ductility, toughness, and creep. The implications of these properties on mechanical stability of devices will then be discussed. Furthermore, we demonstrate that the thermomechanical behavior of polymer-smaller molecule blends used in high performance solar cells is directly related to the long term device stability. We show that the small molecule diffusion measured by secondary ion mass spectroscopy can be directly related to thermal transitions, and how this dictates the blend film properties needed to ensure long-term morphological stability.

Polymer Ordering in Monolayers and Thin-Films Allowed to Reach Local Equilibrium
Hansard Ade; Department of Physics and Organic and Carbon Electronics Lab (ORACEL), North Carolina State University, Raleigh, North Carolina, United States.

Although it is well known that intra- and intermolecular ordering greatly impact the electronic and optoelectronic properties of semiconducting polymers, the interrelationship between ordering of alkyl sidechains and conjugated backbones has not yet been fully detailed. A recent discovery clearly demonstrated that the tendency of the side-chains and the backbone to order is not synergistic [1], rather a competition was observed in six representative semiconducting polymers. The ordering of the respective polymer components is monitored by NEXAS, UV-vis spectroscopy, as well as diffraction and exhibits distinct signatures. Overall, a vertically layered multilayer nanostructure with ordered side-chain similar to classic semiconducting heterostructure bulk epitaxy. In other words, we need to design materials as completely ordered crystals and not partially ordered sublattices.

From Molecular Design to Materials Properties—Developing Theoretical Tools to Aid in the Development of Organic Semiconductors
Chad Risko; University of Kentucky, Lexington, Kentucky, United States.

The design of molecules and polymers for solution-deposited organic semiconductor materials generally considers the chemical modulation of (i) the π-conjugated backbone to modify the electronic and optical characteristics and (ii) the alkyl side chains to govern solubility. As the solid-state material forms, physical interactions among these constituents play important, yet not well understood, roles in directing the molecular-scale packing arrangements that in part determine the final material properties. Further, the functions of the processing solutions are not clear, adding yet another layer of complexity in determining how materials self-assemble. In this presentation we will discuss the development of atomic-scale models that invoke thermodynamic, kinetic, and quantum-chemical methods to deliver insights into the processing and solid-state packings of organic semiconductors. The chemical knowledge developed through these investigations is beginning to refine and offer novel understanding essential to the development of next-generation organic semiconductor active layers, and is opening new pathways for in silico materials development.

2:00 PM EP06.05.02
Towards Data-Driven Explorations of Molecular Organic Semiconductors
Qianxiang Ai; Sean Ryno and Chad Risko; University of Kentucky, Lexington, Kentucky, United States.

Though organic semiconductors have illustrated their potential as industry-relevant materials for electronics applications, there are few guidelines that can take one from designing molecules to constructing functional materials. Relatively weak, non-covalent intermolecular interactions determine the thermodynamic preferences for solid-state packing, while interface interactions and kinetic factors during processing also play important roles. For crystalline materials, crystal structure prediction remains a grand challenge, with an even greater challenge stemming from the need to predict and control the formation of the particular crystal polymorph that provides the best materials characteristics for a given application. Such predictive capabilities, which need to span and draw correlations from the atomic to the macro-scale, will require a united effort from researchers across multiple disciplines.

To address some of these challenges, we have initiated the construction of a database as a digital platform aiming to serve the community with a high-throughput computational workflow and a web-based user interface. Featuring combinatorial inputs from synthetic chemists, theoreticians, experimentalists, and device physicists, the database employs a descriptor-based scheme to explore the correlations between molecules, their solid-state packings, and materials properties. Here, we illustrate database utility through the investigation of functionalized acenes as we refine the structure-packing model that has been proposed to offer predictive capabilities for this materials class.

Critical Role of Electron-Donating Thiophene Group on the Thermomechanical Property of Donor-Acceptor Semiconducting Polymers
Song Zhang and Xiaodan Gu; Polymer Science and Engineering, University of Southern Mississippi, Hattiesburg, Mississippi, United States.

Organic semiconducting polymers are promising candidates for stretchable electronics for their mechanical compliance. Donor-Acceptor type conjugated polymers have been the key drive for recent boost in device performance. Up to date, the effect of the conjugated backbone building block on the thermomechanical property of conjugated polymers has not been carefully studied, despite much work on their influence on the electronic property. In this talk, I will discuss our work on the structure and thin film thermomechanical property relationship for donor-acceptor polymers with systematically varied donor units on the conjugated polymer. To characterize the thermomechanical performance, the pseudo-free standing tensile test was used to obtain the full stress-strain curve. The glass transition temperature was measured for both thin and bulk films using AC-chip calorimetry and DMA, respectively. Thin film morphology was detected using AFM, UV-vis, and GIWAXS for further understanding. OFET devices were fabricated to test the electronic performance. The backbone structure and thermomechanical property relationship was established and applied to the design of new stretchable conjugated polymers.

Non-Conjugated Radical Polymers as Transparent Conductors in Organic Electronic Devices
Bryan W. Boudouris; Davidson School of Chemical Engineering, Purdue University, West Lafayette, Indiana, United States.

Radical polymers are an emerging class of organic electronic materials that are composed of a non-conjugated macromolecular backbone and with stable open-shell moieties present on their pendant groups. These oxidation-reduction-active (redox-active) macromolecules have been oft-used in the realm of electrolyte-supported energy storage devices due to the rapid reaction kinetics associated with the oxidation and/or reduction of the high densities of radical sites present along the polymer chains. To date, their utilization in solid-state organic electronic devices has been limited due to the lack of conjugation along their macromolecular backbone and the idea that this lack of conjugation necessarily limits their ability to conduct charge effectively in the solid state. Here, we demonstrate that radical polymers, in fact, are able to achieve relatively high electrical conductivity values (i.e., > 20 S m⁻¹) if appropriate molecular design criteria are met.

Specifically, two key design rules exist for radical polymers, and these design rules are distinctly different from what is observed in common conjugated semiconducting and conducting polymers. First, in order to ensure that there is a high density of redox-active sites by which to pass charge in the solid state, radical polymers must be synthesized in such a manner that the fraction of pendant groups that have an open-shell character to them approaches unity. While a fairly stringent requirement, this can be accomplished in a straightforward manner by utilizing polymerization schemes that do not follow a radical-mediated pathway. Second, the glass transition temperature of the radical polymer must be lower than the degradation temperature of the radical polymer. This allows for thermal annealing of the radical polymer after it has been cast into a thin film. Through a combination of experiment and computation, we demonstrate that this annealing process is crucial to the formation of a thermodynamically-stable nanoscale structure that allows for electronic communication between the radical pendant groups. When these two design criteria are met, we have been able to demonstrate electrical conductivity values for tailored radical polymers in excess of 20 S m⁻¹. This places our pristine (i.e., not doped) radical polymer electrical conductivity on par with many common commercial grades of doped conjugated polymers [e.g., poly(3,4-ethylene dioxythiophene) doped with poly(styrene sulfonate) (PEDOT:PSS)]. In addition to the device stability benefits associated with a lack of acidic dopants, the non-conjugated macromolecular backbones necessarily allow for high optical transparency values to be achieved across the visible spectrum for our radical polymers. For all of these reasons, radical polymers present themselves as useful materials in myriad optoelectronic and sensing device applications, and they offer the promise of replacing the current state-of-the-art of transparent conducting polymers and composite materials.

In particular, we will describe how specific nitroxide-based radical polymers are implemented as next-generation organic electronic materials in organic photovoltaic (OPV) devices and perovskite solar cells; organic field-effect transistors (OFETs); electrochromic devices; and bioelectronic sensors. The inclusion of the radical polymer layer improves uniformity of charge transport and reduces the contact resistance in the device. Finally, the high transparency in the visible spectrum allows for high-performance electrochromic devices that exhibit relatively rapid switching rates and are stable for a large number of cycles. Thus, we aim to show that radical polymers allow one to tie molecular design directly to device performance in a relatively linear manner.
High Sensitivity Ion-Selective Organic Electrochemical Transistor

EP06.05.02
High Sensitivity Ion-Selective Organic Electrochemical Transistor
Liang Li and Paddy K. L. Chan; Mechanical Engineering, The University of Hong Kong, Hong Kong, Hong Kong.

Ion signals play important roles in different kinds of biomedical processes. Traditionally, the detection methods usually require a relatively large sample size and expensive equipment to perform the ion concentration measurements. Here we proposed to use organic electrochemical transistors (OECTs) to measure the electrochemical signals from the ions. Comparing with the traditional methods, OECTs are conformal and flexible, more importantly, able to transfer to different objects to perform directly in-situ sensing. The OECT can also perform signal amplification function via transduce ion concentration signals to electrical signals. Here we develop the OECT based on the structure of gold source and drain contacts and ion-permeable conducting polymer Poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate)(PEDOT:PSS) as channel. From the experimental results of different metal ions such as Ca\(^{2+}\), the ion sensitivity can be up to 2.5 times of the theoretical Nernst limit at a few hundred millivolts low-voltage operation. We also develop the ion-selective OECTs to detect the body fluid and we will fabricate this device on flexible substrate for future application in real-time ion signals detection. The
unique performance of our devices provide new opportunities in the field of implant biosensors for biomedical diagnostics.

EP06.06.03
Establishing a True Free-Standing Methodology for Characterizing Thin-Film Conjugated Polymer Mechanical Properties not Convoluted by Substrate Interactions Luke Gahanka, Kevin Ramos, Song Zhang and Xiaodan Gu; School of Polymer Science and Engineering, The University of Southern Mississippi, Hattiesburg, Mississippi, United States.

Conjugated polymers are showing ever increasing promise for both current and novel electronic applications. Much of the research for these materials has focused on optimizing electrical properties (such as OPV efficiency or electron mobility) at the detriment of understanding the mechanical properties which are necessary for device commercialization. One reason for this is that the active polymer layer is on the order of 100nm thick (or less) making direct mechanical characterization all but impossible. Our group has utilized the pseudo freestanding tensile test (film on water) to overcome this challenge enabling the calculation of parameters such as Young’s modulus and crack-onset-strain with minimal difficulty. This method has shown consistently lower modulus values than that obtained from buckling metrology. This may be due to a plasticization effect of the water, but the interaction of water with the thin film has not been sufficiently accounted for. Therefore, I will discuss a true free standing tensile test that provides direct mechanical characterization of conjugated polymeric thin films in air. This novel characterization technique was demonstrated on three polymer systems: polystyrene, poly(3-hexylthiophene-2,5-diyl), and polyfluorene at multiple film thicknesses to provide quantitative evidence of any measurable effect water induces in the pseudo freestanding tensile test. The film and bulk glass transition temperatures were measured via AC-chip calorimetry and DMA respectively. This enabled us to ascertain the effectiveness of this methodology across a broad range of dynamic systems. Furthermore, the free standing tensile test enabled in-situ characterization with darkfield microscopy under tensile strain thus providing further understanding in thin film deformation mechanics.

EP06.06.05
Vibrational Anharmonicity in Organic Semiconductors Maar Asher, Efrat Ramati, Boris Rybtchinski and Omer Yaffe; Weizmann Institute of Science, Rehovot, Israel.

Phonons in organic semiconductors are crucial for determining their charge transport properties. Current theoretical models treat these phonons within the harmonic approximation. These models fail many times to predict important electronic properties such as the charge-carrier mobility. Since organic solids have weak intermolecular interactions, the anharmonic components of their low-frequency vibrations are expected to be significant. We hypothesize that the reason for the failure to predict the electronic properties is the neglect of these anharmonic components.

I performed temperature-dependent low-frequency Raman measurements of oligo-acenes to quantify their anharmonicity. Results show a much stronger change in the peak position of the low-frequency modes with temperature compared to inorganic semiconductors. Analysis of these peak shifts shows strong anharmonic behavior - contributed from both thermal expansion and phonon-phonon interactions - likely to have a significant impact on electron-phonon interactions. Comparison of a series of oligo-acenes shows an inverse correlation between anharmonicity and intermolecular electronic coupling. I will also show photoluminescence and reflectance measurements to corroborate the connection between vibrational anharmonicity and the electronic properties of organic semiconductors.

EP06.06.06
Development of Novel Electrochromic Materials Based on Viologen-Conjugates Fengyu Su, Xiaowen Wu, Huan Ling, Yanjun Liu, Dan Luo, Xiaowei Sun and Yanqing Tian; Southern University of Science and Technology, Shenzhen, China.

Electrochromic (EC) materials and their correspondent EC devices (ECD) that change colors on application of voltages have attracted great research interests in the past several decades since they have commercial applications as smart windows, auto dimming rearview mirrors and static displays. Viologen has been widely investigated as an organic EC material since it has excellent redox properties accompanied with distinct color changes. However, most viologens only show color change from transparent or translucent yellow to blue. In order to make viologens more colorful, we designed and synthesized novel materials by inserting triphenyl moieties into bipyridine. These chromophores are expected to have abundant color changes. Further, these new viologen-conjugates possess phosphoric acid groups, which could help them anchor on the titanium dioxide (TiO$_2$) more firmly. A layer of nanostructured TiO$_2$ film (4.0 μm thick, TiO$_2$ particles are about 20 nm large) was coated on conducting F-doped tin oxide (FTO) glass, and the new viologen-conjugate was adsorbed onto TiO$_2$ particles by chemisorption. The films of new viologen-conjugate/TiO$_2$/FTO were characterized by using cyclic voltammetry. Color changes from transparent at 0 V to purple at -0.8 V and rust red at -1.1 V were observed. Next, Prussian blue (PB) was electrodeposited onto FTO glass and used as counter electrode. And then ECD was assembled by combining the working electrode of new viologen-conjugate/TiO$_2$/FTO, counter electrode of PB/FTO, and gel electrolyte. The ECD was characterized by using UV-vis spectrophotometer and electrochemical analysis system. The ECD showed a broad transmittance contrast over 60% at -2.5 V and -2.5 V.

Direct Measurement of Single Molecule Charge Transport—From Molecular Design to Programmable Control Songsong Li, Hao Yu, Kenneth Schwieter, Bo Li, Jeffrey Moore and Charles Schroeder; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Programmable control of electron transport through organic semiconductors is a crucial step for designing integrated electronic devices for energy storage. Recent advances in molecular electronics have brought us closer towards achieving the ultimate limits in miniaturization and spatial and functional control over electronic performance. Despite recent progress, however, we still lack a full understanding of molecular-scale electron transport and how these properties are affected by chemical identity and sequence. In this work, we directly measure single molecule conductance using a scanning tunneling microscope-break junction (STM-BJ) technique. Oxazole-terminated molecules are found to exhibit interesting quantum interference phenomena through central phenyl rings and terminal oxazole rings, which can be used for controlling charge transport. In particular, the quantum interference of the central phenyl group follows a quantum circuit rule such that $G_{\text{central phenyl}} = 6$, whereas the c-type terminal oxazole ring shows constructive quantum interference. We can further precisely tune the conductance of oligophenyls via aromatic interaction with different background molecules. In this way, our work provides the fundamental electron and charge transport information to inform future programmable molecular electronics design.

EP06.06.08
Understanding the Molecular Origin of Polymorphic Transition via Nucleation and Cooperativity and Their Impact on Organic Semiconductors Hyunjoong Chung; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Understanding the molecular origin for better control of polymorphism is critical for the development of high performing, large area production of organic electronics. We explore a series of organic semiconductor systems with the same conjugated core and various bulky side chains to understand the polymorphic phase space. We demonstrate that substituting a bulkier silicon atom for a carbon atom in the side-chains compromises the packing environment such that they inhibit side chain rotation. We prove that either allowing, or preventing, the rotation of bulky sidechains triggers cooperative transition or nucleation and growth, respectively. We investigate the impact of both types of polymorphic transitions on electronic performance. By inducing nucleation and growth, we can access two kinetically stable polymorphs and study their electronic performance. From triggering cooperative transition, we have in situ access to different polymorphs with rapid reversible polymorphic transition for applications in next-generation smart multifunctional materials. This work offers a simple molecular design tool to access both polymorphic transition pathways and incorporate their advantages to organic semiconductors.

EP06.06.09
Tuning the Interfacial and Energetic Interactions Between a Photocexcited Conjugated Polymer and Open-Shell Small Molecules Daniel A. Wilcox, Jordan Snader; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.
Here, we demonstrate that Förster resonance energy transfer (FRET) is the dominant mechanism by which energy transfer occurs from a common conjugated polymer to various radical species using a combination of experimental and computational approaches. Specifically, we determined this by monitoring the fluorescence quenching of poly(3-hexylthiophene) (P3HT) in the presence of three radical species: (1) the galvinoxyl radical; (2) the 2-phenyl-4,4,5,5-tetramethylimidazoline-1-oxide-1-oxyl (PTIO) radical; and (3) the 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) radical. Both in solution and in the solid-state, the galvinoxyl and PTIO radicals showed fluorescence quenching that was on par with that of a common fullerene electron-accepting derivative, phenyl-C₆₁Bu, acridylic acid methyl ester (PCBM). This was due to the considerable overlap of their absorbance spectrum with the fluorescence spectrum of the P3HT species, which indicated that isoe energetic electronic transitions existed for both species. Conversely, TEMPO showed minimal quenching at similar concentrations in solution and at similar loadings in the solid state due to the lack of such an overlap. To support the determination of the mechanism, and to rule out photoinduced charge transfer, a potential competing process, pump-probe transient absorption measurements were employed. An increased rate of exciton decay in P3HT was observed when blended with the galvinoxyl radical and PTIO radical, consistent with an excited state transfer mechanism. Moreover, signals corresponding to the anion species of the quenchers were not observed, suggesting that charge transfer was not occurring at an appreciable rate for the compositions evaluated here. Additionally, computational studies suggested that FRET would occur at a significantly faster rate than photoinduced charge transfer. These computationally-predicted FRET rates were calculated from the spectral overlap of the P3HT fluorescence and the radical quencher absorbance spectra, while charge transfer rates were calculated by extracting Marcus theory parameters for the composite P3HT-quencher systems from density functional theory (DFT) calculations. Therefore, these computational results support the steady-state and time-resolved fluorescence experiments, and the results highlight the precise interactions between open-shell small molecules and closed-shell conjugated polymers in optoelectronic applications. Additionally, these findings suggest that long-range energy transfer can be accomplished in applications when radicals that can act as FRET acceptors are utilized, forming a new design paradigm for future optoelectronic applications.

EP06.06.10 Solution Process Feasible Highly Efficient Organic Light Emitting Diode with Hybrid Metal Oxide Based Hole Injection/Transport Layer Manveer R. Nagar, Rohit Ashok Kumar Yadav and Jwo-Huei Jou; Department of Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan.

Solution-processable hybrid metal oxide (HMOS) active layers have attracted enormous attention because of their ease of fabrication and ability to provide a good balance of light-emitting and charge-transport properties. Organic light-emitting diodes (OLEDs) are fabricated with a combination of electron-injecting/transport layers (EIL), hole-injecting/transport layers (HIL), emissive layers (EML), and electron-transporting layers (ETL) that are used to control the injection, transport, and recombination of charge carriers. Conjugated polymer layers have often been used in OLEDs as they readily provide the necessary charge transport properties. However, in recent years, the use of inorganic materials as hole-injecting/transporting materials has gained importance due to their high energy levels and stability which may reduce device degradation over time. In this work, we present hybrid metal oxide (HMOS) layers that are solution-processable and provide a high electronegativity. The combination of the high electronegativity and high ionization potential with a suitable work function can serve as an excellent hole-injecting/transporting layer. In this work, we present one such hybrid metal oxide (HMOS) layer which we believe will be a great addition to the high energy level and solution-processible hybrid metal oxide layers.

EP06.06.11 Mean Free Path and Band Transport in Transistors Based on Polymer Semiconductors Xiao Wang and Ananth Dodabalapur, University of Texas at Austin, Austin, Texas, United States.

Semiconducting conjugated polymer thin film transistors (TFTs) with mobilities in the range of 0.1~20 cm²/Vs have been reported by many groups. This is a demand for higher mobility polymer TFTs; therefore, an accurate understanding of the physics of charge transport is necessary. However, a complete theoretical understanding and quantitative description of charge transport in such semiconductors has been difficult to attain. The mobilities and mean free paths are simply too low (on the order of intermolecular distance ~3 Å) for the application of conventional semiconductor transport theories. In this presentation, we will describe a very general solution based on the statistical nature of charge transport and introduction of a factor (mean free path factor) related to the probability of mean free path exceeding the minimum transport length. We are then able to apply the Boltzmann transport equation (BTE) with appropriate scattering mechanisms and obtain very good results that agree well with experiment[1]. This approach is very well suited to thin-film transistors based on polymer and organic semiconductors and also many amorphous oxide semiconductors with room temperature mobilities in the range 5~50 cm²/Vs[2]. We combine the mean free path factor, BTE solutions with an extended multiple trap and release (MTR) model that takes into account traps in the device to get an overall response. Several scattering mechanisms are considered based on the material properties. It is found that at low and intermediate temperatures, free carrier scattering by the trapped charge carriers is dominant. Carriers trapped in the semiconductor traps or at the semiconductor-dielectric interface can be considered immobile Coulomb scattering centers, and can scatter mobile carriers efficiently. At high temperatures, basically the room temperature (300K) or above, carrier-phonon scattering starts to dominate. An important phonon scattering mechanism in the semiconductor is the optical deformation potential scattering. Due to the structure of the conjugated polymers, the backbone generates low frequency optical phonons, and the optical deformation potential is fairly large in these soft model materials. This leads to very effective carrier scattering and decrease the mobility at high temperatures. Other scattering mechanisms including polar optical phonon scattering and acoustic phonon scattering are also considered into the evaluation of the band mobility for different temperatures and carrier concentrations. The resulting band mobility of conjugated polymers is in the range of 20~40 cm²/Vs, corresponding to 0.1~20 cm²/Vs for the effective MTR mobility in a TFT device. In the case of low carrier concentration, the carrier free path is assumed to approximately obey the Poisson distribution with occurrence number of zero (exponential distribution) and the mean free path factor. Thus, the mean free path of the carrier can be smaller than the intermolecular distance, there is still a fraction of free carriers that can survive travelling past that distance. This fraction of carriers is considered to participate the actual band transport. Thus, the apparent MTR mobility is further reduced by the factor of the mean free path survivor fraction. We compare results from our calculations with experimental data[1] for donor-acceptor polymers. The agreement is very good and attests the validity of our approach. Our work also points to clear directions that TFT device structures must possess for high performance.

Refs:
implementation of transparent composite electrodes in current heterojunction organic solar cells

Zhao Zhao and Terry Alfald; Arizona State University, Tempe, Arizona, United States.

Recently transparent-composite-electrodes (TCEs) were introduced as a substitute for indium-tin-oxide (ITO) in bulk heterojunction organic solar cells (OSCs). In this study, an anode structure consisting of TiO2/Ag/TiO2 TCE with optimized layer thicknesses was implemented as an OSC to demonstrate its potential as a replacement for ITO. In addition, the compatibility of hole-transfer-layer (HTLs) of either MoO3 or poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) were investigated in terms of their compatibility with the TCE. Corresponding control samples of ITO based OSCs were fabricated using PEDOT:PSS and MoO3 as the HTL. It is found that MoO3 HTLs benefited the OSC that utilizes a TCE as the anode. When using the MoO3 the as HTL, TCE based OSC has better performance than ITO-based OSC; and, it even rivalled the performance of conventional ITO-based OSC that utilizes PEDOT:PSS as the HTL. Outcomes of this study confirmed that even with the slightly lower transmittance in the visible portion of the light spectrum, TCEs did not degrade the light absorption in OSCs, and the efficiency of transporting photo-induced carriers in TCEs anodes was comparable or even better than ITO.

highly sensitive VOC sensor based on fluorinated isoindigo conjugated polymers

Chun-fu Lu1, Song-Fu Liu2, Yi-Fan Chen1, Chin-Ti Chen2, Chi-Yang Chao3 and Wei-Fang W. Su4; National Taiwan University, Taipei, Taiwan; 3Academia Sinica, Taipei, Taiwan.

With the increasing concerns for the environment and the progress in non-invasive diagnosis, monitoring volatile organic compounds (VOCs) have attracted considerable attention. Ammonia and acetone are of particular interest because they are related to chronic kidney disease and diabetes disorder, respectively. Multi-functional donor-acceptor conjugated polymers are potential candidates for building reliable ammonia and acetone sensors due to the recent advancement in the field of thin film transistor. In this report, we demonstrate that the transistor mobility, the device stability and the sensitivity of sensors can be greatly enhanced by incorporating functional groups directly on the polymer main chain. The fluorinated isoindigo polymers exhibit hole mobility with over an order improvement than their un-fluorinated counterparts. The novel polymer transistors sensor can discriminate various VOCs and detect 100 ppb ammonia gas and 50 ppb acetone gas within 2 min in air. This is the most sensitive polymer transistor-based sensor towards acetone ever reported. The influence of fluorination is systematically studied to understand the intermolecular interaction between the analytes and fluorine atoms. Exceptional sensitivity to ammonia is attributed to the hydrogen bond forming between fluorine and ammonia and the sensitivity to acetone is due to the change in the energy levels of frontier orbitals of the fluorinated conjugated polymers enhance the transistor and gas sensing performance, which is essential for building fast response and high sensitivity sensor platform.

dual gate transistors based on dual active layers

Shuyun Huang and Paddy K. L. Chan; The University of Hong Kong, Hong Kong, Hong Kong.

Dual gate transistors based on rubrene/rubrene(p-p channels) and rubrene/DFH-4T(o-o-Diferrocenyl-quinquethiophene)(p-r channels) were fabricated. Traditional dual gate transistors using only one semiconductor active layer will inevitably result in bad injection in one channel. To maximize the charge injection area for both top and bottom channels, we adopted a staggered architecture with dual semiconductor layers. Gold source and electrodes are sandwiched between the bottom channel and the top channel. In the rubrene/rubrene dual channel dual gate OFETs, the average hole mobilities in the saturation regime for both bottom and top channel are around 5 cm2/Vs. The output characteristics for both channels exhibit good linearity in small Vg region, suggesting the charge injection is effective. Depending on the bias configuration, the threshold voltage of the bottom or top channel can be continuously modulated from 35.2 V to 45.6 V. In the rubrene/DFH-4T devices, the operating mode of the dual gate devices can be controlled as a p-channel, n-channel or ambipolar OFET. The AFM (Atomic force microscope) and XRD (X-ray diffraction) characterizations show that the growth of the top DFH-4T semiconductor is regulated by the bottom rubrene single crystals with distinct orientation. The dual gate transistors have the potential to be further constructed into inverters and complex logic circuits.

morphology stabilization using stamping transfer process via controlled PUA mold for perovskite and organic electronic devices

Woongisk Jang1, Min Ji Yi1, Jaesang Cho1, Min Seong Kim1, Ji Hyun Lim1, Byung Gi Kim1, KeumHwan Park2 and Dong Hwan Wang1; Chung-Ang Univ, Seoul, Korea (the Republic of); 1Korea Electronics Technology Institute, Gyeonggi-do, Korea (the Republic of).

Recently, stamping transfer process using by thin films or soft mold has been considered by advanced technology to overcome limits of wet coating such as spin or dip coating, which are composed of deposition of large area and specific region, the material loss, and penetration of solvents. Although the adhesion energy between stamp and targets was minimized for a successful transfer process, many researches have not discussed this factor. In this research, we introduced wetting coefficient related with the adhesion energy. We investigated the adhesion energy mainly depending on the surface energy of the stamp. We applied polyurethane acylate (PUA) as the stamp, of which the surface energy was modified to increase the transfer reproducibility. As a result, high-surface-energy PUA was used to form organic bulk hetero junction (BHJ) layer onto PEDOT:PSS/ITO substrates. The transferred device revealed a comparable efficiency, 95% relative to spin coating device. In order to decrease the fill factor of transferred device, we observed charge recombination and resistance through impedance spectroscopy.[1] Second, we applied stamping transfer to formation of inter-layer in planer-type perovskite photovoltaics. We have successfully fabricated the device with transferred inter-layer, 6,6-phenyl-C61 butyric acid methyl ester (PC71BM), onto perovskite layer by dry stamping transfer condition. The device exhibited enhanced Jsc and efficiency, which were caused by improved coverage of inter-layer on perovskite layer, correlated with increased electron mobility and exciton dissociation.[2] Finally, we fabricated organic photodetectors (OPDs) by stamping transfer process for photo sensitive BHJ layer. We confirmed a comparable performance of the transferred OPDs, compared to the device from spin coating. Especially, the dry transferred device exhibited superior durability (over 90%) for 350 hours to the spin coated device, because of morphology stabilization of photo sensitive layer, which led to suppression of degradation of the layer and burn-in loss.[3] This work provides a promising alternative process which can improve the device operation durability without burn-in loss by a simple and controllable transfer films.

Structuring polymer solutions upon liquid-vapor mass exchange

Jasper Michels; Max Planck Institute, Mainz, Germany.

Organic and hybrid thin film electronic devices, such as memory diodes, solar cells and transistors, typically contain a functional layer based on a blend of multiple polymeric or small-molecular species whose properties cooperatively give rise to a specific function. Depending on the desired functionality, phase separation during thin film solution processing is either encouraged or suppressed. Usually, at least one blend component is polymeric, so that mutual repulsion readily overcomes the entropic driving force to form stable mixtures. For this reason, it is often observed that during solution-casting droplet-like demixed morphology emerge due to (spontaneous) liquid-liquid (L-L) demixing. This presentation focuses on the role of this mode of phase separation in thin film electronics and how it is induced by mass exchange across the liquid-vapor boundary, i.e. solvent evaporation and vapor condensation. I give an overview on the work we have done to theoretically understand the influence of liquid-vapor exchange rates on demixing kinetics, as well as domain structure and composition. Multi-component continuum limit modeling demonstrates how microstructure and feature sizes emerge upon solvent evaporation and/or vapor condensation. The numerical simulations yield morphologies consistent with experimentally observed structures and demonstrate how domain size and phase composition are affected by internal and environmental factors.

Dodecaborane Clusters as Novel Tunable Dopants for Conjugated Polymers

Taylor Aurbry1, Jonathan Axtell1, Victoria Basile1, K.J. Winehell2, Jeffrey Lindemuth2, Sarah H. Tolbert1, Alexander Spokoyny1 and Benjamin J. Schwartz1; 1University of California, Los Angeles, Los Angeles, California, United States; 2Lake Shore Cryotronics, Inc., Westerville, Ohio, United States.

Doping conjugated polymers is an effective way to tune their electronic properties for thin-film electronics applications. Chemical doping of semiconducting polymers involves the introduction of a strong electron acceptor or donor molecule that can undergo charge transfer (CT) with the polymer. The CT reaction creates electrical carriers on the polymer
chain while the dopant molecules remain in the film as countereions. To dope polymer films, we employ a sequential process (SqP) in which a pure polymer layer is deposited first, followed by infiltration of the dopant in a second step using a semi-orthogonal solvent. SqP overcomes the problems typically incurred by blend-doping, where the polymer and dopant are mixed in solution, which results in aggregation at high concentration. The exceptional film quality achievable with our SqP doping method allows us to employ electrical measurements over macroscopic length scales, such as Van der Pauw conductivity measurements as well as AC Hall effect and impedance measurements of carrier mobility.

This work focuses on the use of substituted icosahedral dodecaborane (DDB) clusters of the form $\text{B}_2\text{O}_2\text{R}_2$ as a new class of dopant molecules, where $\text{R}$ is a substituted benzyl group. The redox potentials of DDBs can be rationally tuned via modification of the R-group substituents without a significant change to the size or shape of the dopant molecule. These tunable dopants provide a unique handle on the energetic offset that governs the driving force for doping via integer CT. Here, we disentangle the effects of energetic offset on the production of free and trapped carriers in DDB-doped poly-3-hexylthiophene (P3HT) films.

In DDB-doped P3HT films, in general, we find that conductivity and polaron absorption amplitude increase with increasing reduction potential, yielding conductivities on the order of 12 Scm. Since DDBs tend to localize electron density on their core, we have shown that the bulky corona of substituents on the clusters provide spatial isolation of the corona. The polaron is therefore Coulombically shielded from the corona, thereby reducing electrostatic interactions, resulting in highly delocalized and mobile carriers with mobilities up to 0.1 cm$^2$/Vs and effective conductivities up to 32 S/cm even in very non-crystalline polymer films. In these films, nearly all carriers are free, whereas it has been shown that the core of substituted compounds like FATCNO trap 95% of carriers, due to their small size and non-crystalline properties of the corona. Given the high conductivity but distinct loss off crystallinity observed, we explore the properties of these DDB-doped films as potential thermoelectric materials. The low crystallinities should lead to low thermal conductivities, even while the electrical conductivity is maintained, allowing optimization of the thermoelectric figure of merit.

**Amphiphilic Conjugated Polymers for Nanoparticle Stabilization**

Sonam Saxena, Philipp Meier, Alexander Colsmann, Wallace W. Wong, and David J. Jones.

Solution-processable semiconducting materials in organic solar cells (OSCs) enable the roll-to-roll printing of functional devices. However, the dissolution of these materials commonly requires toxic solvents, thus hindering the translation to industry. To enable large scale printing in industry, they should be formulated as inks using a less toxic medium such as alcohol or even water.

Researchers have fabricated OSCs by dispersing semiconducting materials in water/alcohol with the help of surfactants. However, significant surfactants remained in the active layer even after extensive dialysis, reducing the device performance and solar cell life-time. Recently, devices were fabricated using a dispersion of poly-3-hexylthiophene (P3HT) with iodine-C$_6$Br$_2$ (ICBA) in methanol and showed a 3.8% device efficiency without the need of a surfactant. However, in this case, the performance was highly dependent on the degree of polymer used for dispersion. Herein, we show the requirement of an appropriate surfactant which not only controls the size of nanoparticles but also increases nanoparticle stability whilst maintaining device efficiency.

To address this problem, we synthesized P3HT end-capped with pyridine. We expected this pyridine-P3HT to be protonated on addition of acid and act as a surfactant by making an electrical double layer around the nanoparticles, inducing a repulsive interaction and preventing aggregation, however under thermal annealing the pyridinium salt would decompose removing all trace of the acid. By using a combination of 1.5 w% pyridine-P3HT and trifluoroacetic acid as additives, stable P3HT:ICBA nanoparticle dispersions of up to 30 mg/mL in methanol were achieved. The nanoparticles in these dispersions were 120 ± 5 nm, and the dispersions were stable up to 60 days. Inverted architecture OSC built using these nanoparticle dispersions exhibited 3.4% efficiency, a result that is comparable to the state-of-the-art P3HT:ICBA solar cells fabricated under optimized conditions using chlorinated solvents.

**Vertical Organic Charge Modulated FET Devices for Sensing Applications**

Andrea Spanu, Laura Martinez, Annalisa Bonfiglio, and Piero Cosseddu.

Since the discovery of the first conductive polymer, organic electronics helped disclosing a whole new world of possibilities in the realization of, among several other applications, flexible displays, mechanically compliant (but also implantable and bioreosorbable) sensors and biosensors, and tactile sensors for next generation artificial skin applications.

Despite these remarkable achievements and more than 5 decades of technical advancements, the field of application of organic electronic devices is still relatively narrow, due to the intrinsic properties of the semiconductive materials usually employed. In particular, common limitations are the low switching speed caused by the intrinsic low mobility of the charge carriers within the most common polymers and small molecules used (this limitation preventing most of the organic transistor to be used as reference devices), and the limited devices resolution, the latter issue being mainly due to the difficulty of fabricating short channel transistors while at the same time using low-cost and large area fabrication techniques.

In order to overcome these apparently unavoidable issues, during the last 15 years a new type of organic transistor has been introduced, namely the vertical organic transistor (vOFET). This peculiar “vertical approach” allows to obtain short channels without the need of expensive fabrication techniques, thus representing a very interesting technological advancement with respect to pre-existing OFETs. In this work we report about a novel and easy approach to the realization of vertical organic transistors that includes the use of Parylene C as both the “core” of the vertical structure and the gate insulator. The fabrication process has been optimized in order to have the possibility to obtain highly flexible and ultra-conformable transistors, being such devices fabricated on micrometer-thick films (either Parylene C or polyamide-imide) that, after the device fabrication, can be conveniently detached from the carrier substrate allowing it to be transferred onto whatever kind of surface. Moreover, we will also demonstrate that such approach is particularly suitable for the fabrication of sensing devices. In particular, we employed a double-gated organic transistor called organic charge modulated FET (OCMFET), which has established itself during the past 10 years as a versatile sensor with an ultra-high sensitivity.

The combination of the proposed novel and convenient approach to the fabrication of vertical organic transistors (with the possibility of realizing high-resolution and faster switching devices) and the remarkable features of the OCMFET represents an interesting advancement within the organic electronics scenario, in that it will allow to obtain reference-less, ultra-sensitive sensors arranged in conformable high-density arrays, while keeping the process low-cost, thus offering considerable advantages to the field of organic sensing and biosensing.

**Substituents Engineered Deep-Red to Near-Infrared Phosphorescence from tris-Heteroleptic Iridium(III) Complexes for Solution Processable Red-NIR Organic Light-Emitting Diodes**

Hae Un Kim, Seung Un Ryu and Taiho Park; POSTECH, Pohang, Korea (the Republic of).

Research on near-infrared- (NIR-) emitting materials and devices has been propelled by fundamental and practical application demands surrounding information-secured devices and night-vision displays to phototherapy and civilian medical diagnostics. However, the development of stable, highly efficient, low-cost NIR-emitting luminophores is still a formidable challenge owing to the vulnerability of the small emissive bandgap toward several nonradiative decay pathways, including the overlapping of ground- and excited-state vibrational energies and high-frequency oscillators. Suitable structural designs are mandatory for producing an intense NIR emission. Herein, we developed a series of deep-red to NIR emissive iridium(III) complexes (Ir1–Ir4) to explore the effects of electron-donating and electronwithdrawing substituents anchored on the quinoline moiety of (benz[b]thiophen-2-yl)quinoline cyclometatating ligands. These substituents help engineer the emission bandgap systematically from the deep-red to the NIR region while altering the emission efficiencies drastically. Single-crystal X-ray structures authenticated the exact coordination geometry and intermolecular interactions in these new compounds. We also performed an in-depth and comparative photophysical study in the solution, neat powder, doped polymer film, and freeze matrix at 77 K states to investigate the effects of substitution on the excited-state properties. These studies were conducted in conjunction with density functional theory (DFT) and time-dependent density functional theory (TD-DFT) calculations. Most importantly, the –CH$_3$ substituted Ir1, unsubstituted Ir2, and –CF$_3$ substituted complex (Ir4) were promising novel compounds with bright phosphorescence quantum efficiency in doped polymer films. Using these novel molecules, deep-red to NIR emissive organic light-emitting diodes (OLEDs) were fabricated using a solution-processable method. The unoptimized device exhibited maximum external quantum efficiency (EQE) values of 2.05% and 2.11% for Ir1 and Ir2, respectively.
Emission Gain Narrowing in Organic Semiconductor Single Crystal

Minji Kang, Yeong-A Kim, In-Bok Kim, Dongseong Yang, Yeonsu Choi and Dong-Yu Kim; School of Materials Science and Engineering (SMSE), Gwangju Institute of Science and Technology, Gwangju, Republic of Korea; Department of Mechanical and Aerospace Engineering, University of Missouri-Columbia, Columbia, Missouri, United States; Department of Solid State and Structural Chemistry, Tsinghua University, Shenzhen, China. Inorganic materials with high mechanical flexibility, lightweight, and solution processability are highly desirable as organic electronic devices. We report an inorganic-organic hybrid material, 

Emission Gain Narrowing in Organic Semiconductor Single Crystal

Influence of the Mobility Ratio and Energetics of n-Conjugated Polymers on the Thermoelectric Properties of Polymer Blends

Ashkan Altabaki, Yadong Zhang, Xuyi Luo, Jianguo Mei, Seth R. Marder and Kenneth R. Graham

Chemistry, Purdue University, West Lafayette, Indiana, United States; Chemistry, Georgia Institute of Technology, Atlanta, Georgia, United States; Physics and Astronomy, University of Kentucky, Lexington, Kentucky, United States; Chemistry, University of Kentucky, Lexington, Kentucky, United States.

Conjugated polymers can be used in mechanically flexible and low cost thermoelectric (TE) devices, but their thermoelectric performance must be improved to make them commercially viable. The performance of thermoelectric materials depends on the electrical conductivity, Seebeck coefficient and thermal conductivity. In polymer based TE materials the polymer needs to be doped to become electrically conductive. The higher the doping concentration, the more electrically conductive the material becomes, but generally at the cost of a decrease in the Seebeck coefficient. Blending of n-conjugated polymers has been proposed as a method to minimize the tradeoff between electrical conductivity and the Seebeck coefficient, thus potentially allowing higher power factors to be reached. By blending two polymers, the total density of states (D.O.S.) will be manipulated, which may be used to alter the energy dependence of charge transport in the TE material. The major parameters that we expect to impact the power factor in polymer blends are the mobility ratios between the two pure polymers and the shape of the D.O.S. (i.e., the disorder and the energy offsets between the D.O.S. distributions of each polymer). Here, we modified a model introduced by Bässler and Arkhipov to theoretically probe how these two parameters impact thermoelectric performance. These calculations are then used to fit experimental data of various polymer blends with varying mobility ratios and D.O.S. distributions. We find that adding a polymer with a narrower D.O.S. and higher mobility with respect to host polymer can lead to an enhancement in the power factor.

Donor-Acceptor Copolymers and Sol-Gel Processable ZnO for Hybrid Photodetectors and Thin-Film Transistors

Alec M. Pickett, Tushita Mukhopadhyay, Suman Ray, Xiaqing He, Satish Patil and Suchismita Guha

Physics and Astronomy, University of Missouri–Columbia, Columbia, Missouri, United States; Solid State and Structural Chemistry Unit, Indian Institute of Science, Bangalore, India; Electron Microscopy Core Facility, University of Missouri-Columbia, Columbia, Missouri, United States; Department of Mechanical and Aerospace Engineering, University of Missouri-Columbia, Columbia, Missouri, United States.

Hybrid organic-inorganic semiconductor interfaces have attracted attention in photodiodes and field-effect transistors (FETs) due to the realization of intrinsic p-n junctions and their mechanical flexibility. Organic copolymers based on diketopyrrolopyrrole (DPP) cores have also gained significant interest for application in FETs because of their high p-type carrier mobilities as well as high power conversion efficiencies in solar cell structures. In addition, grazing-incidence x-ray diffraction (GIXRD) reveals crystalline stability of phenoxy-capped DPP-based monomers [1]. With the difficulty of developing high-mobility n-type organic semiconductors [2] due to the necessity of low LUMO levels and ambient environment stability, solution processable inorganic materials are an excellent alternative. ZnO is an intrinsic n-type semiconductor which is non-toxic and sol-gel processable, creating avenues for film patterning [2] and fully solution processed devices. These ZnO films are also able to be easily treated, reducing lattice defects through UV-Ozone processing. This decreases the dark current and increases responsivity in hybrid photodetectors and yields improved electrical performance in FETs. Additionally, cross-sectional electron microscopy techniques reveal hidden characteristics within the morphologies of the films and provide insight as to how processing conditions impact FET and photodiode operation.

We support the acknowledgement of this work through the National Science Foundation under Grant No. ECCS- 1707588

Novel Quinoidal Conjugated Molecules and Polymers for High Performance Organic Field-Effect Transistors

Junyeol Kim, Hansu Hwang, Nam-Koo Kim, Yeon-Ju Kim, Minji Kang, Yeong-A Kim, In-Bok Kim, Dongseong Yang, Yeonsu Choi and Dong-Yu Kim; School of Materials Science and Engineering (SMSE), Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of).

Organic field-effect transistors (OFETs) based on organic semiconductor materials have intensive interest both in the academic and industrial fields because of their application in low-cost and flexible electronics. The structure-property relationship of novel organic semiconductor materials has been explored with the development of device engineering technique leading to understanding charge transport mechanism and device physics. In this work, we have focused on the investigation of structure-property relationship of conjugated molecules based on quinoidal structure. The quinoidal structure has been considered as a promising building block to achieve efficient charge transport due to their high structural planarity arising from a double bond linkage between aromatic rings. Despite the merits as conjugated moiety, the incorporation of the quinoidal platform into the
conjugated polymer backbones has suffered synthetic difficulty. Here, some derivatives of quinoidal small molecules and polymers with various quinoidal platforms were synthesized, and their structure-property relationships was investigated. Moreover, field-effect transistors based on these compounds were fabricated and characterized about electrical properties. Among them, OFETs based on poly(quinoidal thiophene-bithiophene) (PQuT-BT) prepared by off-center spin coating showed the unprecedented highest hole mobility of 8.09 cm²/V·s among reported quinoidal polymers. Furthermore, we fabricated OFET devices based on this polymer via printing methods applying unidirectional shear forces leading to high molecular alignment and device uniformity in large area.

Flexible Transparent Electrodes via Printed Polymer-Sphere Networks for Polymer Photodiode and Light-Emitting Diode
Juan Zhu, Donggeon Han, Xiaodong Wu and Ana C. Arias; Electrical Engineering and Computer Science, University of California, Berkeley, Berkeley, California, United States.

Flexible transparent electrodes have drawn increasing interest due to the rapid development of flexible electronics and sensors. Metal networks is an emerging novel transparent electrode, which has shown potential applications in organic electronics and wearable sensors. However, the techniques which can realize facile fabrication of non-transfer, large-area and low-roughness metal-network are desperately desired. Our work demonstrates a print-compatible method for fully interconnected metal networks directly on the flexible substrate. A patterned high-k dielectric substrate and then convert photolithography into polymer networks. We combine evaporation processes to transfer the networks into interconnected metal structures on the substrate. We demonstrate such transparent electrodes as the top electrodes both in the spin-coat and printed polymer photodiode and light emitting diode. This technique is low-cost, print compatible and can achieve the low-roughness and large-area transparent electrodes directly on the flexible substrate, which shows potential applications in large-area organic electronics.

EP06.06.27
Dynamic Composition of Electrolyte Gated Organic Mixed Ionic Electronic Conductors
Bryan D. Paulsen, Vishak Venkatraman and Jonathan Rivnay; Biomedical Engineering, Northwestern University, Evanston, Illinois, United States.

Organic mixed ionic electronic conductors (OMIECs) are semiconducting polymers able to efficiently transport both ionic and electronic charge, and efficiently transduce ionic and electronic currents. This has led to their success as the channel materials in organic electrochemical transistors (OECTs) for biological sensing applications. By using an experimentally verified TCAD model developed in Silvaco Atlas for the high mobility polymer semiconductor, PDPP-TNT, we show how optimizing the patterning of patterned TFTs, which are defined as narrow semiconductor stripes atop a gate dielectric with air or a low permittivity dielectric between each stripe. A nanostripe TFT device will focus on the latter two sources of nanostripe enhancement since they are more broadly applied to all disordered semiconductor systems.

EP06.06.28
Nanostripe Channel Patterning of Polymer Thin-Film Transistors for Improved Performance
Kelly Liang, Oleksiy O. Krutko and Ananth Dodabalapur; Microelectronics Research Center, The University of Texas at Austin, Austin, Texas, United States.

In recent years, researchers have explored various methods of shaping the active semiconductor layer to improve thin film transistor (TFT) performance. The shaping has varied in methods and architectures from micron scale etched stripes for amorphous metal oxides, to hundreds of nanometers wide printed polymer stripes, and also to textured or grooved substrates for various materials including organics and polymers. It has been reported by these and other works that patterning can improve performance of polymers and it has been observed that patterning improves key transistor characteristic across many TFT material systems. We present a detailed analysis of the electronic origins of improvements seen by nanopatterning devices and a means to optimize TFT device design to enhance these improvements. Our work specifically focuses on the unique advantages of nanostripe patterned TFTs, which are defined as narrow semiconductor stripes atop a gate dielectric with air or a low permittivity dielectric between each stripe. A nanostripe TFT device features multiple strips with a common gate and common source and drain contacts.

There are three main origins of nanostripe enhancement—first is improved morphological order of the disordered materials especially polymers, as previously reported by several groups; second is greatly enhanced induced carrier densities which is especially advantageous for disordered semiconductors which display carrier mobilities that are approximately linearly dependent on carrier concentration; third is improved gate control, similar to FinFET schemes seen in silicon and other semiconductor transistors. With the combined effects of all three, nanostripe devices can expect substantially improved drive currents and gate control over their unpatterened thin-film counterparts. This presentation will focus on the latter two sources of nanostripe enhancement since they are more broadly applied to all disordered semiconductor systems. By using an experimentally verified TCAD model developed in Silvaco Atlas for the high mobility polymer semiconductor, PDPP-TNT, we show how optimizing the patterning of TFTs into nanostrips maximizes enhancement of foundational transistor performance metrics, such as increased carrier mobility, lower of off-current, reduced threshold voltage, and improved subthreshold swing. By adjusting the geometry of the nanostripe—we namely by finding the optimum stripe width and stripe pitch, and making no adjustments to any other material parameters, we show that the drive current can be improved by a factor of 13. The nanostripe geometry focuses electric fields along the edges of stripe, maximizing trap state filling in those areas, to greatly improve carrier transport. While similar effects are seen in nanogroove and FinFET structures, nanostrips (which sit atop the dielectric) generate the most local enhancement. Further experimentation is underway to improve the accuracy of the TCAD model.

EP06.06.30
Raman Crystallography as a Probe of Phonon-Mediated Anisotropic Carrier Mobility in Single Crystal Organic Semiconductors
Adam Biachesi1, Emily Bittle1, Lisa Freni1,2, Andrew Herzing1, Thomas Allisson1, David Gundlach1 and Angela Hight Walker1; (National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 1Department of Chemistry, Lehigh University, Bethlehem, Pennsylvania, United States.

Understanding charge transport in organic semiconductor materials is an important step in the development of high-performance electronics employing these materials. Intermolecular motions are postulated to limit carrier mobility in organic electronics due to the formation of transient charge carrier localization, which prevents band-like transport. Raman spectroscopy is a powerful technique to nondestructively investigate such vibrational modes of organic crystals. These phonons are spatially localized within the lattice and correlate to the underlying crystallographic structure of the material. This provides a straightforward means to investigate the crystallinity, orientation, composition, and phase with high spatial resolution and no sample preparation. Here we present a polarization-orientation Raman spectroscopy analysis of single-crystalline organic semiconductor tetracene. We find five distinct vibrational modes in the low-energy regime (~25 meV) that are ascribed to intermolecular lattice phonons. Polar plots indicate that these motions are characterized in agreement with group theory, directed within the ab plane of single-crystalline tetracene (001), as confirmed by electron diffraction. We then correlate the geometry of these phonon modes with the anisotropic field-effect mobility found within this plane and utilize density functional theory modeling of the corresponding molecular motions to examine the potential impact of orbital overlap between molecules on carrier transport. Collectively, these data suggest that transient localization due to Raman-active intermolecular motion has directionality within the single-crystalline structure of tetracene molecules and, more generally, the lattice motion strongly influences the inherent charge transport behavior and anisotropic character of organic semiconductors.

EP06.06.33
Controlling Doping in Semiconducting Polymers has significantly reduced dark current (~1 × 10⁻³ A/cm²). Organic semiconductors have very low mobility (e.g., 10⁻⁵ cm²/Vs) and a short free mean path [2]. This addresses the challenge of improving conversion efficiency by incorporating highly anisotropic carbon nanomaterials (CNMs) such as carbon nanotubes (CNTs) and/or graphene nanoplatelets (GNPs), which have been shown to improve charge transport towards the electrodes. Although CNMs have been used before in OPVs, the focus of our research is to elucidate the effect of the structural properties of the CNMs on OPV performance. More specifically, we address the issue of improving the performance of a new hybrid OPV device by combining the physical and chemical characteristics of light-sensitive conjugated polymers (CP), e.g. P3HT, with the high electrical conductivity of the CNMs in a composite photoactive layer. Special care is taken to control the optoelectronic properties and PV characteristics of the hybrid OPV through the morphology of the CNMs and to study the improvement of the exciton dissociation efficiency of the CNMs/photosensitive polymer interface, in a planar heterojunction photovoltaics configuration. The obtained results show photoconversion efficiencies of about 3.85 % and 4.05 % for CNTs and GNP loads of 0.5 and 0.8 wt. %, respectively. The main parameters will be presented and an outlook into the future will be discussed accordingly.

**Infrared-to-Visible Up-Conversion OLEDs Using Novel Infrared-Sensitive Low-Bandgap Organic Donors and/or Acceptors**

Vishall Yeddu, Gijun Seo, Hyocheol Jung and De Young Kim; Oklahoma State University, Tulsa, Oklahoma, United States.

Infrared (IR)-to-visible up-conversion organic light-emitting diodes (OLEDs) using various novel low-bandgap organic donors and/or acceptors as the organic IR sensitizing layer were fabricated with an IR sensitivity beyond 1 μm. The novel donors and acceptors have narrow bandgaps of 0.9 – 1.2 eV and showed strong absorption in the visible as well as IR region till 1200nm. IR photodetectors are first fabricated to evaluate the new donors and acceptors as the IR sensitizers in the IR-to-visible up-conversion OLEDs. The multi-layered photodiode structures with an electron blocking layer (EBL) and a hole blocking layer (HBL) are used to reduce its dark current, thus resulting in high detection. Most of photodetectors with novel IR sensitizers showed strong IR sensitivity in the near-IR wavelengths from 700 nm to 1200 nm. The photodetectors with novel IR sensitizers showed detectivities higher than 10¹¹ Jones in the multi-spectral region (300-1100nm) and the maximum detectivity of 3.0 × 10¹² Jones at the wavelength of 800 nm due to significantly reducing dark current (~1 × 10⁻⁴ A/cm² at 0.1V). Using this novel low-bandgap organic materials as the IR sensitizer, IR-to-visible up-conversion OLEDs were fabricated with an IR sensitivity up to 1,200 nm. The IR up-conversion OLED successfully converted invisible near-IR light of 700nm-1200nm directly to visible green light with a peak emission wavelength of 520 nm. This is the very first report of all-organic IR-to-visible up-conversion OLED with near-IR sensitivity beyond 1100 nm which Si-based photodetectors cannot offer.

**Highly-Efficient Solution-Processed Organic Light Emitting Diodes with Blend V:O-PEDOT:PSS Hole-Injection/Hole-Transport Layer**

Rohit Ashok Kumar Yadav, Deepak Kumar Dubey and Jwo-Huei Jou; National Tsing Hua University, Hsinchu, Taiwan.

Organic light-emitting diodes (OLEDs) have attracted huge demand because of their intrinsic characteristics and ability to reach the pinnacle in the field of high-quality flat-panel displays and energy-efficient solid-state lighting. High-efficiency is always a key crux for OLED devices being energy-saving and longer life-span. OLEDs have encountered enormous difficulties in meeting the requirements for large-sized devices due to a major limitation in vacuum thermal evaporation technology. In multi-layered OLED devices, the quantity of the charge injection/transport layer is a crucial factor for the operating-voltage, power-efficiency, and stability of the device. Transition metal oxides have shown great potential owing to their wide range of possible energy level alignments, balanced charge injection, and improvement of carrier mobilities. In this study, we report an efficient low-driving solution processed OLED devices composed of blend V:O-PEDOT:PSS hole-injection/hole-transport layer (HIL/HTL). The electroluminescent characteristics of blend V:O-PEDOT:PSS based devices were studied with the structure ITO/PEDOT:PSS or V:O-PEDOT:PSS:MT-DATA:Ir(2-phenyl)/TPBi/LiF/Al. The V:O-PEDOT:PSS based OLEDs exhibited relatively high device performance and low roll-off than that of the counterpart PEDOT:PSS devices in terms of a maximum luminance of 17,670 cd/m², power-efficiency of 15.7 lm/W, external quantum efficiency of 7.7%, and more importantly low turn-on voltage of 2.2 V. The fabricated device exhibits high color stability, lifetime, and excellent saturation compared to counter devices. These are the highest power efficiencies ever reported for this particular device architecture with blend transition metal oxide-organic complex.
novel concept based on an organic electrochemical transistor and show how these challenges in the field such as state-retention and linear conduction tuning can be overcome. We investigate chemical doping of the active organic semiconductor material with additive amines for improved oxidation state stability over a large range and enhanced device-to-device variability, an essential characteristic for efficient large-scale arrays. Finally, we demonstrate that this device can be entirely fabricated on flexible substrates, introducing neuromorphic computing to large-area flexible electronics and opening up possibilities in brain-machine interfacing and adaptive learning of artificial organs.

Doping Organic Semiconductors for Thin-Film Transistors Julianna Panidi1, Jaspreet Kainth1, Alexandra Paterson2, Martyn McLaughlan1, Martin Heeney4 and Thomas D. Anthopoulos2, 1Department of Physics, Imperial College London, London, United Kingdom; 2KAUST Solar Centre, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 3Department of Materials, Imperial College London, London, United Kingdom; 4Department of Chemistry, Imperial College London, London, United Kingdom.

Improving the performance and reliability of organic electronic devices is necessary for their successful commercialization. New materials combined with improved synthetic routes have so far lead the way to the development of state-of-the-art organic electronic devices and their application in a range of emerging forms of electronics. An alternative and less studied approach towards high performing organic semiconductors (OSC) is the use of molecular dopants as a mean for tuning their physical properties and often the resulting device characteristics. In organic thin film transistors (OTFTs) doping results to improved charge carrier mobility, by eliminating the threshold voltage while reducing parasitic contact resistance. Although highly useful, detailed understanding of the doping mechanism still remains challenging, with the most understood process being that of the integer charge transfer. The key requirement for doping to occur is the minimum energy offset between the dopant and the host material. In the case of n-type materials the dopant has to donate an electron from its highest unoccupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) of the host. Although numerous studies have been reported on p-type doping of organic semiconductors, work on molecular n-doping remains surprisingly limited. The main reason for this is the difficulty of identifying suitable dopants that are stable and efficient.

Here, we report the use of a new molecular dopant that is able to n-dope a number of organic semiconductors, which are then used as the channel materials in OTFTs. We show that key transistor parameters such as charge carrier mobility, contact resistance and threshold voltage improve dramatically upon addition of the dopant. The doping effect was studied using different methods including Electron Paramagnetic Resonance (EPR) and temperature dependent field-effect electron transport measurements. The impact of the dopant on the morphology of the OSCs has also been studied using Atomic Force Microscopy (AFM) and X-Ray diffraction (XRD) measurements, yielding interesting insights on the impact of doping on the layer microstructure for the first time. Overall, this work highlights that controlled doping of organic semiconductor materials is the key for improving the electronic characteristics of n-channel OTFTs.

Ohmic Charge Injection and Low-Power OFETs Achieved by Organic Semiconductor Monolayer Crystals Boyoi Peng and Paddy K. L. Chan; Hong Kong University, Hong Kong, China.

In organic thin-film transistors (OTFTs), the charge accumulation region is within several nm away from dielectric interface. For the monolayer crystals of small-molecule organic semiconductor materials, all the molecules contribute in forming the conductive channel and receive benefits from long-range in-plane ordering. A meniscus-guided solution-processing method is employed to grow monolayer crystals of C49-DNTT with single-crystalline domain size as large as millimeters. Intrinsic field-effect mobility of >12 cm²/V·s is achieved. More importantly, the ultrathin thickness minimizes the charge injection barrier for the top-contact electrodes, allowing an ohmic hole injection and a low contact resistance (Rc, W) of 67±15 ohm cm. The low contact resistance ensures low voltage drops at the metal/semiconductor interface, allowing the device to operate even at VDS = ~1 mV. It opens a new direction of low-power OFET that operates at pico-watts, which can only be achieved by high-mobility short-channel OFETs with very low contact resistance. The physics origin of forming such low contact resistance of OFETs will also be discussed.

Molecular Surface Chemistry for Improved Interfaces in Organic Electronics Jonathan Hopwood1, Jixin Chen2 and Jacob Ciszek1; 1Loyola University Chicago, Chicago, Illinois, United States; 2Chemistry, Ohio University, Athens, Ohio, United States.

Organic optoelectronic devices (OLED, OFETs, etc.) contain at least one, if not multiple instances of overlayers deposited onto organic semiconductors. The generated interface is inherently flawed with issues such as non-ohmic contact, overlayers delamination, or deposition induced damage arising. Traditionally, this is addressed by physical vapor deposition of yet another layer or by reengineering the materials in the device stack. In contrast, a reaction based approach allows for a wider range of function to be installed via molecular components in an organized and oriented manner, while all take advantage the inherent reactivity of the organic molecules which comprise the semiconducting layer. We have developed this approach via a “click-like” Diels-Alder chemistry whereby prototypical acene films (tetracene or pentacene) can be appended with a variety of small molecules to form an interfacial layer only ~5 Å thick. This chemistry is then applied towards improving the metal on semiconductor contact. As a demonstration of principle, Diels-Alder chemistry is utilized to form covalent bonds linking the organic semiconductor with a deposited metal contact thereby eliminating the poor adhesion present in this system. Application of the chemistry towards contact potential shifts is presented, while works towards sensing applications concludes the talk.

9:30 AM EP06.07.06
Individual Contributions of the Source and Drain Contacts to the Total Resistance in Organic Thin-Film Transistors Investigated Using Kelvin Probe Force Microscopy (KPFM) Melanie Brouillard1, 2, Nicolas B. Bercu1, Olivier Simonetti1, Hagen Klauk1 and Louis Giraudet1, 1Université de Reims Champagne-Ardenne, Reims, France; 2Organic Electronics, Max Planck Institute for Solid State Research, Stuttgart, Germany.

An important requirement for organic thin-film transistors (OTFTs) is a reproducibly small and well-controlled contact resistance. A popular method for determining the contact resistance is the transmission line method (TLM), which has the drawback that it is valid only under the assumption that the contact resistance is linear, which is generally not the case. Another drawback is that TLM cannot differentiate between the source resistance (RS) and the drain resistance (RD). Using surface potentiometry on operating OTFTs [1], resistances at the source and drain contacts can be measured independently from the potential drops measured in the transistor channel. We have carried out KPFM measurements on OTFTs with different doping methods [2.3.4,5] and n-type semiconductors [6] fabricated in the bottom-gate, bottom-contact (inverted coplanar) configuration. A 10-nm-thick layer of aluminum oxide deposited by atomic layer deposition was used as the gate dielectric, and gold was used for the source and drain contacts. In some of these OTFTs, the bias sequences applied during the KPFM measurements induced changes of the contact behavior, and in some cases the current-voltage characteristics of the contacts became nonlinear. On these TFTs, potential drops (UI(stray)) were observed on the KPFM profiles both at the source and at the drain contacts. From the simultaneous measurement of the drain current (Id), the contact characteristics (Id/I(U(stray))) relationship were obtained. When the Id/I(U(stray)) relationship is linear, the contact resistance can be obtained from this relationship. In some of the TFTs examined here, the current-voltage characteristics of the source and drain contacts are nonlinear, following a power law with an exponent between 1.5 and 3. In this case, we were able to estimate the contact resistance only to within an order of magnitude. Also, the potential drop at the source contact appears to be significantly larger than the potential drop at the drain contact, as one would expect from a contact exhibiting a large misalignment of the energy levels. To understand how each contact contributes to the total contact resistance, similar measurements were performed at various gate-source voltages. In addition, the measurements were repeated to observe the evolution of the contact characteristics with time.

Recent advances in bioelectronics are making the gap between electronic systems and human body ever closer. Despite these recent successes, the majority of bioelectronic devices still rely on electrode materials which are physically and mechanically dissimilar to biological tissues. Biological tissue is soft and contains large amounts of water with dissolved ionic species. In contrast, most inorganic materials and dry polymers in bioelectronic devices exhibit much higher elastic moduli with virtually no water content. Among many engineering materials, hydrogels show a great promise as ideal interfacing materials to biological tissues, owing to their unique tissue-like mechanical property, water-rich nature, superior biocompatibility, and ease in engineering. However, conventional hydrogels typically lack electronic conductivity, and the ionic conductivity of hydrogels in physiological conditions is very low. Unlike conventional hydrogels, conducting polymer hydrogels uniquely offer both electronic and ionic conductivity, and have been extensively explored for bioelectronic applications, among which hydrogels based on PEDOT:PSS are particularly promising owing to their favorable electrical, mechanical properties, and biocompatibility. Despite recent developments of various PEDOT:PSS hydrogels, several challenges still remain as unresolved questions in the field. For example, electrical conductivity of poly(2,5-dialkyl)-PPV-based hydrogels are typically low (less than 1 S cm\(^{-1}\)) and their poor adhesion with other engineering solids significantly limits their utility in bioelectronic device applications. Moreover, the limited set of accessible advanced fabrication strategies for PEDOT:PSS hydrogels further restrain their impact in applications. In this talk, we will discuss our series of recent developments on preparation, robust adhesion, and 3D printing of highly conductive PEDOT:PSS hydrogels. We start with a simple yet effective method to prepare highly conductive pure PEDOT:PSS hydrogels. Then, we will discuss a novel strategy to facilitate robust bonding of PEDOT:PSS hydrogel on various commonly used device substrates. Lastly, we will discuss the development of a novel direct ink writing 3D printable PEDOT:PSS ink and the resultant printed structures, uniquely enabled by the unprecedented 3D printing capability.

N-Doped Polythiophene Based Polymers for n-OECTs Zivudmorn Khan, Suhao Wang, Mikhail Vagin, Magnus Berggren, Simone Fabiano and Xavier Crispin; Department of Science and Technology (ITS), Linköping University, Norrköping, Sweden.

Organic electrochemical transistors (OECTs) are captivating significant attention owing to their applications in various fields such as molecular sensing, neuromorphic computing, digital logic circuits, cell culture analysis and printed electronics. However, building complementary circuits requires high-performance complementary p-type (hole-transporting) and n-type (electron-transporting) materials. Up to date, most reported OECTs are based on p-type polymers, with n-type lagging far behind mainly due to the lack of efficient and stable n-type conducting polymers. Herein, we report that polythiophene based polymers specifically poly(3,4-ethylenedioxythiophene) (PEDOT) and poly(3-alkylthiophene-2,5-diyl) (P3HT) conventionally p-type electrochemically can be doping to be n-type. The electronic conductivity of both PEDOT and P3HT was estimated to be 744 and 640 mS cm\(^{-1}\), respectively. Both, PEDOT and P3HT can work successfully as efficient n-type channel material for OECTs.

A Simple Technique to Reduce Contact Resistance in Organic Field-Effect Transistors Zachary Lampert1, Katrin Barath1,2, Hyunsu Lee1, Eliot Gunn1, Sebastian Engmann1, Hu Chen1, Martin Guthold1, Iain McCulloch1,3, John Anthony1,2, Lee Richter1, Dean DeLongchamp3 and Oana Juretescu1; 1Department of Physics and Center for Fundamental Materials, Wake Forest University, Winston Salem, North Carolina, United States; 2Department of Biomedical Engineering, Duke University, Durham, North Carolina, United States; 3Materials Science and Engineering Division, National Institute of Standards and Technology, Gaithersburg, Maryland, United States; KAUST Solar Center, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 4Department of Chemistry and Centre for Plastic Electronics, Imperial College London, London, United Kingdom; 5Department of Chemistry, University of Kentucky, Lexington, Kentucky, United States.

Contact effects represent a significant hurdle in the pursuit of the promised potential of organic thin-film transistors (OTFTs). For effective use in radio-frequency identification (RFID) and the other myriad technologies commonly ascribed to OTFTs, devices must operate in the high kHz to low MHz range, which requires a combination of high-mobility semiconductor and short channel length. However, transistors with short channel lengths must be accompanied by a drastic reduction in contact resistance. The channel conductance scales with channel length, whereas contact resistance is independent of this reduction in scale and, without a proportional decrease in contact resistance, results in a reduced effective device mobility. For these reasons, the development of functional devices based on organic semiconductors requires significantly diminished contact resistance.

In this work, we focus on a simple, yet effective method to engineer OTFT electrodes with exceptionally low contact resistance and high device performance. We fabricate staggered-structure OFETs in the bottom-contact, top-gate configuration using Ti/Au source and drain contacts treated with pentafluorobenzeneiodithiol (PFBT), and Cytop as the top-gate dielectric, while as semiconductor we tested both small molecules and polymers. We evaluated the performance of OFETs using the same architecture with contact deposition rates varied between 0.5 Å s\(^{-1}\) and 2.5 Å s\(^{-1}\). In 2.8-difluoro-5,11-his-triethyl(ethylenyl) anthradithiophene (dif-TES ADT) devices we found an increase in mobility from \(\mu = 3.7 \text{ cm}^2\text{ V}^{-1}\text{ s}^{-1}\) obtained at a rate of 2.5 Å s\(^{-1}\) to \(\mu = 19.2 \text{ cm}^2\text{ V}^{-1}\text{ s}^{-1}\) at 0.5 Å s\(^{-1}\) Similarly, in the copolymer indacenodithiophene-co-benzothiadiazole (C4DT-BT), the mobility increases from \(\mu = 3.3 \text{ cm}^2\text{ V}^{-1}\text{ s}^{-1}\) at 2.5 Å s\(^{-1}\) to \(\mu = 12.0 \text{ cm}^2\text{ V}^{-1}\text{ s}^{-1}\). To determine if these results were due to a difference in semiconductor film microstructure, we performed microbeam grazing incidence wide-angle X-ray scattering (\(\mu\)GIWAXS) and NEXAFS but find no significant differences. We assessed the contact resistance of these devices using the gated transmission line method (gated-TLM) and find that the largely improved mobility at 0.5 Å s\(^{-1}\) coincides with a significant reduction in contact resistance, with the lowest value of 200 Ω cm being obtained in the polymer devices. From scanning Kelvin probe microscopy, we discovered that the origin of the reduced contact resistance is the presence of high work function surface domains resulting from local SAM order, that facilitate injection into the semiconductor. The massively improved performance in both small-molecule and polymer semiconductors indicates that the reduced rate of source and drain contacts is an important parameter to modify in order to reach the low contact resistances necessary for the integration of OFETs into existing technologies.1

A New Concept of Electrode for Highly Efficient Ambipolar Carrier Injection in Organic Semiconductors Katsumi Tanigaki1,2, Thangavel Kanagasekaran1,2, Taiki Miura1 and Hidekazu Shimotani1; 1Department of Physics, Graduate School of Science, Tohoku Univ, Sendai, Japan; 2Department of Physics, WPI-AIMR, Sendai, Japan.

Carrier injection from metal electrodes to semiconductors and electrical transport in semiconductor active layers are the most two important key actions in electronic devices. Generally, two types of semiconductors can be considered: One being semiconductor (OSCs) based on carbon based molecules and the other being inorganic semiconductors (ISCs). The former has a clean surface without dangling bonds in π-bonded system, and the latter is in a σ-bonded one and frequently has dangling bonds on its surface and metal-semiconductor interface structure. Such a phenomenon is known as Fermi level pinning leading to a vacuum level shift at the MS interface known as the Bardeen limit. Low-voltage Organic Field-Effect Transistors Printed on Plastic Operating Above 10 MHz

A. Perinot1, M. Giorgio1,2, M. Cairo1
1Politecnico di Milano, Milano, Italy; 2Istituto Italiano di Tecnologia, Milano, Italy.

Printed polymer field-effect transistors (FETs) have been considered for many novel applications towards large area and flexible electronics, since they can enable pervasive integration of electronic functionalities in all sorts of appliances, their portability and wearability. However, printed polymer FETs fabricated with scalable tools fail to achieve the minimum speed required for example to drive high-resolution displays or to read the signal from a real-time imager, where a transition frequency (fT) i.e. the highest device operating frequency, above 10 MHz is required. Such a goal is even more critical to achieve with low operating voltages and on cheap plastic foils. Here, we demonstrate that high-frequency, low-voltage, polymer field-effect transistors can be fabricated on plastic with the sole use of a combination of scalable printing and digital laser-based techniques. These devices achieve fT in the MHz range already at 2 V, and reaches a record 14 MHz at 7 V. These devices can be successfully integrated into a rectifying circuit on plastic operating at 13.56 MHz, allowing to supply a DC voltage to RF devices and tags fabricated with cost-effective production processes.

Printed Low Voltage Organic Field-Effect Transistors and Circuits on Paper Substrate

G. Casula, S. Lai, A. Bonfiglio, P. Cosseddu
Electrical and Electronic Engineering, University of Cagliari, Cagliari, Italy.

Recently, electrical devices based on paper or paper-like substrates have attracted considerable attention as a possible next-generation technology capable of replacing plastic-based electronics. Indeed, compared with conventional flexible substrates employed in electronic devices, paper features ubiquity, extremely low costs, eco-sustainability, as well as flexibility and bendability. Thank to these merits, in the last years the use of paper or paper-like substrates has been explored in different applications, ranging from basic electronic components to complicated devices and circuits. Basic electronic component are essential in every paper electronics application. In particular, the transistor is the fundamental component in most electronics systems. In order to develop flexible paper electronic devices, inexpensive and highly efficient fabrication methods are necessary. Printing techniques, such as inkjet printing, has gained a growing interest for depositing functional materials. Thank to scalability and manufacture cost, inkjet printing on paper is more competitive than other approaches. However, so far only few works report about thin film transistors (TFTs) printed on paper substrates. In this work, a low voltage organic field effect transistor (OFET) fabricated by inkjet printing on paper is presented. In particular, Bottom Gate- Bottom Contact devices were fabricated. A PEDOT:PSS-based commercial ink was employed for patterning gate, source and drain contacts by means of inkjet printing. A thin film of Parylene C has been deposited as organic insulator by means of chemical Vapour Deposition. Finally, a p-type organic semiconductor, namely PEDT-Pentacene, was inkjet-printed through an homoe-made ink. Alternatively, an n-type organic semiconductor, namely Alq3, was deposited by spin coating. All devices were fabricated on a p-e:smart paper type 2 from Felix Schoeller. This is a 185 ± 10 µm thick flexible paper-based substrate covered with a nonporous surface coating and a hydrophile primer layer. Reproducible electrical performances were obtained on a set of more than 50 devices. In particular, low operating voltages (as high as 5 V), significant charge carrier mobility (in the range 0.4 cm²/Vs for p-type OFETs and 0.01 cm²/Vs for n-type OFETs), and a quasi-zero threshold voltage were recorded. Taking advantage on the fact that both p-type and n-type OFETs have been fabricated, complementary electronic circuits have been successfully fabricated and tested. In particular, complementary inverters with a valuable gain (10 V/V) and noise margins (of about 2 V) were initially fabricated. Starting from such basic building blocks, other logic ports, namely AND, OR, NAND and NOR, were fabricated and tested. These results pave the way for a future development of complex electronic systems that can be fabricated on paper by means of cost-effective techniques and with enhanced properties of portability (enabled by low voltage operation) and functionality (enabled by complementary circuit logic).
Isotropic Self-Assembly Process of a Low Crystalline Interactions

Ray Diffraction (GIXRD) analysis revealed that the orientation of the oCVD PEDOT film is dependent on the deposition temperature and (P/P0) orientation of oCVD PEDOT changed from predominantly edge-on orientation (h00) to predominantly face-on orientation (0K0) with an increase in deposition temperatures and a decrease in P/P0 of the oxidant vapor. The optical properties of oCVD PEDOT are of essential importance for application as transparent conductors while there is a trade-off between transparency and sheet resistivity. It was found that the figure of merit (FOM) which is defined as the ratio of direct current conductivity (σdc) to optical conductivity (σop) increases by a decrease in P/P0 of the oxidant vapor.

Meniscus-Guided Large-Area Thin-Film Formation of Organic Semiconductors with Crystallization Control

The electronic properties of solution-processable small molecule organic semiconductors have rapidly improved in recent years, rendering them highly promising for various low-cost large-area flexible electronic applications. Here we present solution shearing as a promising technique to increase the electron mobility (μe) of a low crystalline polymer. We demonstrate this approach using NDI-based copolymers (PNDI-FTVT), with dithienylethene having the 3-position instead of hydrogen. The two fluorene substituents on the FTVT unit impart a dipole moment in the polymer backbone, leading to a fast and robust aggregation process (mainly a kinetic process), which suppresses NDI-driven self-assembly process (a thermodynamic process). This kinetic process limits the growing crystals; thus, the resulting smaller crystals improve electrical connection between crystal domains. In addition, robust aggregates driven by FTVT units in amorphous domains afforded a thermally stable morphology in the solid state. This microstructure resulted in improved μe of transistor devices by lowering energetic disorder as well as the reinforced film morphology at elevated temperature.

Scalable Fabrication of Highly Crystalline Organic Semiconductor Thin-Film Array by Screen Printing

Screen printing has been widely applied in electronic industry, since it has several distinct advantages such as large scale, low temperature processability, low cost and efficient productivity. However, due to the requirement of high viscosity of ink, and the relatively large printed film thickness, screen printing is usually used to fabricate metal electrode, while it remains a significant challenge to fabricate high quality organic small molecule semiconductors (OSCs) crystalline film. Herein, a simple method for the fabrication of organic semiconductors, in which the high throughput and target productivities are essential, is presented, which employs solution shearing technique to generate high quality organic thin-films for organic transistors. In this presentation, an example of an additive manufacturing approach for electronics that integrates processes such as fused-deposition modelling, paste extrusion, ink-jet printing, and pick-and-place, as well as in-line metrology methods will be described. Using these tools and techniques a number of printed and hybrid devices have been made including: 1) simple organic-based logic circuits were demonstrated using our technique.

Achieving Outstanding Thin-Film Deformability of Semiconducting Polymers Through Modulating Molecular Packing in Nanoscale

Polymer semiconductors nowadays have been investigated for use in future electronics that have good electrical performance, mechanical compliance and large scale processability. The performance of polymers has been enhanced by designing molecules with improved electronic and mechanical properties. Although comparable electrical performance to traditional inorganic semiconductors can be achieved by polymeric semiconductors, it is still challenge to simultaneously introduce stretchability at the molecular level, in order to create mechanically robust semiconducting polymers. Typically, mechanical resilience and ductility of polymer active thin layer can be tailored through chemical design, such as inserting functional units in polymer backbone or manipulating alkyl side chains. However, such methodologies involve complicated chemistry process, and triggered batch-to-batch variations. We therefore develop a new approach by physically adding organic small molecules, which possess high boiling point and low vapor pressure, into semiconducting polymers. By delivering such small molecules between polymer chains, the lamellar packing distance of semiconducting polymer can be modulated from 24.6 Å to 27.9 Å. This 3 Å volume opening using our method indeed greatly improve the thin film deformability due to the enhanced polymer chain dynamics in nanoscale. The semiconducting film can be stretched up to 300% without cracks. Finally, a charge carrier mobility of 1.8 cm2/V·s is achieved as the active layer stretched under 100%, which is one of the best performance among stretchable polymer semiconductors in the research community.

Scalable Fabrication of Highly Crystalline Organic Semiconductor Thin-Film Array by Screen Printing

Screen printing has been widely applied in electronic industry, since it has several distinct advantages such as large scale, low temperature processability, low cost and efficient productivity. However, due to the requirement of high viscosity of ink, and the relatively large printed film thickness, screen printing is usually used to fabricate metal electrode, while it remains a significant challenge to fabricate high quality organic small molecule semiconductors (OSCs) crystalline film. Herein, a simple method for the fabrication of
various small-molecular OSCs crystalline film using ultra-low viscosity OSCs/insulating polymer blends by screen printing is reported. The film thickness is reduced to tens of nanometers by tuning the squeezing velocity and concentration of ink. Meanwhile, the quality and crystal domain size is largely improved by using screen printed banks prior to printing to confine OSCs crystallization and minimize nucleation sites, resulting in higher devices performance. As a result, the as-prepared C71-BTBT organic field-effect transistors (OFETs) and device array achieved an excellent performance with the highest hole mobility up to 12.10 cm² V⁻¹s⁻¹, and the on/off ratio is up to 8×10⁶, which is on par with its single crystal counterparts. In addition, the uniform distribution of mobility in 8×8 array indicated the scalability of this method. Meanwhile, this method can also be applied for other OSC materials such as C71-DPA. The high-performance OFET device demonstrated that screen printing is suitable for the scalable manufacture of organic electronic circuit. The successful fabrication of organic semiconductor layer by printing method is the key step toward full printed flexible electronics.

### Structure Formation in High Performing Organic Transistors

**Lee Richter**, Dawei Wu, Maria Kaplan, Hyun Wook Ro, Sebastian Engmann, R. J. Kline, Daniel Fischer, Dean DeLongchamp, Eliot Gann, Lars Thorsen, Christopher McNeill, Juliaanna Pance, and Thomas D. Anthopoulos; National Institute of Standards and Technology, Gaithersburg, Maryland, United States; Theis Research, La Jolla, California, United States; Australian Synchrotron, Clayton, Victoria, Australia; Monash University, Clayton, Victoria, Australia; Imperial College London, London, United Kingdom; King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

As the demand for high performance displays increases, the required performance for solution processed transistors for backplanes has increased. Target mobilities to drive AMOLED displays are now in the 10 cm² V⁻¹ s⁻¹ range, competitive with amorphous oxides. While advances in materials continue, over-all ink design and film processing present additional opportunities for device improvement. Two general approaches to improved devices have emerged: production of aligned channels via directional coating and production of vertically structured channels from blend-based inks. Using insitu X-ray and optical probes, we will explore the development of structure in these platforms. Due to the pi-stacking motif of most semiconducting polymers, the local mobility is intrinsically anisotropic. Therefore fabrication of aligned films enables further optimization of device performance. Blade coating is an excellent prototyping tool for production deposition techniques such as slot die coating and, due to its direction character, can result in aligned films. We report results from blade coating a number of high performing polymer materials. Depending on polymer and deposition regime, highly aligned films can be produced. The aligned films typically exhibit significant (c.a. 5 times) greater mobility than isotropic films. Detailed morphological studies suggest that the improvement in transport is related to alignment of the inter-crystallite regions (tie-chains). In-situ studies indicate that the coating induced alignment nucleates near the air interface and is facilitated by the presence of a lyotropic liquid crystal phase. In blend-based inks, vertical segregation between the active material and the matrix can result in advantageous ordering at either the buried or air interface. This can lead to improved device performance in either bottom or top gate architectures. In-situ probes again provide detailed insights into the development of vertical stratification and active layer crystallization.

5nm and Beyond BEOL (Back End of the Line) Interconnect and Heterogeneous Integration Strategies to Continue Moore’s Law Scaling  
Lawrence Clevenger; IBM T.J. Watson Research Ctr, Albany, New York, United States.

As semiconductor technology nodes scale towards 3 nm, there are acute difficulties in achieving interconnect scaling due to novel device architectures and dimensionality, design, performance and reliability issues. There are key interconnect scaling and packaging heterogeneous integration strategies for future technology nodes. Co-optimizing these strategies determines the overall best definition to enable continued Moore’s law scaling.

For future semiconductor nodes, the ability of optical patterning to support the required interconnect pitches is in doubt. This is the driving factor for the introduction of EUV lithography to continue dimensional scaling. Even with EUV patterning, there are additional design methodology challenges such as the lack of wiring track level reduction due to process related block level scaling issues. From a traditional materials science perspective, BEOL resistance and capacitance is a significant portion of the parasitic degradation of overall technology performance. As physical wire and via sizes decrease, BEOL resistance increases exponentially with decreasing area due to surface and grain boundary scattering and a lack of scaling for Cu diffusion barriers such as TaN. Challenges for BEOL capacitance include integration issues which drive the effective dielectric constant higher than the modeled values. BEOL reliability is challenged by operation voltage requirements and by novel device architectures which strain electromigration and dielectric breakdown performance.

To mitigate these challenges and continue Moore’s law scaling, novel design methodologies decrease the number of wiring tracks in standard cell libraries and increase the wiring levels to improve both performance and density. EUV lithography is replacing optical lithography to enhance design and performance, requiring fewer design rule restrictions, improving patterning tolerances, and enabling bi-directional metal and process simplification. Hardware teams will implement novel processes to enable recovery of resistance and capacitance scaling and to support electromigration and time dependent dielectric breakdown reliability. These patterning and process improvements are needed to support novel device architectures in technologies such as scaled FinFET and Stacked-Si-Nanosheets.

To further mitigate challenges in interconnect scaling, heterogeneous integration of IP has been migrating from SoC (System on a Chip) to SIP (System in Package). This introduces the challenge to use novel packaging techniques with high density interconnects to achieve enhanced functionality and improve bandwidth and latency. There are novel architectural, integration and material related innovations that address the challenges for the continuing enablement of Moore’s law scaling.

**11:00 AM *EP07.01.02***
Amorphous low-dielectric constant (low-$k$) and high-dielectric constant (high-$k$) materials have dominated the nanoelectronic materials research scene over the past decade, but have recently reached a state of maturity and perhaps their scaling limits. Based on this, one may ponder the direction of nanoelectronic dielectric materials research and the future of the field. However, as we will clarify, there is still plenty of room to grow!

In this address, we seek to illustrate that high-$k$ and low-$k$ dielectrics represent just a tiny fraction of the numerous dielectric materials utilized in nanoelectronic products and that numerous new applications for dielectric materials are emerging as the industry transitions to novel patterning schemes and prepares for life post CMOS scaling. We will begin by briefly exploring the entirety of dielectric materials utilized in advanced nanoelectronic products with a particular focus on often ignored etch stopping, diffusion barrier, and passivation dielectrics and their more specialized requirements. We will then transition to examining the various novel pitch division schemes being developed to cope with the delay of EUV lithography and the abundant new dielectric material applications these schemes create. We will specifically focus on the various new spacer and hard mask dielectrics that pitch division requires, their colorful etch selectivity requirements, and suggest future research needed to enable even more exotic patterning schemes. We will further examine how what was once old can become new again and specifically explore how both high-$k$ and low-$k$ dielectrics are being utilized to fill the needs of future beyond CMOS devices. In particular, the application of high-$k$ and low-$k$ dielectrics in novel resistive switching device applications will be examined. We will conclude by reviewing the unique obstacles that dielectric materials present for the realization of advanced cryogenic quantum computing architectures and the necessary associated research vectors to prevent dielectrics from becoming quantum computing’s Achilles heel.

Molecular Design of Ultrastiff ULK Dielectric Hybrid Films—Implications of Network Connectivity and Precursor Geometry  
Karsu I. Kliche and Reinhold Daußard; Stanford University, Stanford, California, United States.

The successful integration of ULK dielectric films into microelectronic device interconnects has been challenging due to their poor thermal and mechanical properties. We have developed computational tools to investigate the fundamental molecular level parameters controlling the properties of these materials, and also have shown that they exhibit very surprising phenomena ranging from asymmetric elastic behavior to non-affine deformations, and can be engineered to exhibit time dependent inelastic deformation characteristics. In this work, through molecular dynamics simulations we present new design strategies at the molecular level focusing on two unique ways to effectively enhance the mechanical properties: Firstly, we demonstrate how hyperconnected networks with a connectivity exceeding the chemical coordination number of silicon increase elastic modulus. Secondly, we show how hyperstiff precursor molecules themselves with specific geometrical features, which have not been previously considered, can be exploited to further reinforce the rigidity of hyperconnected films. We define a hyperstiff precursor as one with a cyclic planar organic group, an example of which is triethoxysilyl benzenne (1,3,5-benzene).

The impact of utilizing these two main parameters is such that we are able to design ultrastiff hybrid films with a modulus that goes beyond that of fully dense silica, while still maintaining an ultra low density and dielectric coefficient. One immediate implication of the design of these ultrastiff hybrid networks manifests itself as a new and highly effective method to improve the mechanical robustness of nanoporous hybrid films. Our results show that the nanoporous films designed with an ultrastiff hybrid matrix lead to three to four times increase in the elastic modulus compared to porous films with traditionally bridged network containing less stiff organic chains, such as ethane-bridged oxycarbosilane (Et-OCS). This substantial increase in the stiffness of nanoporous hybrid films is a crucial step taken to minimize the limitations due to poor mechanical properties, thereby allowing for new opportunities to fully benefit from the ultra low dielectric constant of porous thin films.

Polysiloxane Thin Films Deposited by iCVD—Application to Through-Silicon via Insulation  
Vincent Jousseaud, Celine Ribiere, Gilles Romero, Pierre-Emile Philip, Daniel Scvelo, Yorrick Exbrayat, Antonio Roman, Christophe Lieitra, Stephane Minoret, Sophie Verrun, Bruce Altenmus, Thierry Mourier, Jacques Faguel, Université Grenoble Alpes, Grenoble, France; CEA, LETI, Grenoble, France; Tokyo Electron Europe Limited, Meylan, France; Tokyo Electron US Holdings, Albany, New York, United States; Tokyo Electron US Holdings, Austin, Texas, United States.

Three-dimensional integrated circuit (3 IC) integration attracts much attention because it has the potential to enhance IC performance and allows the integration of heterogeneous devices [1]. One approach consists in stacking vertically several chips which are electrically connected with through-Si vias (TSVs). Among the different ways to create TSVs, via-middle integration allows the TSV realization between the front end of line and the back end of line (BEOL) while TSVs are built after the BEOL in via-last integration. One of the key steps in the TSV fabrication is their electrical insulation from the silicon substrate. Usually, SiO$_2$ deposited by Plasma-Enhanced CVD or by Sub-Atmospheric CVD depending on the integration scheme, is used as the TSV-liner material. However, the use of SiO$_2$ presents some limitations in order to realize advanced 3 IC, such as a poor step coverage (using PECVD) and higher dielectric constant compared to the low-$k$ interlayer dielectric material of BEOL. Through-silicon via with polymer liners has attracted attention because these polymers have a low dielectric constant and their expected mechanical compliance can enable higher TSV integration by suppressing the TSV-induced stress [2]. However, even though several demonstrations were published in the literature, the TSV insulation using organic polymers is not yet adopted in this work, organosiloxane thin films were deposited by initiated Chemical Vapor Deposition (iCVD). This deposition technique, which is a low-energy (no plasma) and solvent-free method, allows to deposit organic or hybrid polymers at low substrate temperature, thus compatible with the TSV-last thermal budget requirements. Poly(V3D3) thin films were deposited from trivinyl-trimethyl-cyclo-trisiloxane as the monomer and tert-butyl-oxide as the initiator. First, the impact of process conditions on the deposition rate, chemical composition and step coverage was investigated. A combination of FTIR, ellipsometry, ellipsometric porosimetry, ToF-SIMS analysis, SEM and electrical characterizations was used to characterize the structure and the properties of the films. It is shown that poly(V3D3) thin films deposited at low temperature (typically lower than 100°C) can present low dielectric constant (down to 2.7) with conformality close to 50% in 10*100 μm TSVs. Moreover, the impact of annealing on the thermal stability of the films was studied. After appropriate curing (thermal-only or UV-assisted), the dielectric film is stable up to 400°C. Finally, a full TSV integration was completed (via-middle 100°C) can present low dielectric constant (down to 2.7) with conformality close to 50% in 10*100 μm TSVs. Moreover, the impact of annealing on the thermal stability of the films was studied. After appropriate curing (thermal-only or UV-assisted), the dielectric film is stable up to 400°C. Finally, a full TSV integration was completed (via-middle 100°C).

material candidates and integration schemes.

**Intermetallic Compounds as Possible Cu Alternatives**

Junichi Koke, Linghan Chen, Daisuke Ando and Yuji Sutou; Department of Materials Science, Tohoku University, Sendai, Japan.

In local interconnection of advanced LSI, copper alternative materials have been sought to mitigate the increase of Cu line resistivity with decreasing line width. The required properties for the alternatives are small value of $\tau_{0}$, i.e. low resistivity in narrow lines, low diffusivity for good electro-migration resistance under high current density, low melting temperature for easy grain growth at low process temperature, small Young’s modulus for easy CMP. Proposed materials to date include pure metals, alloys, carbides, nitrides, and silicides. In addition, low and stable material cost is an important factor to be considered. To provide feasible alternatives which satisfy these properties, we focus intermetallic compounds. For example, NiAl is an ordered bcc compound having a bulk resistivity of 9 mW-cm. It is a well-known heat resistant material having a high melting point of 1638 °C, thus a good electromigration reliability may be expected. Furthermore, NiAl has a large cohesion energy of ≈568 kJ/mol, hence the interdiffusion and detrimental reaction of individual Ni or Al ions with Si and SiO <sub>2</sub> may be suppressed. In addition, Al oxide has heat of formation of ≈1678 kJ/mol, much higher than ≈911 kJ/mol of SiO<sub>2</sub>, so there is a tendency for Al atoms to bond with O atoms at the NiAl/SiO<sub>2</sub> interface, possibly leading to good adhesion. Experimental results showed good adhesion and no interdiffusion between NiAl film and SiO<sub>2</sub>/Si substrate. Similar results were obtained in other selected intermetallic compounds. The possibility of intermetallic compounds will be discussed in detail as the Cu alternative.

2:30 PM EP07.02.03
**The Effects of Dioxide Molecules on the Electrodeposition of Cobalt**

Qiang Huang, Yang Hu, Tyler Lyons and William Sides; University of Alabama, Tuscaloosa, Alabama, United States.

Electroplated damascene copper has been used for more than 20 years for interconnects in semiconductor and microelectronic industry[1]. As the structures continue to scale, the coarse grains formed during annealing become increasingly difficult to fit into the fine structures, resulting in higher resistance and poorer electro-migration[2]. In addition, as the dimension of structure approaches or falls below the electron mean free path of copper, the resistivity exponentially increases[3], demanding a material change for future technologies. This talk presents fundamental studies on the electrodeposition of cobalt in presence of a class of organic additives, dioxime, to modulate the deposition rate and impurities in cobalt. Suppression of cobalt deposition was observed upon the addition of dioxime molecules and such suppression effect was found to result from an adsorbed Co-oxime complex structures, which breaks down upon the application of more negative bias. Such break down not only kicks off the deposition of cobalt but also results in the incorporation of impurity elements, such as Carbon, Hydrogen and Oxygen. The nucleation and growth at the beginning of deposition was studied, aiming to understand the limitation on the formation of continuous cobalt films. A two-step nucleation phenomenon was observed for the first time due to the reduction reactions from the chelates and free cobalt ions. A second chemical species was used to purposely introduce different impurity elements into the deposited Co films, aiming to understand the effects of different impurities on the grain structure of cobalt.

**The Formation of Nano-Voids in Electroless Cu Layers**

Tobias Bernhard; Electronics PTH, Atotech Deutschland GmbH, Berlin, Germany.

The electrical reliability of multilayer HDI/BGA-PCBs<sup>1</sup> is mainly affected by the thermo-mechanical stability of stacked micro via interconnections. Here, a critical failure mode is the stress related crack between the electrolytically filled via and the target pad, commonly known as target pad separation. The junction includes two Cu-Cu-interfaces, one between the target Cu pad and the thin electroless Cu layer and the second between electroless Cu and electrolytic Cu.

Large nano-voids (with dimensions of several ten to several hundred nm) and inhibited Cu recrystallization across the interfaces are the two main indications of a weak link to the target pad. These failures are mostly related to insufficient etching and cleaning of the target pad or persistently adsorbed organic residues at the sputtered Cu-surfaces and are well observable via standard inspection tools such as cross-sectioning and electro or ion-polishing in combination with SEM<sup>2</sup>. Recently, closer inspections of such junctions were performed via Transmission Electron Microscopy on thinned lamellas down to 50-60 nm. In a transmission mode of TEM (HAADF<sup>3</sup>-mode) a substantial density (up to 30000 µm<sup>-2</sup>) of circular shaped “black spots” were found with diameters of lower than 10 nm, i.e. below the spatial resolution of commercial FIB/SEM<sup>4</sup>-tools. These “black spots” are localized within or closed to the electroless Cu-layer.

In the first part of the paper we will present HR-STEM, XEDS<sup>5</sup> and EF-TEM<sup>6</sup> measurements, in order to identify the origin of the “black spots” in the TEM-images. Here STEM/HAADF and Bright-Field TEM point to less material inside of these “black spots”, whereas energy filtering TEM indicates less average lamella thickness within the features. In combination with XEDS-mapping, where no chemical composition difference between the spot region and the Cu-bulk region was found, we conclude that the observed black spots are most likely voids. To evaluate the impact on the junction reliability and to find probable root causes of this newly discovered void-phenomenon, an extensive field study of more than 400 TEM investigations was performed. TEM in combination with XEDS enables the localization of the electroless Cu layer in the junction by detecting the codeposited Ni (typ.: 0.2-1.5 at%<sup>5</sup>) and a precise assignment of the nano-void affected interfaces or layers.

This nano-void field study comprised the investigation of HDI and BGA-multilayer PCBs with stacked vias produced by several industry partners and single layer reliability test boards produced in industry like on-site facilities (Atotech Techcenters), accompanied by some laboratory plating tests. Different types of industrially relevant electroless Cu pretreatments, Pd-activator systems, electroless Cu baths and filling Cu-electrolytes were included in the test matrix, as well as the impact of subsequent thermal treatments (one to ten IR-reflow<sup>7</sup> cycles).

Based on this field study, we will present in the second part of the paper a classification of the most relevant nano-void phenomena, determined by the affected interfaces/layers and their appearance after plating or subsequent thermal treatments (IR-reflow). Formation mechanisms and root causes will be discussed as well.

**Reliability Statistics for Next-Generation Interconnects—The Combination of Physical Modeling and Statistical Techniques**

Shinji Yokogawa; The University of Electro-Communications, Chofu, Japan.

The accurate reliability prediction in the development phase is one of the big challenges to achieve the next generation of interconnects. Moreover, for the early adoption of the technologies, the early failure due to process variability defects and a late failure determined by the intrinsic characteristics of materials should be evaluated and improved simultaneously. However, it is difficult to evaluate them accurately for the less-mature technology because of production performance variabilities and small size experiments. The combining of physical modeling and statistical techniques is one of the approaches to solve the lack of stabilities. Conventional statistical methods to estimate chip-level reliability are described with a competing policy, as the weakest link. Underlying features of the lifetime characteristics are explained by the distribution functions that have
definite shape and scale parameters like Weibull and Lognormal distributions. These functions well describe the intrinsic lifetime characteristics but do not express the impacts of the degree of completion. Recently, the distribution families that have two shape parameters is applied to understand and explain the variability impacts. To utilize them effectively, the correlation between the physical mechanism of failure and the shape of distribution must be considered theoretical and experimental.

In this talk, two applications of the statistical distribution are introduced about the lifetime of back-end reliability. The first application is a time-dependent dielectric breakdown (TDDB) under defect clustering condition in back-end-of-line (BEOL) and middle-of-line (MOL) explained by the generalized Burr type XII distribution (GBXII). Because the decrease in spacing has become too excessive, impacts of process variations on product yield and reliability have also become much pronounced. The spacing variation represents the variation of reliability stress and accelerates the breakdown phenomenon around a small space called the "clustering defect." Therefore, understanding the defect impacts on lifetime distribution provides information on not only reliability estimation but also the process variability and TDDB in BEOL and MOL. The GBXII has two shape parameters and, one of them is the clustering parameter that indicates the degree of the defect clustering. A statistical method for the GBXII analysis on TDDB will be introduced.

The second application is a simple prediction method for chip-level electromigration based on segment lifetime. From the distribution of segment lifetime and current density, the chip-level lifetime distribution is approximated by the generalized gamma distribution (GGD). The second shape parameter of the GGD can indicate whether the chip-level distribution is close to the lognormal or Weibull distribution in conjunction with lifetime variation due to process fluctuation and circuit size. Proposed method using GGD can provide the prediction of the chip-level electromigration lifetime for a novel technology without a real circuit design. These approaches enable to understand impacts of the process variation and the circuit size. It will provide the necessary information for the early adoption of the novel technology to use.

EP07.02.06 The Effect of Electrical Current Stressing on Microstructure and Properties of Sn You-Chi Meng, Chien-Lung Liang and Kwang-Lung Lin; Material Science and Engineering, National Cheng Kung University, Tainan, Taiwan.

Electric current stressing has been reported to affect the microstructure of metallic materials along with the variations in mechanical properties and other material performance. The electric current stressing can facilitate recrystallization behavior and thus lower the recrystallization temperature of metals. In the present study, the microstructure-properties correlation of pure Sn metals induced by electric current stressing was investigated. The pure Sn strip was quenched in liquid nitrogen after designed periods and cycles of electric current stressing. The mechanical and electrical properties of the pure Sn strips were investigated using Vickers micro-hardness tester and 4-point probe, respectively. The micro-hardness increases with respect to the current density ranging from 5000 to 6500 A/cm² and reaches a maximum value at 6500 A/cm². The maximum enhancement in micro-hardness shows a 5% increment compared with the value of the as-annealed specimen. However, the electric current stressing at higher current densities (7000 and 7500 A/cm²) lowers the micro-hardness, showing a two-stage mechanical property variation between relatively low current density one (5000-6500 A/cm²) and relatively high current density one (7000-7500 A/cm²). In general, all the electric current stressing conditions investigated were found to enhance the micro-hardness of the Sn strips. Dissimilar to the trend of micro-hardness, the sheet resistance of the pure Sn strip slightly decreases after cycles of direct current stressing. The average grain size and grain orientation of Sn metals were investigated using electron back scattered diffraction analysis. The results show that an increasing number fraction of fine grains, corresponding to a general lowering in grain dimension, with the increasing electric current density at the first stage of relatively low ones (5000-6500 A/cm²). However, grain coarsening was observed at relatively high current densities (7000-7500 A/cm²) due to the Joule heating effect. The activation energy for the two-stage micro-hardness variations induced by electric current stressing was estimated, and the mechanisms behind were further disclosed in this research.

Optimizing Growth of TaSe₃ Nanowires via Chemical Vapor Deposition
Aimee Martinez, Thomas Empante, Michelle Wurch and Ludwig Bartels; University of California, Riverside, Riverside, California, United States.

Tantalum triselenide (TaSe₃) is part of the transition metal trichalcogenides (TMTs) family and are of interest due to their high conductivity and low dimensionality. These quasi 1D nanorod structures show promise for future applications as replacement interconnect materials as copper reaches its limits due to surface and grain boundary scattering effects. The main goal of this work is to develop a facile synthesis method and study the properties of these nanorod materials as the cross sections is thinned to the nanometer scale. Here we present a novel chemical vapor deposition (CVD) method which produces TaSe₃ nanorods directly on an SiO₂/Si substrate in under an hour. There nanorods are characterized using Raman spectroscopy and electronic transport measurements revealing their behavior when scaled down to the nanometer scale.

Study of the Structure, Electrical Conductivity of Cr-Cu Thin-Film Composition on a Glass Substrate
Sergey M. Karabanov; Ryazan State Radio Engineering University, Ryazan, Russian Federation.

Cu films are widely used for interconnections in microelectronics. In some applications, reliable thin-film connecting elements having high electrical conductivity, mechanical stability and adhesion to the glass substrate are required. In this case the length of the elements amounts to tens of centimeters. In this paper, Cu was used as the basis for the connecting elements. To ensure high adhesion Cr was used as an underlayer. The substrate material was glass made of SiO₂ (73%), Na₂O (13%), CaO (8.5%) and other oxides. Cu and Cr films were applied by thermo-vacuum evaporation at residual pressure in the chamber of 10⁻⁶ – 5×10⁻⁷ mmHg. The structure of the films was analyzed on a JEOL-50A scanning microscope. For the study of defect formation, electron and light microscopes were used.

The paper investigates the structure, electrical conductivity, adhesion, defect formation of Cu, Cu-Cr, Cr-Cu-Cr thin-film conductors. As a result of the conducted research, the regularities of changes of the film structure, electrical conductivity, adhesion, defect formation depending on the technological process parameters were established. Physical and technological mechanisms determining the observed patterns are considered. The research results are used in the technological regulations for the devices production.

EP07.03.06
Effects of Dielectric Curing and Plasma Treatment Conditions on the Interfacial Reliability of RDL for Fan-Out Wafer Level Packaging
Young-Bae Park¹, Gahui Kim¹, Kirak Son¹ and Dogeun Kim²; ¹Andong National University, Andong-si, Korea (the Republic of); ²Korea Institute of Materials Science, Changwon, Korea (the Republic of).

As personal mobile and IoT products are more and more popular, and IC technology is more and more advanced, fan-out wafer level packaging (FOWLP) technology is therefore valued and developed highly. FOWLP is one of the latest trends in microelectronics packaging. FOWLP is a novel concept intended to increase the number of external I/O connections and achieve greater integration within small form factor systems. FOWLP has a high potential in significant package miniaturization concerning package volume but also in thickness. A key ingredient enabling the FOWLP is the redistribution layer (RDL), which rearranges I/O locations. The redistribution layer is a stacked copper-dielectric structure. In fan-out packages, Si chips are directly attached to the RDL, and the molding compound provides the necessary mechanical support. To manufacture these packages, there are several challenging requirements for dielectric materials to be cured at low temperature of (~<250 °C). Low temperature curing requirements for dielectric materials exist since devices embedded with memory chips by the molded compound show low heat resistance, strong adhesion to the copper RDL, stability and adhesion to the glass substrate are required. In this case the length of the elements amounts to tens of centimeters. As a result of the conducted research, the regularities of changes of the film structure, electrical conductivity, adhesion, defect formation depending on the technological process parameters were established. Physical and technological mechanisms determining the observed patterns are considered. The research results are used in the technological regulations for the devices production.

EP07.03.07
Etch Characteristics of Copper Thin Film Using Continuous-Wave and Pulse-Modulated Plasmas of CH₂COOH/Ar
Chee Won Chung, Jin Su Ryu, Jae Sang Choi, Eun Taek Lim and Moon Hwan Cha; Inha University, Incheon, Korea (the Republic of).

Copper has low leakage and low power consumption due to its lower resistance and faster signal transmission than aluminum. Copper has a high electron migration resistance and is a stable interconnect material. When copper is used as an interconnect, it is prepared by damascene process which includes electroplating and chemical mechanical polishing. Since copper has very low reactivity and copper compounds often have high vapor pressure, it is known to be very hard material to etch using a conventional dry etching. As the critical dimension of the devices is diminished under tens of nanometer, the fatal disadvantages of the damascene process are revealed, which demands the development of novel dry etching technique of copper thin films.

In this study, the etch characteristics of copper thin films masked with SiO₂ films were examined under CH₂COOH/Ar gas using inductively coupled plasma reactive ion etching. The etch rate of copper films and SiO₂ hard mask, and the etch selectivity of copper films to SiO₂ mask, and the etch profile were investigated as a function of CH₂COOH in CH₂COOH/Ar gas. Major etch variables including coil rf power, bias voltages, and the process pressure were applied to evaluate the etch rate, etch selectivity and etch profile.

The evolution of etch profile of copper films in CH₂COOH/Ar was observed to understand the etch process. The optical emission spectroscopy of the plasmas produced from various CH₂COOH concentration in CH₂COOH/Ar was measured to determine the active species in the plasmas. In addition, the energy dispersive X-ray spectroscopy and X-ray photoelectron spectroscopy for the etched copper surfaces were performed to elucidate the etch mechanism by identifying the copper compounds, if any.

Besides, pulse-modulated plasma has been applied to etch copper films, which has the variables such as the on-off duty ratio and the frequency of the plasma. The effects of pulse-modulated plasma on the etch characteristics of copper were examined. The etching by pulse-modulated plasma is expected to reduce redeposition and etching by-products compared to that by continuous wave plasma.

Acknowledgments This research was supported by the MOTIE(Ministry of Trade, Industry & Energy (10080450) and KSRC(Korea Semiconductor Research Consortium) support program for the development of the future semiconductor device.
Advanced packaging solutions, particularly 3D integration technologies, are additional boosters for performance and functionality of microelectronic products. However, at the same time, 3D heterogeneous system integration becomes increasingly challenging for product reliability. This talk will address the nondestructive localization and characterization of defects in interconnects to mitigate reliability-limiting effects in 3D IC stacks. Particularly, the geometry of 3D Through-Silicon-Via (TSV)/micro-bump stacks and defects (voids and micro-cracks) in these metallic structures as well as micro-cracks in Cu/low-k Back-End-of-Line (BEOL) stacks caused by thermomechanical stress (Chip-Package Interaction, CPI) will be discussed. We will demonstrate the applicability of sub-micron and nano X-ray computed tomography (XCT) for nondestructive 3D imaging of advanced packaging and BEOL interconnect structures. The shape of solder interconnects and TSV etch profiles are imaged as well. Defects like filling voids in Cu TSVs and micro-cracks in AgSn solder micro-bumps are clearly visualized too using full-chip region-of-interest tomography [1].

Package-induced thermomechanical stress increases the risk of failure caused by delamination along metal/dielectric interfaces or fracture in dielectrics with low fracture toughness in BEOL stacks. The 3D visualization of crack evolution in Cu/low-k interconnect stacks is demonstrated using an experimental setup which combines X-ray microscopy with in-situ mechanical loading. High-resolution 3D image sequences based on nano XCT are acquired during mechanical loading within the X-ray microscope to visualize crack opening and propagation in fully integrated BEOL structures with about 100 nm resolution [2]. As a result, the weakest layers and interfaces are identified, and the robustness of the BEOL stack against chip-package interaction is evaluated. The obtained results provide valuable information for reliability engineering and design-for-reliability (DFR) in semiconductor industry.

Laboratory micro and nano XCT offer intrinsic advantages in the fields of 3D imaging, physical failure analysis, and metrology of electrical interconnects in semiconductor products for both advanced packaging and on-chip interconnect structures by employing a multi-scale approach. Perspectives to overcome two major limitations of state-of-the-art nano XCT tools, i.e. the necessity of sample preparation (typically less than 50 mm thickness, depending on the material composition, if 8 keV photons are used) and low imaging throughput, are discussed. A novel tool concept for X-ray microscopy at high photon energies, using advanced X-ray sources with high flux and the option of multi-energy photons [3], and of advanced X-ray optics with high efficiency at photon energies > 10 keV [4], will be presented.

SESSION EP07.04.02
Integration for Superconducting Qubits

Danna Rosenberg; Lincoln Laboratory, Lexington, Massachusetts, United States.

Superconducting qubits are a prime candidate for constructing a large-scale quantum processor due to their lithographic scalability, speed, and relatively long coherence times. As superconducting quantum processors move beyond the few-qubit scale, it will become increasingly important to develop techniques for addressing large numbers of qubits without degrading their performance. 3D integration can alleviate interconnect crowding and enable the construction of large-scale arrays of coherent superconducting qubits. At Lincoln Laboratory, we are pursuing an approach where high-coherence qubits are isolated from a potentially lossy readout and interconnect chip by an intermediate chip with superconducting through-silicon vias. The three-tier stack is bonded using indium bump bonds, which provide structural support and can be used to galvanically connect metal on different chips. We will present our recent work on developing and characterizing critical components for 3D integration, including indium bumps and superconducting through-silicon vias, and discuss progress towards building 3D integrated coupled qubits.

This research was funded by the Office of the Director of National Intelligence (ODNI), Intelligence Advanced Research Projects Activity (IARPA) and by the Assistant Secretary of Defense for Research & Engineering under Air Force Contract No. FA8721-05-C-0002. 9:30 AM EP07.04.03
3D Sequential Technology—Reliability of Cu/low-k Interconnects at High Temperature

Sylvain Beaurepaire1,2, Chloe Guerin1,2, Vincent Jousseaume1,2, Patrice Gomon1,2, Ahmad Bsiemy1,2, Vincent Maurel1,2, Xavier Federspiel1,2, David Ney1 and Claire Fenouillet-Beranger1,2; Université Grenoble Alpes, Grenoble, France; CEA-Leti, MINATEC Campus, Grenoble, France; LTM, UGA/CNRS/CEA, Grenoble, France; CEA-LETI, MINATEC Campus, Grenoble, France; STMicroelectronics, Crolles, France.

3D sequential integration is a promising approach to obtain a vertically stacked FETs (Field Effect Transistors) scheme [1]. This integration offers a very small 3D contact pitch which leads to a wide spectrum of applications like the increase of integration density beyond device scaling [2]. Such an integration requires to limit the thermal budget of top FET processing (T=500°C) [3]. A major challenge is to fabricate high-performance FETs at the top level without electrical characteristic degradation of the bottom active layers.

In order to fulfill the 3D sequential integration requirements, the use of Cu metal lines and ultra low-k dielectric materials between the two FET levels is mandatory. This intermediate Back End Of Line (iBEOL) is still challenging. Indeed, the thermal budget used to process top transistors is far higher than what is usually requested for CMOS interconnects [4], and it can greatly influence material properties and generate defects into the Cu metal lines and in the low-k dielectric.

In this work, the thermal stability of state-of-the-art BEOL structures with four levels of standard Cu/low-k interconnects was evaluated by applying different post-annealing. For this study, experiments were performed on a damascene BEOL integration of state of the art 28 node FDSOI technology on 300 mm wafers [5]. Inter-Metal-Dielectric was composed of 100 nm of porous SiOCH and 20 nm of SiCNH etch stop layer. A SiCNH layer encapsulated the four metal lines/ via levels. Then, different annealing processes (at variable temperatures from 400°C to 600°C) were applied to simulate the thermal budget that the wafers go through during the realization of the top level FETs. Electrical reliability tests on metal 1&2 and on via 1&2 were performed after the removal of the SiCNH encapsulating layer.

The breakdown voltage for line to line and via to line is not significantly modified after a thermal annealing at 500°C for 2h. At higher annealing temperatures, a degradation of the time to breakdown is observed but these modifications cannot be attributed to metal line degradation since no change in the line resistance has been observed. To better understand the mechanisms involved during thermal annealing on the integrated dielectric, the impact of a thermal process on the intrinsic properties of a porous low-k in free surface condition (no capping) was studied. Firstly, constant voltage stress experiments were performed on simple Metal-Insulation-Metal structures with the same low-k as the one used in the four metal levels integration. Secondly, in depth material characterizations such as FTIR, ellipsometry, Electron Spin Resonance were performed. By combining these material data with electrical reliability tests on integrated structures, this work shows that Cu/low-k interconnects can be used in the intermediate BEOL for 3D sequential integration. It brings also a better understanding of the stability and the reliability of these interconnects at temperatures above the classical BEOL one.

9:45 AM BREAK
Metal-organic frameworks (MOFs) are an intriguing class of porous crystalline materials with record internal surface areas. There is tremendous potential for integrating MOFs into microelectronics, e.g., as active sensor coatings or low-k dielectrics.[1] A key enabling step in leveraging the properties of MOFs in microelectronics will be the development of robust thin film deposition methods. Thus far, typical procedures for the deposition of MOF thin films are incompatible with microelectronic fabrication because of corrosion and contamination issues.

We recently demonstrated chemical vapor deposition (CVD) of MOF thin films.[2] The MOF-CVD process allows conformal growth of thin films and extends MOF processing to a range of other quasi-1D van der Waals materials with the goal of identifying the best material for the interconnects. The local temperature measurements have been conducted using micro-Raman spectroscopy in order to determine the behavior near room temperature (f is frequency). However, at low temperature it is dominated by the Lorentzian bulges of the generation–recombination noise at low temperatures, which is unusual for metals. Unexpectedly, the corner frequency of the observed Lorentzian peaks revealed a strong sensitivity to the applied bias. This dependence on electric field was explained by the Frenkel–Poole effect in the scenario where the voltage drop happens predominantly on the defects, which block the quasi-1D conduction channels. We also have investigated electrical characteristics of a range of other quasi-1D materials.

Synthesis and Characterization of TaSe2 Nanorods via Facile CVD Processes
Thomas Empante, Ainée Martinez, Michelle Wurch and Ludwig Bartels; University of California, Riverside, Riverside, California, United States.

Transition metal trichalcogenides (TMTs) like that of tantalum triselenide (TaSe2) are of interest due to their low, dimensional, quasi 1D structure and high conductivity. These materials have generally been synthesized using a chemical vapor transport (CVT) process at high temperatures followed by mechanical and/or chemical exfoliation and transferred onto a substrate. Here we present a novel breakthrough in synthesizing these materials through chemical vapor deposition (CVD). The TaSe2 nanorods are synthesized directly onto the desired substrate using relatively low temperatures and under one-hour process times. The obtained results are important for developing the ultimately downscaled local interconnects for future electronic technologies and provides further understanding of the material and its implications for TMTs possible use in future nanometer scale interconnect applications.

11:00 AM EP07.05.03
Current Carrying Capacity and Low-Frequency Noise in Quasi-One-Dimensional Van der Waals Nanowires and Nanoribbons
Adane Geremew1, Ruben Salgado1, Amirmahdi Mohammadzadeh1, Matthew Bloodgood2, Tina Salguero3 and Alexander A. Balandin; University of California, Riverside, Riverside, California, United States; 2Chemistry, University of Georgia, Athens, Georgia, United States; 3Chemistry, University of California, Berkeley, California, United States.

As the aggressive scaling in the complementary metal-oxide semiconductor (CMOS) technology continues, there is a growing need to examine new materials that can be used for nm-scale local interconnects. At present, the current density sustained by Cu interconnects in CMOS technology is between 2 MA/cm2 to 3 MA/cm2. We recently proposed that one quasi-one-dimensional (1D) van der Waals materials, such as transition metal trichalcogenides (TMTs), have properties attractive for applications in nm-scale electronics.[1-2]. In a way similar to transition metal dichalcogenides (TMDs), which exfoliate into 2D layers, TMTs exfoliate, or can be grown into, quasi-1D atomic thread bundles[1-4]. We found that metallic TaSe2 nanoribbons have breakdown current density on the order of ~10 MA/cm2[1]. In principle, such quasi-1D materials could be ultimately downscaled by exfoliation, or grown directly, into nanowires with a cross-section of ~1 nm × 1 nm, which corresponds to an individual atomic thread, i.e. MX2 chain. In this presentation we show that nanoribbons made of ZrTe5, another member of the TMT family, reveal exceptionally high current density, on the order of ~100 MA/cm2, at the peak of the stressing DC current [3]. We have used low-frequency noise (LFN) spectroscopy to investigate carrier recombination in such materials and verify reliability of the van der Waals interconnects [4]. It was found that LFN in ZrTe5 reveals conventional 1/f behavior near room temperature (f is frequency). However, at low temperature it is dominated by the Lorentzian bulges of the generation–recombination noise at low temperatures, which is unusual for metals. Unexpectedly, the corner frequency of the observed Lorentzian peaks revealed a strong sensitivity to the applied bias. This dependence on electric field was explained by the Frenkel–Poole effect in the scenario where the voltage drop happens predominantly on the defects, which block the quasi-1D conduction channels. We also have investigated electrical characteristics of a range of other quasi-1D van der Waals materials with the goal of identifying the best material for the interconnects. The local temperature measurements have been conducted using micro-Raman spectroscopy in order to determine the breakdown mechanism in the quasi-1D van der Waals metallic interconnects. The obtained results are important for developing the ultimately downscaled local interconnects for future electronic technologies.

This work was supported, in part, by the Semiconductor Research Corporation (SRC) contract 2018-NM-2796: One-Dimensional Single-Crystal van-der-Waals Metals: Ultimately-Downscaled Interconnects with Exceptional Current-Carrying Capacity and Reliability, and by the National Science Foundation (NSF) through the Emerging Frontiers of Research Initiative (EFRi) 2-DARE project: Novel Switching Phenomena in Atomic Heterostructures for Multifunctional Applications (NSF EFRi-1433395).

11:15 AM EP07.05.04
Metal Based Self-Healable Electrodes for Foldable Electronics with High Reliability
Minjae Choi, Young-Geun Park, Hyeon Seok An, Jiuk Jang and Jang-Ung Park; Material Science and Engineering, Yonsei University, Seodaemun-gu, Korea (the Republic of).

Self-healable electrodes can improve the durability and the reliability of electronic devices. In recent years, the need of self-healing ability in materials grows in the field of deformable electronics such as foldable or stretchable devices. However, until now, most of developed self-healable electrodes require additional healing agents or several stimuli such as heat, magnetic field, or UV irradiation to restore the electrical conductivity. Also, some of them takes long time to self-heal after being damaged. And, the healing ability of the electrical conductivity is not maintained through only the low number of breaking and healing cycles. Herein, self-healable electrodes based on silver nanoparticles which make up the disadvantages of other self-healable electrodes have been developed. Because the silver makes the main conductive path of the electrodes, the electrical conductivity of the self-healable electrodes is 2×10^4 S/m, which is similar level to other metals. The self-healing phenomenon of electrodes is taken by high-speed camera. If the electrodes are cracked by external forces, they reconnect in 10 milliseconds without any external stimuli or healing agents. The electrodes recover 90% of the initial conductivity during cyclic test of 50 times. Unlike the other metal electrodes, these silver-based electrodes have 60% stretchability. Furthermore, these self-healable electrodes are patterned by photolithography, which can be applied to the conventional fabrication process of electronic circuits. The electrodes are applied to foldable organic light-emitting diodes, maintaining the luminescence after folding the devices.

15:41 AM EP07.05.06
Chemical Vapor Deposition of Nanoporous Metal-Organic Frameworks (MOF-CVD) and Their Integration as Low-k Dielectrics
Rob Ameloot; Center for Surface Chemistry and Catalysis, KU Leuven, Leuven, Belgium.

Metal-organic frameworks (MOFs) are an intriguing class of porous crystalline materials with record internal surface areas. There is tremendous potential for integrating MOFs into microelectronics, e.g., as active sensor coatings or low-k dielectrics.[1] A key enabling step in leveraging the properties of MOFs in microelectronics will be the development of robust thin film deposition methods. Thus far, typical procedures for the deposition of MOF thin films are incompatible with microelectronic fabrication because of corrosion and contamination issues.

We recently demonstrated chemical vapor deposition (CVD) for MOF thin films.[2] The MOF-CVD process allows conformal growth of thin films and extends MOF processing to one of the most commonly used techniques in thin film research and manufacturing. Two important challenges were tackled to realize this process: vapor phase supply of precursors and crystallization at the vapor-solid interface. To our knowledge, this is the first vapor phase process for conformal film deposition of a crystalline and microporous network material. Future directions and potential applications of MOF-CVD coatings will be discussed, with special attention to their integration as low-k dielectrics.

Sputter Deposited Amorphous Carbon for Hard Mask with High Etch Resistance

Young-Chang Joo; Seoul National University, Seoul, Korea (the Republic of).

As the area shrinkage of semiconductor devices with high memory density, the high aspect ratio pattern is needed such as 3D NAND flash. To create a vertical pattern with a mask, mask is needed to be thicker for etching it longer. However, a thick mask distorts the shape of the pattern with a shadowing effect. Therefore, it is necessary to have a hard mask that can be made thinner. The vertical structure is fabricated by plasma based dry etching process with hard masks, which have superior etch resistance. Therefore, it is necessary to study the properties of hard mask materials for deeply patterned devices having higher memory density. The hard mask should have more etch resistant to plasma reactive gas than conventional organic soft mask for deeper patterning. It must also be easily removed after the etching process. These conditions are well satisfied with amorphous carbon, which is the most promising material for hard mask. Amorphous carbon is known that the kind of bonding is changed according to the process conditions. Carbon has various atomic bonds like sp³ of diamond and sp² of graphite. The difference in carbon bond between the two materials greatly affects the properties such as mechanical and electrical properties. In this study, we have studied how the etch characteristics change with the change of bonding nature of amorphous.

Amorphous Carbon (a-C) was deposited on SiO₂/Si by DC magnetron sputter system using graphite solid target for higher purity and lower roughness than CVD process. The deposition pressure and acceleration voltage was controlled to modify the bonding structure of the carbon film, and the bonding was dramatically modified depending on the conditions of pressure, which was an important parameter for the etching characteristics. In case of the low-pressure deposition process, sp³-bonding rich amorphous carbon film was fabricated and had an excellent etching resistance. The other hand, high-pressure deposition process, sp²-bonding rich amorphous carbon film was fabricated and had a poor etching resistance. In order to understand the degradation process of the carbon hardmask induced by the penetration of fluorine ion into the film during dry etching, the phenomenon of fluorine penetration into the film with respect to carbon bonds was proved by density function theory (DFT) calculation. Through the DFT calculation, it is unveiled that the energy barrier for the fluorine atom through sp³ bonding path is much larger than that of the fluorine atom through sp² bonding path in the amorphous carbon.

The doping, which is very well-known process to modify the bonding structure of the carbon film. We fabricate the amorphous carbon film with nitrogen, boron, silicon, and tungsten doping. The effect of the doping elements on the bonding structure of the amorphous carbon film will be discussed.

Wet-Chemical Etching of Ruthenium for Advanced Interconnects

Harold Philipson¹, Nils Mouwen¹, ², Sander Teck¹, ², Wouter Monnens¹, Quoc Toan Le¹, Frank Holsteays¹ and Herbert Struyf²; ¹imec, Leuven, Belgium; ²Technology Campus Groep T, KU Leuven, Leuven, Belgium; ³KU Leuven, Leuven, Belgium.

For damascene metallization, the semiconductor industry uses barrier / liner / seed stacks, such as TaN / Ru / Cu, in which Ru ensures a good adhesion of the Cu seed layer on the TaN barrier, as well as enables ‘reflow’ of the Cu seed to facilitate the Cu filling process by electrochemical deposition (ECD). Next, chemo-mechanical planarization (CMP) is done to achieve metallization which is embedded in a dielectric matrix. Presently, Cu constitutes the largest material fraction as conductor in damascene trenches and is deposited by ECD. In future interconnect technology nodes, Ru is considered a strong candidate to replace Cu, as it shows less electromigration.

Controlled removal of metals is a critical step at many points in a processing flow, such as for bevel cleaning, wafer backside cleaning, and fully aligned vias. For the latter example, a metal recess etch is needed. CMP yields planarized substrates, however, it cannot remove material in a controlled way. For the metal recess etch, the CMP slurries, such as bromate (BrO₃⁻) or periodate (IO₄⁻), are utilized. The etch rate and selectivity of metals such as Ru can be modified by adding oxidizing agents in CMP slurries.

In our contribution, we discuss the (electro)chemistry involved in Ru etching and discuss results for selected oxidizing agents. The etch process is characterized in terms of surface roughness, cleanliness, and etch rate. Solution chemistry as well as stability were characterized using UV-vis spectroscopy. Compatibility with low-k dielectric material was investigated and characterized using Fourier transform infrared spectroscopy.

Oxygen-Assisted Etching of Pt in Supercritical CO₂ Solutions

Eiichi Kondoh; University of Yamanashi, Kofu, Japan.

Platinum has been used as an electrode material in transistors, ferroelectric memories, and recently in magnetic tunnel junction (MTJ) devices. Pt is known as a hard-to-dry etch material due to its nobleness and low volatility of its halides. In past Pt plasma etching, physical sputtering functioned as a dominant etching principle. MTJs have a rather complex thin film stack structure consisting of various metallic layers such as CoFeB, NiFe, MgO, and Co, where MgO is sandwiched with ferromagnetic metals. These ferromagnetic elements (Co, Fe, and Ni) also form low-vapor-pressure chlorides; thus, they should be sputteretched, although sputter etching leads to a deadly sputter residue at the sidewall of a ferromagnetic tunnel junction. Recently atomic layer etching has been gaining a strong attention, whereas the usage of plasma chemistry does not abate its problems. The application of wet chemistry to the residue removal is more problematic owing to its limitation to nanostructures, electrochemical attacks, and etching selectivity.

In the present work, Pt thin films were etched in supercritical CO₂ fluids. Hexafluoroacetylacetone (Hfaca), a fluorinated compound, was added to a supercritical CO₂ fluid together with O₂ at elevated temperatures. Experimental set-up, various process parameter dependences, and Pt oxidation status will be presented.
8:30 AM *EP07.07.01
Electrochemical ALD for Enabling Advanced BEOL Scaling Yezdi Deddi; Lam Research Corporation, Fremont, California, United States.

As BEOL interconnect dimensions continue to shrink, future generation devices will require precise atomic level thickness control for BEOL seed layers. Here, we present the latest developments in interconnect metallization using a new wet process called electrochemical atomic layer deposition (eALD). In this talk, we will discuss innovative modifications to eALD that make this process scalable to full wafers and amenable to the deposition of a variety of metals and alloys. We will review recent success in achieving void-free metallization of sub-20nm interconnect features. We will also explore integration approaches including electroless ALD processing that would enable future interconnect technology nodes.

9:00 AM *EP07.07.02
Approaches to Area Selective Deposition for Next Generation Interconnects Stacey F. Bent; Department of Chemical Engineering, Stanford University, Stanford, California, United States.

Selective deposition is likely to become an important process in pattern fabrication for next-generation interconnects. Bottom-up growth strategies such as selective deposition provide advantages in reduced process complexity and improved pattern fidelity. In this presentation, I will describe different approaches to achieve area selective atomic layer deposition (ALD) for materials systems important to back end of line processing. ALD is a good choice for selective deposition because its chemical specificity provides a means to achieve selectivity on a spatially patterned substrate. One successful approach uses inhibitory layers such as self-assembled monolayers (SAMs) to alter the native surface reactivity, allowing ALD selectivity to be achieved. I will show that this process provides good selectivity for thin deposited films, and demonstrate selective deposition on different materials, including low-k dielectrics and metals such as Cu, Co, W and Ru. Because area selective ALD processes often break down after more than a few nanometers of material is deposited, strategies to overcome the undesired ALD nucleation on the inhibitory layer and achieve significantly higher selectivity in area selective ALD are also important. Two such strategies that improve the final selectivity will be described, including SAM repair between ALD cycles and a self-correcting process in which selective deposition is combined with selective etching. ALD of low-k dielectric thin films as well as selective ALD on low-k dielectric/Cu patterns will also be discussed.

9:30 AM EP07.07.03
Atomic Layer Deposition of Ru for Copper Metallization Anil Mane, Yan Zhang and Jeffrey Elam; Argonne National Laboratory, Lemont, Illinois, United States.

Contact metallization in large-scale semiconductor devices such as logic, memory, MEMS, and SoC using 2.5D and 3D interposers requires a high quality and conductivity metal barrier/seed layer for subsequent metal electroplating. Ruthenium metal has a bulk resistivity of 7.1 μΩ cm, a work function of 4.7 eV, and a low solid solubility with strong adhesion to Cu, making Ru an attractive contact metal barrier metal or seed layer for Cu electroplating. There have been numerous reports of Ru ALD using a variety of precursors. However, technical challenges remain including the need for high growth temperature, very long nucleation delay, and the use of plasma that limits Ru conformality in high aspect ratio features. Currently, there is a strong desire and demand for 3D-devices where high quality, uniform, and conformal metal growth on high aspect ratio structures for ultra largescale integration (ULSI) process flow including for 2.5D and 3D interposer substrates creation.

Here we have developed a low temperature (200°C) Ru atomic layer deposition process using Ru(DMBD)(CO)3 and O2 precursors. To enhance the Ru nucleation and growth, especially at low temperature, we performed low temperature Pt ALD using Pt(MeCp)Me2 and O2 to deposit a sub-monolayer Pt seed layer that greatly accelerates the subsequent Ru nucleation. High quality Ru films were deposited on a variety of substrates including Si(100), fused silica, Al2O3 and TiN. The ALD Ru films were uniform across the 18” deposition zone of our tubular ALD reactor. Thin Ru films were characterized by XPS, SEM, TEM, four point IV measurements, XRD and XRF. We have also performed Cu electroplating on the ALD Ru layers and found that the Ru films deposited using the Pt seed layer exhibited excellent Cu electroplating. Here we will present details of the Ru ALD and Cu electroplating.

Hyper-Selective Co Metal ALD on Cu and Pt Without Passivation Steven Wolf; Michael Breeden, Scott Ueda and Andrew Kummel; University of California, San Diego, La Jolla, California, United States.

It is desired to have selective metal deposition for bottom-up fill for both middle-of-line (MOL or MEL) and back-end-of-line (BEOL) processing. This would induce formation and growth of larger grains, which are expected to decrease via and interconnect resistance by reducing grain boundaries and decreasing surface roughness. In addition, bottom-up growth may remove the need for nucleation layers on low-k dielectrics (SiCOH) since the nucleation will occur only on the bottom surface. The key metals for bottom-up growth include cobalt and ruthenium; cobalt is particularly important since it was used as both a capping layer on Cu to protect it from oxidation, and in sub 10 nm vias, where Co is considered to be a better conductor than Cu due to Co having a smaller electron mean free path and problems with Cu electroplating in sub 10 nm vias.

ALD cobalt metal was explored using a metal-organic cobalt precursor, Bis(1,4-di-tert-butyl-1,3-diazadienyl) cobalt (Co(dad)), and either a co-reactant of formic acid (HCOOH) or tert-butylamine (TBA) at 180°C on Cu, Pt, and SiO2 substrates. The deposited Co films were studied using in-situ x-ray photoelectron spectroscopy (XPS) and atomic force microscopy (AFM). Cross-sectional scanning electron microscopy (SEM) and 4-point probe measurements were performed to check film thickness and resistivity, respectively.

It was found that there is nearly infinite selective deposition of Co on a conductor and not an SiO2 for 180°C ALD with Co(dad); and HCOOH. XPS was performed after 100 ALD cycles followed by an additional 100 cycles on UHV annealed Pt vs SiO2. On Pt, a thick (~10 nm) CoxOy film deposits while virtually no deposition results on SiO2. AFM images show no change on SiO2 before and after Co ALD cycles consistent with no nuclei formation, while the Co on Pt surface roughness remains below 1.8 nm. To verify self-limiting precursor exposures consistent with ALD, a saturation study was performed and monitored with XPS; this study highlighted the effect of individual additional half cycle amounts that result in self-limiting Co(dad), and HCOOH exposures consistent with ALD. Additionally, this study revealed a novel mechanism about the reaction. Previously it was thought the HCOOH dissociatively chemisorbed to produce atomic H which removed the ligands from Co(dad). Instead, XPS showed that HCOOH did not remove the ligands but instead induced a ligand-exchange process. The Co 2p peak indicated the HCOOH leaves a higher binding energy component on the surface consistent with a formate on the surface.

Deposition with HCOOH was attempted on Cu substrates; however, the substrate Cu signal never decreased to zero consistent with etching by HCOOH so an alkyl amine co-reactant (TBA) was also studied. For Co(dad) + TBA ALD at 180°C, reduced Co metal films were deposited on Cu and Pt substrates with hyper-selectivity against SiO2. Films as thick as 30 nm were grown on the conductors without etching the substrates. On SiO2, only 4% CoOx, was deposited after an initial 50 ALD cycles. After an additional 250 ALD cycles, there was still only 4% CoOx, consistent with saturation and hyper-selectivity. AFM imaging from ALD with TBA confirmed low surface roughness ALD on Pt and Cu, while only small (~5 nm) CoOx particles were present on SiO2.

Hyper-selective Co metal deposition was produced from Co(dad); and both co-reactants (HCOOH and TBA). Utilizing HCOOH, no deposition was seen on SiO2 consistent with infinite deposition, however HCOOH was observed to etch Cu. By switching to TBA, no Cu etching was observed and similar metallic Co films were deposited with only 4% CoOx, on SiO2, independent of the number of Co ALD cycles. The self-limiting deposition on SiO2 is a novel mechanism of selectivity through the formation of an oxide particulate, which results in hyper-selectivity.

10:30 AM EP07.07.05
As have been widely known, The NAND Flash business is transitioning from the conventional two dimensional, planar structure to three dimensional (3D), vertical structures to meet storage density requirements. Also, in 3D V-NAND Flash memory devices, and device scaling has been achieved by vertical stacking of thin film transistors (TFTs) in multiple layer configurations, without heavily relying on advances in lithography. 3D V-NAND Flash memory device fabrication involves many processes that have never before been used in mass production of semiconductor devices, and are extraordinarily challenging. Precise control of every process step is required.

Thickness reduction of 3D Channel layers is a very challenging issue due to the scale-down, vertical etch, and gapfill process limitation of devices. For overcoming these issues, Alternate deposition of ultra-thin films and selective etching are required for successful fabrication of vertically stacked layers used in 3D V-NAND Flash memory devices. In particular, after it has formed a vertical gate channel by the multiple Oxide-Nitride (ON) stack layers, and the gapfill process for gate isolation is switching from the existing Chemical Vapor Deposition (CVD) Type deposition process to the new Atomic Layer Deposition (ALD) type.

In general, the ALD process has known as the most stable and effective process in the gapfill process up to now by controlling the atomic-layer depositions by the precursor and the source loading time. However, in the gapfill process of 3D NAND flash device with an over 50th floors, as the number of stacked layers increases, the area to gapfill increases proportionally. And ALD process has encountered other new huddles for stable processes. Those are the characteristic deference of gapfill material in the top/bottom area, the void by overhang increasing in top area, and the re-spattering phenomenon by ion bombardment in bottom area. Finally, these unstable ALD processes has triggered a metal bridge to cause an electronic leakage, and the degradation of device characteristic in Word Line (WL) block fail by channel threshold voltage(Vt) drop.

ALD process has evaluated in process parameter optimization to improve deposition conformality by the controls in source gas compositions, source/co-gas partial pressure, RF power or RF process time, burst pulse flow ratio, and chamber press. However, the evaluations to improve the step coverage of the ALD layer has been improved results by dropping the deposition ratio. In other words, to improve the conformality of ALD Layer has been unavoidable to lose the production efficiency. The enforcement of source gas plasma density could make the material characteristics of ALD layer stable but the conformality severe weaken.

In this study, we have evaluated the shape change possibility of as-deposited ALD layer and the strengthening the ALD layer by optimizing the post treatment. We have measured with high resolution cross-sectional transmission electron microscopy (HRXTEM) in real patterned wafer for the ALD layer conformality transition trace by post treatment ALD Layer Thickness. And then, we have evaluated Wet Etch Rate (WER) in 300:1 HF diluted solution for the ALD layer densification trace. We have demonstrated the possibility of ALD Shape and material characteristics improvement. And we have evaluated the possibility of post treatment of high temperature ALD without loss in production efficiency as like Units Per Hour (UPH).

10:45 AM EP07.07.06
Surface Engineering by Plasma and Organic Films to Enable Area Selective Deposition in BEOL Silvia Armini, Ivan Zyulkov and Mattia Pasquali; imec, Leuven, Belgium.

Integrating bottom-up area-selective building-blocks in microelectronics has a disruptive potential because of the unique capability of engineering new structures and architectures. Atomic layer deposition (ALD) is an enabling technology, yet understanding the surfaces and their modification is crucial to leverage area-selective ALD (AS-ALD) in this field. The understanding of general selectivity mechanisms and the compatibility of plasma surface modifications with existing materials and processes, both at research and production scale, will greatly facilitate AS-ALD integration in microelectronics. The use of self-assembled monolayers to inhibit the nucleation and growth of ALD films is an alternative route to bottom-up area-selective nanofabrication. In our work, we demonstrate i) a straightforward plasma surface modification process capable of inhibiting Ru ALD nucleation on an amorphous carbon surface while still allowing instantaneous nucleation and linear growth on Si-containing materials; ii) metal and/or dielectric surface passivation by molecular organic films which enable AS-ALD of dielectric materials on dielectric surfaces and/or AS-ALD of metallic films on metal surface. Demonstration of ASD on patterned critical dimensions below 50 nm and applications of ASD in back-end-of-line (BEOL) will be illustrated.

11:00 AM EP07.07.07
Electrochemical Nanoimprinting of 3D Hierarchical Micro- and Nano-Structures in Silicon Bruno Azeredo1, Aliaksandr Sharstniou1 and Stanislau Niauznour2; 1 Arizona State University, Mesa, Arizona, United States; 2 Belarusian State University, Minsk, Belarus.

Freeform 3D single-crystal silicon micro- and nanostructures offer the opportunity to topologically define the refractive index of a medium. In turn, they enable realization of a myriad of optical devices such as classical elements, metasurface-based elements for silicon photonics, x-ray flat-lenses, optical resonators for biosensing, biomimetic lenses & imagers, and graded-index materials for photovoltaics and space applications. However, existing parallel bulk micromaching processes for silicon do not offer the ability to fabricate freeform structures with specific challenges when it comes to hierarchical micro and nanoscale 3D features, particularly during reactive etching, which in turn limits resolution, aspect-ratio and surface roughness. This paper demonstrates an electrochemical nanoimprinting process for single-crystal semiconductors for directly etching 3D features into silicon wafers. It is shown that stamps made of porous catalysts play a critical role in enabling diffusion of chemical species during imprinting which, in turn, allows for morphology control of imprinted silicon features with sub-20 nm resolution in 3D. This process delivers mirror surface finish (RMS < 5 nm), low-defect density, and large-area patterning (>1 cm²) in a single imprinting operation. Further, it outperforms the resolution and scalability of leading serial (e.g. FIB, electron beam) and parallel (e.g. gray-scale lithography) methods altogether by an order of magnitude, allowing for fast replication of patterns onto hard materials from a soft mold. This technique bypasses the need for dry etching and is potentially compatible with roll-to-roll platforms, amorphous and poly silicon and III-V semiconductors. In turn, it may pave the way for the manufacturing of complex objects for infrared optics.

SESSION EP08.01: Characterization of Phase Change Materials
Session Chair: Robert Simpson
Tuesday Morning, April 23, 2019
PCC North, 200 Level, Room 222 B

10:30 AM EP08.01.01
Nanosecond Resolved Probing of Single Silicon Nanostructure Reversible Phase Change Letian Wang1, Heng Pan2 and Costas Grigoropoulos1; 1University of California, Berkeley, Berkeley, California, United States; 2Missouri University of Science and Technology, Rolla, Missouri, United States.

On-demand phase transformation of silicon is of great technical importance for electronics, MEMES and photonics. While numerous efforts have been made towards
understanding the phase change of thin films, scientific knowledge is limited in nanoscale phase transformation.

Here we probed the nanosecond resolved crystallization and amorphization dynamics of a single silicon nanostructure with 200nm diameter. Based on the Mie resonance and thermo-optic effect, we successfully identified the heating, melting, deformation, solidification and cooling states during the phase transformations. The results revealed the superlateral crystallization of 2ns time scale and amorphization of 10ns. Combined with comprehensive heat-transfer and Monte Carlo based nucleation and phase change simulation, the study offered significant insights into the different super-coolings, cooling rates and corresponded mechanisms of crystallization and amorphization.

Materials with rationally controlled properties play important parts in the development of new and advanced technologies. For instance, the thermoelectric, phase-change, or topologically insulating materials can be traced back, to a significant extent, to the nature of bonding in materials. Here, we develop a two-dimensional map based on a quantum-topological description of electron sharing and electron transfer. This map intuitively identifies the fundamental nature of ionic, metallic, and covalent bonding in a range of elements and binary materials. Furthermore, it highlights a distinct region for a mechanism recently termed “metavalent” bonding. Extending this map into the third dimension by including physical properties of application interest, we show that bonding in metavalent compounds differs from the classical textbooks views of bonding. This map could be used to help designing new materials: by searching for desired properties in a 3D space and then mapping this back onto the 2D plane of bonding.

11:00 AM *EP08.01.03
Multiferroics in Interfacial Phase-Change Memory Junji Tominaga; National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan

It is almost ten years since interfacial phase-change memory (iPCM) was developed. Although iPCM was originally designed to save switching energy of phase-change memory (PCM) by reducing entropy energy loss at the phase transition as small as possible, it was found later that the layered structures may provide a good platform to study topological insulators and related semimetals (Dirac and Weyl). The topological properties of iPCM rely on the crystalline structures, which satisfy or not the spatial inversion symmetry. If the iPCM has the symmetry, magnetic properties are not induced because the electronic band structures are degenerated. This is the case for Kool, Petrov and inverted-Petrov phases. On the other hand, the only ferroelectric phase of iPCM breaks the symmetry, which lifts two different spin bands, resulting in magnetized. Interestingly, the magnetic properties attribute to p-electrons in Ge, Sb and Te, which are all non-magnetic elements.

Multiferroics is a keyword for future electronics as well as topological insulator. However, it is still difficult to induce large electrical and magnetic properties at room temperature. It relies on that electric dipole moments are usually related to p-electrons while the magnetic moments are to d-electrons. If a large magnetic moment is induced from p-electrons, a giant multiferroics would be possible. A combination of a topological insulator and a ferroelectric insulator may open a new era to realize such the multifunctionality. Topological insulators, such as Bi$_2$Te$_3$ and Sb$_2$Te$_3$, usually satisfy both spatial inversion and time reversal symmetry. The topological surface bands are mainly made of the band inversion of 6p- or 5p-electrons of Te, Sb and Bi. On the other hand, GeTe is known as a ferroelectric material, which has a large spin-orbit coupling (SOC) compared with other oxide ferroelectric materials. Due to the large SOC, it shows a large Rashba-like spin split bands. It is noted here that the existence of an electric dipole moment breaks the spatial inversion symmetry. If thin films of Sb$_2$Te$_3$ and GeTe are piled up alternatively, what happens on the band structure as the bulk film? Actually, both layers can share a lattice plane using (0001) and (111) through van der Waals force. As the bulk film, the spatial inversion symmetry is broken. Therefore, plural Dirac cones appear apart from the Γ-point in the k-space, resulting in a Weyl semimetal. Weyl semimetals are magnetic sensitive because spin bands are lifted from the band degenerations.

In the presentation, we show several experimental results of the Weyl semimetal from superlattices consisted of GeTe and Sb$_2$Te$_3$ sublayers at room temperature.

Phase Change Materials Probed by Angularly Resolved Photoelectron Spectroscopy and Scanning Tunneling Spectroscopy Markus Morgenstern; Institute of Physics B, RWTH Aachen University, Aachen, Germany.

Epitaxially grown GeSbTe alloys in the metastable rock-salt phase and the stable trigonal phase are transferred in ultrahigh vacuum to employ angularly resolved photoelectron spectroscopy (ARPES) and scanning tunneling spectroscopy (STS). Firstly, we map the band structure of Ge$_2$Sb$_2$Te$_5$ [1] within the whole Brillouin zone, which exhibits valence band maxima away from the G point and well below the Fermi level. Hence, the Fermi level is pinned in the disorder broadened part of the bands constituting a so-called pseudo-Fermi-surface, where each enclosed state contributes only partially to the conductivity. The resulting hole density of this pseudo Fermi-surface agrees well with results from Hall measurements of the same sample type.

Moreover, via two-photon ARPES, we found an in-gap surface state with largely linear dispersion and a circular dichroism being mirror symmetric in k-space as expected for a topological surface state. Estimates, however, showed that the intrinsic bulk carrier density overwhelms the charge carrier density from this surface state significantly, such that the surface state is likely not relevant for the transport properties of metastable Ge$_2$Sb$_2$Te$_5$.

Using STS, we established methods to probe the subsurface GeSb layer, which includes vacancies and is located below the covering Te layer [2]. It turns out that the subsurface layer is relatively ordered such that individual defects can be spotted. Finally, we contact the GeSbTe layers with the STM tip and are able to switch the resulting circuit between states of different conductivity via applying voltages of about 1V.

existing tuning mechanisms are slow and volatile. In contrast, phase change materials (PCMs) offer non-volatile programmability on sub-nanosecond time scales. Unfortunately the common phase change materials, which were originally developed for data storage, strongly absorb visible light and tend to exhibit a relatively small change to the real part of the refractive index, \( \Delta \Re(n) \), in the visible spectrum. A large \( \Delta \Re(n) \) is required to tune the resonant frequency of photonics structures. Therefore, new phase change materials that exhibit a large \( \Delta \Re(n) \) must be designed specifically to transmit visible light.

Antimony sulphide (Sb\(_2\)S\(_3\)) is a somewhat misunderstood PCM. It exhibits a large \( \Delta \Re(n) \) between its amorphous and crystalline phases\(^1\) and transmits visible light. It was originally explored in the 1990s for data storage applications but was soon forgotten because it seemed difficult to amorphise using laser pulses\(^2\). At the time PCMs were being developed for rewritable compact discs (CDs) and digital versatile discs (DVDs), which operated at wavelengths of 780 nm and 658 nm respectively. The large band gap of Sb\(_2\)S\(_3\) prevented it from efficiently absorbing the laser energy, which is required to heat the material and induce structural phase transitions. However, recently we designed resonator structures that strongly enhance the absorption of Sb\(_2\)S\(_3\) and in turn allow it to be efficiently heated and subsequently amorphised on a nanosecond time scale using laser pulses\(^1\).

We have now applied Sb\(_2\)S\(_3\) to a variety of different optical resonator structures, which allow control of both the intensity and phase of the transmitted light. In this talk, the properties of Sb\(_2\)S\(_3\) will be presented, and the performance of our latest reprogrammable visible photonics devices will be discussed.

Reconfiguration of silicon photonic integrated circuits relying on the weak, volatile thermo-optic or electro-optic effect of silicon usually suffers from large footprint and energy consumption. Here, integrating a phase-change material, Ge\(_2\)Sb\(_2\)Te\(_5\) (GST) with silicon microring resonators, we demonstrate an energy-efficient, compact, non-volatile, reprogrammable platform. By adjusting the energy and number of free-space laser pulses applied to the GST, we characterize the strong broadband attenuation and optical phase modulation effects of the platform, and perform quasi-continuous tuning enabled by the thermo-optically-induced phase changes. As a result, a non-volatile optical switch with high extinction ratio as large as 33 dB is demonstrated. We also demonstrated new device design to demonstrate low loss directional coupler, even though the material itself has very low loss. Finally, using thermal heater based on silicon p-i-n junction, we demonstrated electrical actuation of the phase transition. Few cycles of switching were demonstrated.

2:30 PM **EP08.02.03**

**Photonic Computing Using Non-von Neumann and Neuromorphic Techniques and Phase Change Materials**

Harish Bhaskaran (Department of Materials, University of Oxford, Oxford, United Kingdom).

In this talk, I shall cover recent developments in the field of evanescently couple phase change materials-based photonic devices. Specifically, the use of such devices to carry out non-von Neumann computing approaches, where processing and memory can be co-located, but on integrated photonic chips will be the primary topic. Specific examples related to matrix-vector multiplications as well as scaling up these techniques towards larger matrices, carrying out electro-optical conversions and reducing power and wafer real estate requirements will also be discussed.

3:00 PM BREAK

The number of broadband infrared (IR) materials that are commercially available is very limited. This in turn limits the design of current Electro-Optical / Infrared (EO/IR) sensors; making them bulky and expensive to manufacture. However, next generation EO/IR sensors, will require more compact, lighter and cost-effective systems for applications where size, weight, power and cost (SWaP-C) becomes a limitation. Due to this fact, the design of next generation EO/IR sensors will require novel multi-functional materials, with tailorable optical properties that can be engineered to serve complex optical functions. In this work, we highlight the development of broadband IR materials including chalcogenide glass-ceramics and chalcogenide phase change materials with tailorable optical properties. The local refractive index of the material is modified by controlling the local concentration of nanocrystals in the glass matrix using a laser; thus, facilitating the fabrication of complex gradient index (GRIN) components. In this work, we exploit this additional degree of freedom, not available in traditional IR materials, to develop more compact optical designs to enable next generation EO/IR sensors for SWaP-C limited applications.

We demonstrate the imaging power of our broadband GRIN materials by designing, fabricating and characterizing a flat GRIN lens. Typically, 1-in diameter coupons are readily fabricated. The progress in manufacturing readiness level (MRL) will also be discussed. Finally, the properties of novel broadband phase change materials will be highlighted. This material exhibits a large refractive index dispersion, in the order of 1.5, across the IR spectrum. The design, fabrication and characterization of reconfigurable flat metasurfaces will also be presented.

Chalcogenide semiconductor alloys offer a uniquely functional and compositionally-controllable material base for nanophotonic, plasmonic and optical-frequency metamaterial applications. They variously present high- and low-index dielectric, low-epsilon and plasmonic properties at near-UV to near-IR wavelengths, coupled to a capacity for fast, non-volatile, electrically–optically-induced switching between phase states with markedly different properties. We present recent developments in their application to non-volatile reconfiguration in photonic metamaterials, including: switchable ‘structural colors’ underpinned by a transition between characteristically dielectric and plasmonic states; and the first optically-switchable UV/HEV dielectric metamaterials, wherein the functional chalcogenide is hybridized with a transparent, high-index dielectric supporting the resonant mode and phase-switching, unusually, changes resonance quality but not spectral position.

4:30 PM EP08.03.03
The Development and Application of Tunable Phase-Change Band-Pass Filters Liam Trimby, David Wright and Anna Bal'dycheva; University of Exeter, Exeter, United Kingdom.

A periodic array of sub-wavelength apertures in a thin metal film exhibits high transmission (transparency) for a narrow wavelength band, with the majority of light otherwise reflected, a phenomenon known as extraordinary optical transmission (EOT) [1]. In this work, such a hole-array is coated in a phase-change material (PCM), specifically Ge$_2$Sb$_2$Te$_5$ or Ge$_2$Sb$_2$Te$_6$, whose refractive index changes the wavelength at which incident light can couple into the metallic hole-array. Since the refractive index of the PCM can be altered by changing its phase-state, the PCM layer enables the EOT transmission peak to be dynamically tuned (shifted) in wavelength, so providing the functionality of a tunable band-pass filter [2]. Moreover, such filters can work in almost any wavelength range for which a suitably low-loss PCM is available. Here we show filtering operation in the 3 to 5 µm and 8 to 12 µm infrared wavebands. Since such filters are ultra-thin, solid-state and can be continuously tuned, they are suited to multispectral imaging and display applications. They also possess large field enhancements within the holes, opening up the possibility for use as chemical sensors with enhanced sensitivity. Many advantages of phase-change materials in general transfer to these filters, namely fast (ns) nonvolatile (years) switching, with excellent cycling endurance [3]. It is also possible to add or remove additional characteristics to these filters, such as polarization or angular sensitivity, by carefully selecting the shape of the holes used to pattern the metallic layer [4].

For multispectral imaging applications, the PCM band-pass filter is placed in the optical path between a scene and a high-speed camera. Multiple images are then taken as the center wavelength of the filter is scanned continuously over the waveband of interest by progressively crystallizing the PCM layer. The advantages of this method are the wide wavelength range applicability, and that spectral resolution can be improved using a higher speed camera or tuning the filter less rapidly (by lowering the temperature used for crystallization of the PCM layer).

Another possible application that we explore is the provision auto-referencing chemical sensors that utilize infrared absorption spectroscopy for analyte identification. Here the filter’s resonance wavelength is designed to match the primary absorption peak of the analyte. The high field enhancement within the filter’s hole-array causes strong absorption at what would normally be the high transmission wavelength, so yielding high measurement sensitivity. The filter can then be tuned to a region in which the analyte does not absorb, and a baseline taken to allow for auto-referencing.

Finally, we consider a third potential application, that of infrared displays. Here, by layering one filter on top of another we can control both the transmission wavelength and the transmitted intensity. Such a configuration could thus be combined with a broad-band infrared source to produce sub-wavelength thick, kHz refresh rate, infrared displays capable of producing almost any arbitrary test image (e.g. for sensor calibration, target identification etc.).

Terahertz Spectroscopic Characterization of Ge$_2$Sb$_2$Te$_5$ Phase Change Materials Kotaro Makino$^1$, Kosaku Kato$^2$, Yuta Saito$^3$, Paul Fons$^4$, Alexander Kolobov$^{1, 3}$, Junji Tominaga$^1$, Takashi Nakano$^2$ and Makoto Nakajima$^3$; 1National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 2Institute of Laser Engineering (ILE), Osaka University, Suita, Japan; 3Department of Physical Electronics, Herzen University, St. Petersburg, Russian Federation.

Ge-Sb-Te (GST) phase change materials exhibit a structural phase transition between amorphous and two crystalline phases. With increase in temperature, amorphous GST transforms into cubic and hexagonal crystals at around 150 °C and 350 °C, respectively. During this phase change process, not only optical reflectivity, but also carrier density and mobility significantly enhance. Based on these properties, various kinds of new optical and electrical applications, such as optical memory/logic, display, and RF switch, have been proposed. However, optical properties in the terahertz (THz) frequency region have not been fully unveiled, although GST is expected to be utilized for THz optoelectronic device applications [1]. In this study, we employed a transmission-type THz time-domain spectroscopy (THz-TDS) and evaluated the optical properties of GST thin films in the THz frequency range. The samples were Ge$_2$Sb$_2$Te$_5$ alloy films (100 nm) deposited on Al$_2$O$_3$ substrates. Zr$_2$Si$_2$O$_7$ protection layers (20 nm) were then deposited. The GST film was grown at room temperature and then annealed at 150 – 400 °C for an hour to obtain crystalline GST films. It was found that the absorption coefficient increases over the entire frequency range of the measurement (0.2 ~ 2.5 THz) with increase in the annealing temperature. The obtained flat transmittance curves are a characteristic of Drude absorption and indicate that the temperature and then annealed at 150 ~ 400 °C for an hour to obtain crystalline GST films. It was found that the absorption coefficient increases over the entire frequency range of

We present the highly ordered array of vanadium dioxide (VO$_2$) nanodots using nanoporous templates fabricated by block copolymers-based lithography. Thin layers of poly(vinyl alcohol) (PVA) and polystyrene-block-poly(2-vinyl pyridine) (S2VP) are subsequently prepared on a silicon (Si), glass, and sapphire (Al$_2$O$_3$) substrate by spin-coating method. Then, the S2VP thin film on the PVA layer is solvent-annealed in toluene vapor for inducing its self-assembly, so that hexagonally packed poly(2-vinyl pyridine) (P2VP) cylinders oriented vertically to the surface are achieved. After the S2VP thin film is immersed in ethanol which is a selective solvent of P2VP blocks, the resulting film shows hexagonally packed nanoporous structures on its surface. Subsequently, the layer of VO$_2$ is uniformly deposited on nanoporous templates using vanadium (V) target with magnetron sputtering system. As the underlying PVA template as a sacrificial layer is removed by washing with water, only hexagonal array of VO$_2$ dots is remained on the surface. Since VO$_2$ is a phase-change material driven by temperature, electrical properties of these VO$_2$ dots are characterized by varying temperatures.
Much attention has been paid to next-generation memory devices capable of low-power consumption and high-density integration. We have recently reported a novel nonvolatile memory device (Voltage switching Random Access Memory: VolRAM) based on the change in the standard electrode potential. The advantage of this device is the low-power consumption, however, the relation between the applied pulses voltages for switching and power consumption remains unclear. Accordingly, we studied memory operations using pulsed voltages, regarding power consumption.

The device consists of a stack of Li, Li$_2$PO$_4$ solid electrolyte, and Ni thin films on glass substrate. All the processes including fabrication and evaluation were performed without exposing samples to air using our custom-made system. We first fabricated VolRAM devices with a stacked structure of Li(1 µm)/Li$_2$PO$_4$(1 µm)/Ni(100 nm) on glass substrates, with a typical diameter of 0.5 mm. For VolRAM operation, we applied rectangular wave pulsed voltages (maximum of 4.5 V vs. Li) between Ni-Li electrodes as the initial state with an open-circuit voltage of 0.95 V (Low-voltage state). Both of the pulse-width and waiting time between each pulse were set to 100 ms. The amount of Li migration during voltage application was calculated by the time integration of current observed in the circuit. After applying the pulsed voltages, the time dependence of the open-circuit voltage was measured.

The open-circuit voltage increased as the number of application pulses increased. The voltage states of VolRAM successfully switched from low-voltage state to intermediate- and high-voltage state by the applications with 2 and 20 pulses, respectively. Note that the amount of Li ions migrating in the two pulses was 26.1 pC/µm$^2$. If we assume this device to be the size of 20 nm × 20 nm, the power required for switching is 5 × 10$^{-14}$ J. This value is very small compared with the typical energy required by a DRAM device: 10$^{-13}$ J. Thus, we succeeded in the operation of VolRAM by applying pulsed voltages with very low power consumption.

References
tension etc.). Post-printing processing of the thin films involves sintering/curing which could need high temperature and must be optimized for not only different printing methods but also for different inks and specific applications. As 3D printing can create arbitrary structures, it will be invaluable if the technology can be applied to print optical waveguides, gratings or oscillators. To take a step towards this, we report a step-by-step process for inkjet printing of chalcogenide glass starting from glass synthesis. Chalcogenide glasses (ChGs) are phase change materials that are widely used in optical and electrical memory because of their high refractive index, transparency in infrared (IR) region, high resistivity contrast between two phases and thermally driven amorphous-to-crystalline phase change. As an amorphous material, they have a remarkable tolerance to impurities, compositional variance and radiation-induced damage. Their phase transition to a crystalline condition caused high interest due to the application in the electronic or optical recording. While this requires development and synthesis of low-temperature switching mechanisms, recent advancements in ChGs application as temperature sensors in nuclear facilities demand glasses with high crystallization temperature ($T_c$) and high refractive index ($n$). High coordination number and relatively strong chemical bonds of Ge containing binary ChGs make them promising candidates in that aspect. The printing process starts with glass synthesis and then nanoparticles (diameter $\leq$ 100 nm) are obtained by an optimized wet milling of the bulk glass followed by ultrasonication. Cylcocode is used to suspend the nanoparticles and to avoid agglomeration, ethyl cellulose is added as a surfactant. Once the particle size and viscosity (2-30 cP for Dimatix) are characterized by a DLS system and a Rheometer respectively, the ink is used in a Dimatix inkjet printer to obtain printed thin films. Printing requires optimization of the ink parameters, as well as the piezoelectric nozzle controlling performance. Development of these specific parameters and the sintering process optimization for obtaining of homogeneous thin films are described in details and discussed based on the ChG glasses composition. Reflective indices and extinction coefficients of the thin films were measured as the films were produced and after heating at various target temperatures up to their crystallization temperature directly in a hot stage in an ellipsometer using light of 270 nm to 1650 nm. The surface morphology of the films was studied using scanning electron microscopy (SEM) and atomic force microscopy (AFM).

**EP08.04.06** Vis-NIR Responsive Metal-Insulator Transition in Ag-Decorated VO$_2$ Nanorod Arrays **Kookun Hong, Jun Min Suh, Seokhoon Choi and Ho Won Jang**; Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

Metal-insulator transition (MIT) in strongly correlated materials has enormous potential with scientific and technological impacts in future oxide nanoelectronic devices. While photo-driven MIT can provide opportunities to extend the novel functionality of strongly correlated materials, there have rarely been reports on it. Here we report MIT provoked by visible-near infrared (Vis-NIR) light in Ag-decorated VO$_2$ nanorod arrays (NRs) due to localized surface plasmon resonance (LSPR). Under Vis-NIR illumination, strong electric fields, generated at the interface between Ag nanoparticles and VO$_2$ NRs by LSPR, affect the electronic state of VO$_2$ and provoke MIT and structural phase transition in VO$_2$ NRs. Due to LSPR-induced MIT in VO$_2$ under Vis-NIR illumination, Ag-decorated VO$_2$ NRs exhibit MIT-driven broad spectral response with high and fast response. Our study will open up the new strategy to trigger MIT, a new functionalization in strongly correlated materials and serves as a valuable proof-of-concept for next generation optoelectronic devices with fast switching speed, large optical band gap and large refractive index change. We have shown that by using Sb$_2$S$_3$ in a simple optical resonator, the resonant frequency can be manipulated without the need of phase change materials. The fundamental resonance change can be inferred.

**EP08.04.07** Pump-Probe Approach to Optical Phase Change Material Characterization **Gary Sevison,** $^1$-2, Joshua A. Burrow$^1$, Pengfei Guo$^1$, Andrew Sarangan$^1$, Joshua Hendrickson$^1$ and Inaad Aguil$^1$,$^3$; $^1$Electro-Optics, University of Dayton, Dayton, Ohio, United States; $^2$Air Force Research Laboratory, Dayton, Ohio, United States; $^3$Physics, University of Dayton, Dayton, Ohio, United States.

Phase change materials (PCMs) are currently being explored for use in a number of photonics applications due to their interesting characteristics. These materials have the ability to switch to multiple different states in a non-volatile fashion. These states can have drastically different optical characteristics. By controlling the state of the material, the amplitude and phase of light passing through or reflected off the material can be controlled. This can lead to the creation of many different photonic devices including high-speed light modulators and optical memories. We characterize the temporal dynamics and quantity of crystalization of GeSb$_2$Te$_5$ (GST) utilizing a pump-probe setup. The pulses to facilitate the switching are created via a CW 1550 nm NP Photonics laser, an arbitrary waveform generator (AWG), and an electro-optic modulator (EOM). The pulses are then amplified by an erbium doped fiber amplifier (EDFA). Post EDFA, the probe laser (a 1580 nm CW Agilent laser amplified by a second EDFA) is coupled into the same fiber using an 80/20 fiber splitter. The probe power needs to be low enough that there is not extra heating of the sample, which would affect the phase change characteristics, but high enough to be detectable after reflection. The resulting mixed signal is then passed through a free-space EOM (used to pick off an arbitrary number of pulses) and coalesced with a 780 nm laser that is used for visually positioning the pump and probe lasers on the sample. The light then is sent into a microscope where it is incident on the GST on silicon sample. The reflected light is coupled back into a fiber and passes through two wavelength division multiplexers (WDMs) in order to separate out the probe signal from the pump before being detected by a 3.5 GHz photodetector and recorded on a digital phosphor oscilloscope with a resolution of 2 ns. As the phase is changed via the pulses, the probe laser sees a change in the reflectivity. The amount of change in the material can be determined by the reflectivity measurement from the probe laser and the temporal dynamics can be gleaned from the resulting graph. In our results we see multiple levels of reflectivity indicating partial change of the GST. After a number of pulses (dictated by the power of each pulse), the reflectivity levels off indicating that the GST is fully changed up to the penetration depth of the laser. From the shape of the graph the cooling times as well as information about the mechanisms of the change can be inferred.

**EP08.04.09** Resistance Drift and Crystallization Processes in the Reset State of GST—Based PCMs **Kazimierz J. Plucinski:** Military University of Technology, Warsaw, Poland.

The amorphous phase in the reset state of GST-based phase-change memory (PCM) cells shows a resistance increase in time according to power law $[1]$ with an exponent dependent on the size of the programmable region. This large increase in resistivity with time (resistance drift) during the ageing of the amorphous phase has up till now limited the multi-level storage capability, i.e. hindered the development of ultrahigh multi-level storage devices. In explanations of the phenomenon of resistivity increase in the reset state of these PCMs published to date, a significant role has been attributed to the creation and growing of subcritical crystalline nuclei inside the amorphous area. The results of analysis of the kinetics of the increase of the population and evolution of subcritical nuclei on the phenomenon of resistivity increase of the amorphous phase in reset state of PCMs are presented here. They are based on previously published research results for compound in the GeTe-Sb$_2$Te$_5$ tie line (e.g. $[2,3]$)

**EP08.04.10** Wide Bandgap Phase Change Chalcogenide Tuned Visible Photonicies **Weiling Dong**, $^1$ Hailong Liu, $^1$ Jitendra Behena, $^1$ Li Lu, $^1$ Ray Ng, $^1$ Kandamathane Sreekanth, $^1$ Xilin Zhou, $^1$ Joel Yang$^1$,$^2$ and Robert Simpson$^1$; $^1$Singapore University of Technology and Design, Singapore, Singapore; $^2$Institute of Materials Research and Engineering, A-STAR, Singapore, Singapore; $^3$Division of Physics and Applied Physics School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore.

Controlling light-matter interactions enables a wide range of applications from optical sensing to imaging and communications. However, for a given nanostructure, the optical response from the light-matter interaction is usually fixed after the device is fabricated. The optical response can be modulated by changing the nanostructure mechanically or by using materials with controllable refractive index. Phase-change materials exhibit a huge property contrast between their structural phases. And the phase transition can be typically invoked in nanoseconds. So far, the most commonly used phase change material for tunable photonicics research is GeSb$_2$Te$_5$. However, GeSb$_2$Te$_5$ is that its absorption coefficient in the visible spectrum is very high, which whilst the change in the real component of the refractive index in the visible spectrum is relatively small. This limits the usefulness of GeSb$_2$Te$_5$ in the visible spectrum. In contrast, SnS$_2$S$_3$, a chalcogenide that has not been studied widely, is a good alternative for visible photonic devices due to its fast switching speed, large optical band gap and large refractive index change. We have shown that by using SnS$_2$S$_3$ in a simple optical resonator, the resonant frequency can be easily tuned by inducing a phase transition in SnS$_2$S$_3$ $[1]$. This phase transition is induced by optical or electrical heating. By changing the thickness and structural state of SnS$_2$S$_3$, the resonant wavelength of the structure can be tuned to cover the whole visible spectrum. Indeed, the maximum resonance shift was 110 nm $[1]$. Note that this simple structure is easily manufactured by industrially scalable techniques. We conclude that SnS$_2$S$_3$-based tunable photonicics is promising for a broad range of applications, such as reconfigurable waveguide systems, spectrometer, and display technologies.

Fast Periodic Spiking in VO₂ Driven by a Carbon Nanotube Heater
Stephanie Bobaichuk², Suhas Kumar¹, Gregory Pitner², Connor McClellan², Jaewoo Jeong³, Mahesh Samant¹, Stuart S. Parkin¹, H.S. Philip Wong⁴, R. Stanley Williams⁴ and Eric Pop⁵; HP Labs, Palo Alto, California, United States; ²Stanford University, Stanford, California, United States; ³IBM Almaden Research Center, San Jose, California, United States.

The emergence of data-driven computing has prompted a search for systems based on new computational elements. One novel paradigm is the use of spikes, or neuron-like action potentials, to communicate and compute. However, implementing such a neuromorphic system in physical hardware requires compact devices that can produce controllable, low-energy, and fast spiking.

One approach is to exploit instabilities in the transient dynamics of VO₂, which produce periodic spiking when used in a relaxation oscillator, corresponding to periodic heating and cooling across its Mott-metal-insulator transition. Speeding up these devices requires aggressive shrinking to minimize both the electrical and thermal time constants of these oscillations. To effectively scale such VO₂ devices to sub-10 nm widths, in previous work we used metallic carbon nanotubes (CNTs) with ~1 nm diameter as nanoscale heaters in physical contact with an electrically parallel thin film of VO₂ [1].

In this work we demonstrate that a single CNT-VO₂ device forms a Pearson-Anson relaxation oscillator when driven by a DC source, generating neuron-like periodic spiking. The highly localized Joule heating of the CNT acts to trigger and confine the insulator-metal transition in the VO₂ to nanoscale dimensions, greatly reducing the effective thermal mass of the device. This reduction of thermal time constant allows the device to oscillate very rapidly across its Mott transition. Compared to a VO₂-only device, the CNT-VO₂ devices showed a reduction in quasi-static switching voltage accompanied by (a) an increase in the spiking frequency by over 3 orders of magnitude, (b) a decrease in the spike’s transient duration by 3-4 orders of magnitude, and (c) a decrease in pulse energy by 2 orders of magnitude. We also constructed a compact model that could quantitatively reproduce these observations, providing insights into the thermal oscillation effects induced by the CNT.

We further characterized the tunability and scalability of our CNT-VO₂ devices. We found that the spiking frequency of a single device can be tuned by nearly an order of magnitude by adjusting the DC bias conditions. Our results also showed that the spike width and energy decrease with length, with our shortest 300 nm devices showing sub-20 ns spike widths.

In summary, we demonstrated that the addition of a CNT nanoscale heater results in a significant improvement in the dynamical behavior of VO₂-based oscillators. This provides an accessible path to scaling electronic devices by thermally engineering and localizing the dynamics of an otherwise bulk transition mechanism.

8:45 AM EP08.05.02
Thermal Regulation of Space-Craft Using Engineered Vanadium Dioxide Films in Multilayer Optical Coatings
David Woolf, Colin Hesselt, Albert J. Wright and Joel Hensley; Physical Sciences, Inc., Andover, Massachusetts, United States.

Reducing the phase transition temperature of vanadium dioxide (VO₂) to near-room temperature is necessary many thermochromic applications including space radiators. In this work, we demonstrate fabrication of thin films of VO₂ doped with fluorine and tungsten via an aqueous sol-gel method. These films are incorporated into multilayer dielectric stacks that optimize the optical properties of two decades of the electromagnetic spectrum (0.4 - 40 microns) to maintain high solar reflectivity and modulate their emissivity in response to variable heat loads. By doping the films, the phase transition temperature of VO₂ can be reduced from 68 C to less than 30 C, making this technology compatible with both manned and unmanned spacecraft.

9:00 AM EP08.05.03
Boron Doped VO₂ Devices Demonstrating Cycling Dependent Hysteresis
Heidi Clarke¹, Diane G. Sellers¹, Erick Braham¹, Ruben Villarreal¹, Timothy Brown¹, Raymundo Araújo¹, Sampark Banerjee¹ and Patrick J. Shambaeger¹; ¹Chemistry, Texas A&M University, College Station, Texas, United States; ²Materials Science & Engineering, Texas A&M University, College Station, Texas, United States.

Previous investigations on doping of VO₂ to enable tuning of transformation temperature, hysteresis width, and magnitude of the metal-insulator transition (MIT) in VO₂ have primarily focused on substitutional dopants. In a novel post-synthetic diffusive annealing technique, Boron has been introduced as an interstitial dopant which both depresses the phase transition temperature (10 °C/at % B) and introduces an increase of the heating transition temperature as a function of time and temperature below the transition temperature i.e. a thermal history dependence of hysteresis width. Here, the origins of this unique kinetic hysteresis are proposed to stem from B dopant relaxation within the host lattice following the crystallographic phase transition (low-temperature M1 to high-temperature R phase) and will be discussed in the context of structural characterization (near edge x-ray absorption) and density functional theory calculations. Furthermore, in order to probe the effects of B-doping on the resistivity of VO₂, two-terminal devices were photo-lithographically fabricated from single crystal B-doped VO₂ particles with a range of Boron concentrations. Electrical characterization demonstrated that introduction of Boron lowers the resistivity of the low-temperature M1 phase thereby reducing the magnitude of the change in resistivity across the MIT, while introducing a unique kinetic dependence of resistivity. Finally, current pulses will be used to electrically trigger the phase transition to demonstrate viable device behavior. As well as presenting a novel system in which to explore the effect of interstitial dopants on kinetic hysteresis, B-doped VO₂ devices demonstrating varied, kinetically accessible resistance states could be of use in neuromorphic computing applications.

Unique Properties of Isostructural VO₂ Thin-Film Heterostructures
Adele Moatti; Materials Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States.

Control over the concurrent occurrence of structural (monoclinic to tetragonal) and electrical (insulator to the conductor) transitions presents a formidable challenge for VO₂-based thin film devices. Speed, lifetime and reliability of these devices can be significantly improved by utilizing solely electrical transition while eliminating structural transition. We design a novel strain-stabilized isostructural VO₂ epitaxial thin-film system where the electrical transition occurs at ~77 °C without any observable structural transition. A thin-film heterostructures with a completely relaxed NiO buffer layer has been synthesized allowing a complete control over strains in VO₂ films. We discover that these isostructural thin film devices demonstrating varied, kinetically accessible resistance states could be of use in neuromorphic computing applications.

It is observed that the programming current in a memristor is decreased by using 2D materials that emulate the synaptic properties is a crucial building block for brain-inspired computational systems. In today’s data-centric world, where some of the most useful computing tasks are to extract meaningful information from massive amount of unstructured data, neuromorphic computing can provide low-energy high throughput computing. The challenge in data-centric computing with the conventional computing architecture lies in the energy and latency bottleneck of off-chip memory access (i.e. “memory wall”) which do not scale down with the scaling of the technology node. Deep neural network (DNN) is a class of artificial neural networks (ANNs) that benefits from both the availability of big data (large amount of multi-media data for model training) and the continual performance improvement in analog devices in the past decade. However, the memory hierarchy of today’s computing architectures is not specifically designed to leverage the predictive dataflow and potential data reuse of DNN processing, resulting in longer latency and insufficient energy-efficiency for memory access. To reduce these expensive memory access, hardware accelerators for DNNs are designed to employ more fine-grained local memory hierarchy and more specialized dataflow design, which improves the energy efficiency and throughput while maintaining DNN’s inference accuracy. However, the “memory bottleneck” in modern DNNs may not be fully addressed by the acceleration architectures alone. Emerging memory technologies have the potential to play an important and unique role. As these technologies can potentially offer up to tera-bytes of on-chip data storage with a wide range of energy-delay optimization opportunities, they may complement SRAM and DRAM for more efficient DNN inference acceleration. A possible application of the emerging non-volatile memory (NVM) devices is to serve as in-memory computing element where multi-level resistance response of an NVM can store the analog synaptic weights of a DNN on-chip. In another in-memory computing scheme, a crossbar array of non-volatile memory devices can perform the multiply-and-accumulate (MAC) operation at a lower energy cost when the input vector is encoded as an analog voltage and the weight matrix is encoded as analog resistance (conductance) values stored in the memory devices. The ability of the NVMs like RRAM, PCM, CBAM to change its resistance values gradually as a function of the applied voltage pulse across its electrode is the key to performing analog in-memory MAC operation. This paper provides an overview of the current state-of-the-art non-volatile memory devices used for neuromorphic hardwares in applications ranging from biology based learning models to conventional machine learning algorithms solved using neural networks. Furthermore, a more focused overview of the device-level trade-offs required for hardware acceleration of neural network architectures using analog in-memory MAC operation is presented. In general, larger conductance range, more intermediate states, and higher resistance are desirable for both inference and training. For inference, an ideal device should also have linear I-V relationship and long retention time. For training, symmetric and linear pulse response, small device-to-device and cycle-to-cycle variation, and good endurance are crucial. Our review reveals that controlling the oxygen ion movement during pulse switching in RRAM can be a promising way to achieve the aforementioned performance goals. Placing an oxygen ion barrier to make a bilayer RRAM and confinement of the generated heat during switching have shown significant improvement in analog switching. Better thermal management in RRAM can also provide filament stability that could improve reliability like retention and endurance. If the ideal device can be achieved, the MAC array using NVMs can provide ultra-low energy, high throughput computing without compromising bit precision that is currently missing in the neural network accelerator landscape.
Ferroelectrics as phase-transition materials have promising applications in both logic and memory technologies beyond CMOS. Neuromorphic architectures, such as neural networks and artificial brains [1][2], require synergy among neurons and synapses to achieve cognition and classification functionalities. In spite of the fact that traditional CMOS technologies provide some topology to achieve these functionalities, emerging devices, such as ferroelectrics field-effect-transistors (FEFETs), offer significant benefits in terms of power, performance, and area as physical platform for implementing neural networks due to their unique properties—hysteresis, non-volatility, multi-state, and etc. In the past a few years, FEFETs have demonstrated great potential in implementing artificial synaptic devices [3]-[5]; however, the demonstration of artificial neurons built on ferroelectric devices is still pending. In this talk, we will present experimental demonstration of ferroelectric spiking neuron based on a compact IT-1FFETT structure and projected performance of spiking neural network based on ferroelectric neurons for unsupervised clustering on MNIST dataset [6]. Ferroelectric spiking neurons utilize abrupt hysteric transition feature of ferroelectrics such that there are unstable states in the current-voltage characteristics of FEFETs [7]. FEFET hysteresis can be dynamically tuned by bias conditions which allows for inhibition functionality. Artificial neurons based on metal-semiconductor-metal transition (MIT) devices [8], suffer from a fundamental shortcoming—all these neurons are excitatory. In contrast, ferroelectric spiking neurons have built-in excitatory and inhibitory input connections, which are essential to enable high accuracy in unsupervised learning, increases sparsity in spiking, and efficient implementation of synaptic weights.

In summary, spiking neurons based on FEFETs provide compact and efficient implementation of artificial neurons and have great potential in developing spiking neural networks and other neuromorphic applications.

individual vias connecting the resulting network to electrode pads were written and deposited. Network quantifying simulations revealed a small-world coefficient of 2.89, shortest path length of 3.61 and clustering coefficient of 0.057. When electroformed, this system exhibited switching between LRS and HRS at ±7 V. To investigate the role of electrode-membrant interfaces, copper tungsten films were deposited on copper substrates using chemical solution deposition. After patterning top tungsten electrodes and electroforming, IV measurements revealed memristive behavior and exhibited switching between LRS and HRS at ±0.7 V. In this presentation, the fabrication process and the memristive characteristics (endurance, resistance retention, pulse measurements, etc.) of the above listed systems will be discussed in detail.

11:45 AM EP08.06/EP09.05.07

Inspired by neural computing, the pursuit of ultralow power neuromorphic architectures with highly distributed memory and parallel processing capability has recently gained more traction. However, emulation of biological signal processing via artificial neuromorphic architectures does not exploit the immense interplay between local activities and global neauron modulations observed in biological neural networks, and hence are unable to mimic complex biologically plausible adaptive functions like heterosynaptic plasticity and homeostasis. Here, we demonstrate emulation of complex neuronal behaviours like heterosynaptic plasticity, homeostasis, association, correlation and coincidence in a single neuristor via a novel dual-gated architecture. This multiple gating approach allows one gate to capture the effect of local activity correlations and the second gate to represent global neuron modulations, allowing additional modulations which augment their plasticity and enabling higher order temporal correlations at a unitary level. Moreover, the dual-gate operation extends the available dynamic range of synaptic conductance while maintaining symmetry in the weight-update operation, expanding the number of accessible memory states. Finally, operating neuristors in the sub-threshold regime enables synaptic weight changes with high gain, while maintaining ultralow power consumption of the order of femto-Joules.

A New Approach to Accessing the Semiconductor-to-Metal Transition in Two-Dimensional Crystals Using Ionomers Susan Fullerton, Ke Xu, Aaron Woeppe1, Jierui Liang, Eli Bostian, Hangjun Ding and Eric Beckman; Chemical and Petroleum Engineering, University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

Many approaches to induce the semiconductor-to-metal phase transition in two-dimensional (2D) crystals via strain involve global strain of the entire substrate as opposed to local strain of individual devices. In this work, we present a new approach to induce the transition where individual devices are addressed via field-effect modulation of an ionomer (i.e., single-ion conductor). Specifically, strain is induced in each device using a voltage applied to the top gate of an electric-double layer (EDL)-gated, field-effect transistor (FET). The mechanism to induce strain is the same mechanism responsible for actuation in ionic polymer metal composites (IPMC’s), which mimic the behavior of muscle. The active layer in an IPMC is a single-ion conductor, which deforms under applied voltage due an electrostatic imbalance created by the formation of an EDL on one polymer/electrode interface but not the other. The imbalance occurs because only cations, and not anions, are free to diffuse in the electrolyte. Modeling indicates cation densities up to 5 x 10^4 ions/cm^2 at the ionomer/electrode interface under 2V applied gate bias, which is theoretically predicted to induce several percent strain on the 2D crystal—enough to induce the phase transition. Experimentally, a custom-synthesized ionomer is used to electrostatically gate both graphene and MoTe2 FETs. Compared with backgating through SiO2, transfer characteristics on both EDL-gated graphene and MoTe2 FETs reveal a similar enhancement of the n-branch using both the ionomer and a dual-ion conductor (i.e., one with mobile cations and anions). The ionomer decreases the subthreshold swing in the n-branch of the MoTe2 FET from 5000 to 250 mV/dec and increases the current density and on/off ratio by two orders of magnitude. However, as expected, the ionomer quenches the p-branches in both the graphene and the MoTe2 FETs because the anions are immobilized and therefore cannot form an EDL by inducing holes in the channel. This is the first demonstration of an ionomer-gated 2D FET and it lays the groundwork for further simulate a phase change memory device in series with an OTS using our finite element phase change model [6]–[8].

EP08.07.01

Phase change memory is a resistive non-volatile memory technology that stores information in the crystalline (conductive) or amorphous (resistive) phase of a material such as the chalcogenide Ge2Sb2Te5. Phase change memory can be implemented as a crossbar array, allowing for very dense storage, and it is back-end-of-line compatible, allowing for on-chip fabrication to eliminate the von Neumann (off-chip memory access) bottleneck. Crossbar arrays connect many devices in parallel with individual devices read and written by selecting the appropriate word and bit lines. They are susceptible to large leakage currents due to the many parallel devices between non-selected and selected lines, and thus require a current limiting access device in series with every memory cell. Ovonic threshold switches (OTSs) are such devices. OTSs are highly resistive in the off state but switch to a highly conductive on state at some threshold voltage due to a field-dependent conductor mechanism in amorphous chalcogenides. They remain on while a minimum holding current passes through the device, then rapidly switch off. As access devices, OTSs must be designed such that all unselected devices remain off while a selected device passes enough current to read or write a memory cell regardless of the initial state of any memory cell in the array [1]. However, there is still debate on the mechanism(s) behind ovonic switching and thus on how a given design will behave. Recent models that explain ovonic switching include (i) field-based switching due to the filling of trap states near the fermi band in amorphous Ge2Sb2Te5 (a-GST) [2], (ii) field-assisted crystallization, where crystals are stable in phase change materials and unstable in OTSs once the field is removed [3], and (iii) a field-assisted thermal phenomenon in doped a-GST [4]. We model ovonic switching in a-GST as a field-assisted thermal phenomenon by coupling field and temperature dependent conductivity terms [5], simulate switching in COMSOL Multiphysics, and find good agreement with experimental ovionic switching data for a-GST. We further simulate a phase change memory device in series with an OTS using our finite element phase change model [6]–[8].

Volatile Threshold Switching and Non-Volatile Bipolar Resistive Switching in Mixed Phased a-VOx Asymmetric Crossbar Devices Shrinu Nirantar, Md. Ataur Rahman, Mohammad Taha, Taimur Ahmed, Matthew Field, Madhu Bhuskaran, Sumeet Walia and Sharath Srinivas; School of Engineering, RMIT University, Melbourne, Victoria, Australia.

Vanadium oxide shows versatile properties which can be triggered using temperature as well as electric bias. Due to this, it has been proven to be a potential material in the field of resistive random access memory both as a memory element and selector. Here, we fabricate asymmetric cross-points devices of amorphous vanadium oxide films to analyse its
resistive switching performance related to different oxide phases as well as phase-change induced insulator-to-metal transition. Devices show a characteristic volatile threshold switching after electroforming at high voltages, whereas lower voltages reveal a forming-free non-volatile bipolar resistive switching behaviour. Volatile switching performance is apolar, stable, reversible, and symmetric for over 10^4 consecutive cycles. While, non-volatile bipolar resistive switching is asymmetric and stable over 200 cycles. Based on the achieved electrical characterisation and compositional analysis, it is suggested that the volatile threshold switching is due to the presence of VO₂ component, while non-volatile switching is due to the presence of V₅O₄ component in the mixed phase amorphous vanadium oxide film. This work highlights the occurrence of bifunctional memory behaviour in amorphous cross-point devices and further provides guidelines to tailor the switching behaviour.

Operation and Materials Choice for Chalcogenide Selector Devices
John Robertson; Cambridge University, Cambridge, United Kingdom.

The electronic structure and conduction mechanism in chalcogenide-based Ovonic threshold switches (OTS) used as selectors in cross-point memory arrays is derived from density functional calculations and quasi-Fermi level models. The experimentally most favorable compositions are found to lie in the 4:2 coordinated region of the phase stability maps of IV-VI semiconductors. The switching mechanism in OTS is primarily electronic. It uses a specific electronic structure, with a wide tail of localized states below the conduction band edge. In amorphous GeSe₂-x the valence band top consists of high effective mass Se pt states with few band tails. The conduction band consists of Ge-Se antibonding states with low effective mass, and with a broad tail of localized Ge-Ge antibonding states below this band edge. This leads to the OTS behavior. At high fields the electron quasi-EF moves up through these tail states, lowering the conductivity activation energy, and giving the non-linear switching process. GeSe₂-x is the most favorable OTS material because it has the optimum band gap.

Fundamental, Thermal and Energy Limits of Phase-Change Memory
Eric Pop, Christopher Neumann, Sanchit Deshmukh, Isha Datye, Stephanie Bohaichuk and Miguel Munoz Rojo; Electrical Engineering and Materials Science and Engineering, Stanford University, Stanford, California, United States.

The reversible material phase transition in chalcogenide compounds, known as phase-change memory (PCM) has been studied for half a century [1]. More recently, some PCM devices have been approaching the fundamental scaling limits of this technology [2]. This talk will present recent highlights from our research on PCM and related materials [3]. The results span from measurements of thermal and electrical properties of PCM devices and their interfaces, to understanding their fundamental size and energy limitations. For example, we show that the energy-efficiency of PCM programming can be significantly improved by reducing the pulse width (down to few nanoseconds). We use Raman thermometry and scanning thermal microscopy (SThM) to probe the temperature in functioning PCM devices [4,5], and uncover thermal and electrical contact resistance effects. We also introduce PCM devices which rely on emerging two-dimensional (2D) materials like graphene or MoTe₂, either as thermal insulation barriers [6] or as the switching material itself. Finally, we use carbon nanotubes (CNTs) as ultra-narrow electrodes to probe the insulator to metal (ITM) transition of VO₂ at the nanoscale. These results probe the fundamental limitations of PCM technology, as required to guide future energy-efficient designs.

4:00 PM EP08.08.02
Computational Analysis of Complex Amorphization/Crystallization Dynamics in Large Phase Change Memory Devices

Phase change memory devices become practical for non-volatile storage at small dimensions due to reduced power and predictable device operation. In larger scale devices, cells can be locally melted due to filament formation and liquid filaments can be retained in parts of the cell for a long time even if most or all of the cells are initially amorphized during long fall-times. The complex amorphization and crystallization dynamics make these large cells more unpredictable and enable their applications as physically unclonable functions (PUF) [1,2].

Computational analysis of the complex amorphization-crystallization dynamics in phase change memory devices with large geometries is important to understand the evolution of phase distributions and temperature profiles during programming of these devices. In this work, we conduct electrothermal finite element simulations of reset operation on a large GeSb₂Te₅ (GST) cell using the framework we have developed in COMSOL multiphysics [3]-[9] and analyze the complex dynamics of amorphization, nucleation and growth during electrical stress. We input voltage waveforms measured from electrical characterization of on-oxide GST line cells with bottom metal contact pads and SiNₓ capping. A 2D polycrystalline model of the experimentally measured cells (~360 nm wide, ~400 nm long and ~50 nm thick) is constructed in the simulations. Access devices are modeled using the spice models. The simulations capture some of the interplay between changes in the device resistance due to heating and phase changes and current fluctuations.

Investigation of Resistance Drift in GeSb₂Te₅ Phase Change Memory Line Cells at Low Temperatures—Contributions of Charge Trapping
ABM Hasan Talukder, Rajan Saeed Khan, Kimberly Nguyen, Madison Nadolny, Nafisa Noor, Faruk Dirisaglik, Adam Cywar, Sadid Muneer, Helena Silva and Ali Gokirmak; Electrical and Computer Engineering, University of Connecticut, Storrs, Connecticut, United States; ²Electrical and Electronics Engineering, Eskişehir Osmangazi University, Eskişehir, Turkey.
Phase change memory (PCM) is one of the most promising non-volatile memory technologies that offers low-power, high-speed, and high-density operations. PCM utilizes the large resistivity contrast between amorphous and crystalline phases of chalcogenide materials such as Ge\(_2\)Sb\(_2\)Te\(_5\) (GST). The large resistivity contrast between the phases allows multilevel-cell (MLC) operation, which comes with some challenges including the upward resistance drift observed in PCM cells. A cell programmed to a certain state, if experiences resistance drift, may be incorrectly read some time after programming.

High-speed electrical characterization techniques allow us to monitor resistance drift behavior of the amorphous GST cells for a very short duration [1] and the slow DC measurements can be used to monitor the drift over a long period of time [2]. Our earlier resistance drift measurements were performed in 300 K to 675 K range [1]. In this work, we have amorphized GST line cells at cryogenic temperatures (down to 85 K) and monitored their resistance drift. We observe significant resistance drift of the amorphous GST at low temperatures. The viscosity of the material is expected to be very high to allow any significant structural relaxation at these low temperatures. Furthermore, we observe significant sensitivity to light: cells exposed to light for a period of time show a drop in resistance, and a recovery of the resistance after light is blocked. The time scale for these changes are in the order of seconds to minutes, suggesting that the changes in the resistance are predominantly due to emptying and filling of charge traps, and not due to thermal perturbations on the cells due to exposure to light.

Since we do not expect a rapid change in the number of charge traps via structural relaxation at cryogenic temperatures, our observations point to filling of the existing charge traps (charge trapping) as the main reason for upward resistance drift in phase change memory cells. Based on these results, we predict that it is possible to suppress resistance drift by increased capacitive coupling between the active region of PCM cells and the surrounding electrodes.

4:30 PM EP08.08.04 Evaluating PCM Asymmetry by a Three-Terminal Device Kirill V. Mitrofanov, Yuta Saito, Noriyuki Miya, Paul Fons, Alexander Kolobov and Janji Tominaga; National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

Interfacial phase-change memory (iPCM) devices based on a Ge-Te/Sb-Te superlattice have lower switching energy than conventional phase-change memory due to optimization of the structure of the chalcogenide layers allowing minimization of the thermal losses associated with the switching process [1]. To date it has been widely believed that the structural changes responsible for switching in iPCM occur at the interfaces of the superlattice structure [2-4]. Recently, however, it has been proposed that resistive switching in iPCM may occur within a very narrow region of the superlattice device structure that has a specific atomic ordering. In the current work, the superlattice volume that is switched in iPCM was minimized by introducing a laterally connected contact to the superlattice film located between the two contacts perpendicular to the superlattice growth direction (van der Waals gaps plane in a superlattice structure). The resultant three-terminal iPCM device allowed the testing of selective regions of the device. This configuration is especially useful for the characterization of asymmetric iPCM devices and bipolar switching performance. The latter is believed to be related to the contact interfaces, which could be identified by the use of the third electrode. Previously, it was shown that iPCM devices based on Ge-Te/Sb-Te superlattices have a different switching thermal dependence than alloy-based phase-change memory [5]. In addition, multi-level and bipolar switching and external magnetic field effects [6] of iPCM devices resistance were found. The newly proposed device structure will allow for detailed characterization of these effects as well as the partial volume switching of iPCM.

In conclusion, the dependence of iPCM switching on the distribution of the applied switching electric field within the volume of Ge-Te/Sb-Te superlattices was studied with the use of a three-terminal device architecture. The effects of bipolar switching, high temperature operation and external magnetic field were assessed.

This work was supported by JST-CREST (JPMJCR14F1). A part of this study was supported by NIMS Nanofabrication Platform in Nanotechnology Platform Project sponsored by the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan.

4:45 PM EP08.08.05 Multi-Contact Phase Change Toggle Multiplexer Raihan Sayeed Khan, Nadim H. Kar’an, Jake Scoggin, Zachary Woods, Helena Silva and Ali Gokirmak; University of Connecticut, Storrs, Connecticut, United States.

Phase change memory (PCM) is a non-volatile memory technology which utilizes resistance contrast of amorphous and crystalline phases of phase change materials such as Ge\(_2\)Sb\(_2\)Te\(_5\) (GST). PCM cells are two-contact devices which offer fast read/write speed, high density, large endurance, and possibility of monolithic integration with CMOS at the back-end-of-the-line. There has been a growing interest in integration of PCM devices for computation in memory and neuromorphic computing. It is possible to implement logic functions, multiplexing and data routing using phase change elements with multiple contacts [1], [2]. The logic functionality is achieved using two physical mechanisms that can be implemented at nanoscale: (i) isolation of some of the contacts from the others using local amorphization between other contact pairs, (ii) thermal cross-talk between the regions that are heated to be melted and the previously amorphized regions. The first allows for isolation of some of the input and the output terminals, and the second allows for toggle operations through crystallization of some regions while others are being amorphized. 6-contact phase-change devices can be implemented as toggle multiplexers or flip-flops when interfaced with 5 CMOS transistors, using ~50% CMOS footprint compared to the conventional CMOS alternatives with the added advantage of non-volatility. This approach can enable monolithic integration of 100s of GB of PCM atop CPUs for computer-on-chip applications.

We have performed a 2D computational analysis of six-contact phase change logic devices using our finite element framework that can simultaneously capture amorphization-crystallization dynamics including nucleation, growth, and grain boundary melting and electro-thermal phenomena in COMSOL Multiphysics [3]–[5]. Our analysis includes structural changes responsible for switching in iPCM occur at the interfaces of the superlattice structure [2-4]. Recently, however, it has been proposed that resistive switching in iPCM may occur within a very narrow region of the superlattice device structure that has a specific atomic ordering. In the current work, the superlattice volume that is switched in iPCM was minimized by introducing a laterally connected contact to the superlattice film located between the two contacts perpendicular to the superlattice growth direction (van der Waals gaps plane in a superlattice structure). The resultant three-terminal iPCM device allowed the testing of selective regions of the device. This configuration is especially useful for the characterization of asymmetric iPCM devices and bipolar switching performance. The latter is believed to be related to the contact interfaces, which could be identified by the use of the third electrode. Previously, it was shown that iPCM devices based on Ge-Te/Sb-Te superlattices have a different switching thermal dependence than alloy-based phase-change memory [5]. In addition, multi-level and bipolar switching and external magnetic field effects [6] of iPCM devices resistance were found. The newly proposed device structure will allow for detailed characterization of these effects as well as the partial volume switching of iPCM.

In conclusion, the dependence of iPCM switching on the distribution of the applied switching electric field within the volume of Ge-Te/Sb-Te superlattices was studied with the use of a three-terminal device architecture. The effects of bipolar switching, high temperature operation and external magnetic field were assessed.

References:
Phase-change memory (PCM) is an industrial concerned technology that can be used both for traditional computer architecture and other new emerging architectures [1], such as in-memory computation. Generally, the transitions between order and disorder phases are employed to record data. However, one of the drawbacks of PCM is the relatively high power consumption. Therefore, controlling the transition without going through the amorphous phase in these materials is one of possible methods to reduce switching energy. In this talk, we will introduce two cases recently explored with DFT calculations for order-order transition for PCM materials. The first case is the stacking-fault motion induced Insulator-metal transition in GeTe:Sn:Te superlattices [2]. This transition may provide a significant change of carrier concentration and indicate a low energy-consumption process with a low energy barrier of atom motion for PCM. Secondly, we have developed multi-phase-field model for the crystallization of GST which takes into account three phases: the amorphous state, stoichiometric GST and a Ge-rich crystalline phase. We use a pseudo-binary approximation of the phase diagram and couple the phase fields to a single concentration field. The kinetic parameters of the model are determined from data on stoichiometric GST available in the literature [4]. As a first application, we study the isothermal crystallization of a homogeneous Ge-enriched amorphous GST film. The critical nuclei of the Ge-rich crystalline phase are always computed, and the results are compared to classical nucleation theory. Growth of supercritical nuclei is then simulated, and the results are compared to recent experimental data [5].

9:30 AM EP08.09.02
Multi-Phase-Field Modelling of Microstructure Formation During the Non-Congruent Crystallization of an Amorphous Alloy of Germanium, Antimony and Tellurium Raphaël Marie1, 2, Olga Cuetel, Serge Blonkowski, Thomas Philippe and Mathis Plapp, PMC Ecole Polytechnique/CNRS, Palaiseau, France; STMicroelectronics, Grenoble, France; CEA LETI, Grenoble, France.

Phase change materials (PCM) can exist in two different states, namely, as amorphous and crystalline solids, which can have markedly different physical properties. This is the basis for the usage of PCM for data storage applications. The ternary alloy of germanium, antimony and tellurium (GST) has been intensely studied, because at the stoichiometric composition Ge5Sb2Te12, the amorphous phase can crystallize congruently (without changing in composition) and rapidly. This makes it a material of choice for random access memory devices (pc-RAM). However, the amorphous phase spontaneously crystallizes at relatively low temperature (160 °C). For automotive applications, this temperature has to be increased, for example by enriching the stoichiometric GST with germanium [1]. However, then the crystallization is accompanied by a composition change: upon crystallization, the additional Ge segregates into the amorphous phase, which can lead to the nucleation and growth of a new crystalline phase which is rich in Ge. For the development of new materials for automotive applications devices, it is important to better understand this complex microstructure formation process.

Phase-field models are continuum models based on nonequilibrium thermodynamics [2,3]. Interfaces and surfaces are implicitly described by one or several scalar fields that often can be identified with order parameters. Their time evolution is naturally coupled to the transport of chemical components by diffusion. We have developed a grand-canonical multi-phase-field model for the crystallization of GST which takes into account three phases: the amorphous state, stoichiometric GST and a Ge-rich crystalline phase. We use a pseudo-binary approximation of the phase diagram and couple the phase fields to a single concentration field. The kinetic parameters of the model are determined from data on stoichiometric GST available in the literature [4]. As a first application, we study the isothermal crystallization of a homogeneous Ge-enriched amorphous GST film. The critical nuclei of the Ge-rich crystalline phase are always computed, and the results are compared to classical nucleation theory. Growth of supercritical nuclei is then simulated, and the results are compared to recent experimental data [5].

9:45 AM EP08.09.03
Ultrafast Photo-Induced Phase Transition in 2D MoTe2: Bo Peng1, 2, Hao Zhang1 and Heyuan Zhu1; 1Fudan University, Shanghai, China; 2University of Cambridge, Cambridge, United Kingdom.

Using first-principles calculations, we confirm that purely electronic excitation plays a dominant role in laser-induced phase transition of MoTe2. This unique effect is induced by ultra-rapid bond dissociation. Under different wavelength laser excitation, the potential energy surface for lattice vibrational modes can be modified precisely to generate the intermediate phase along the phase transition pathway, enabling controllable phase transformation. The excited carrier concentrations at different excitation energies are estimated. Moreover, we find that the laser-generated local heat cannot account for thermally-induced phase change. The photo-induced phase transition can occur within hundreds of femtoseconds before the excited electrons transfer their energy to the lattice. Taking advantage of optically-induced electronic excitation, a rapid and controllable phase transformation with sub-micron precision can be realized in monolayer MoTe2, opening a new door for precise control of selective phase transition by tuning laser wavelength.

A Machine-Learned Interatomic Potential for the Elemental Phase Change Material Sb Daniele Dragone1, Joerg Behler2 and Marco Bernasconi1; 1University of Milano-Bicocca, Milano, Italy; 2Institute for Physical Chemistry and Theoretical Chemistry, University of Goettingen, Goettingen, Germany.

Elemental antimony has been recently shown to be a suitable material for electronic phase change memories (PCM) when confined in ultrathin films [1]. Despite the extreme proneness to crystallization in the bulk, amorphous Sb has been demonstrated to be stable at 300 K for sufficiently long time to be used in PCM when it is grown in films as thin as 3 nm confined by capping layers [1]. The reasons behind the amorphization of the phosphorus phase under these conditions are, however, unclear. Atomistic simulations can provide insights onto the several effects that might concur to stabilize the amorphous phase in confined geometry. To this end, we have generated an interatomic potential for antimony by using a machine learning approach, namely by fitting a large database of ab-initio energies by means of the neural network scheme introduced by Behler and Parrinello [2]. The same method was used previously to generate an interatomic potential for the phase change compound GeTe [3]. The potential has been validated by computing the structural properties of the crystalline, amorphous and liquid phases of bulk antimony. Then molecular dynamics simulations based on the neural network potential have been performed to investigate the crystallization kinetics of Sb in confined geometries. Possible effects on the crystallization kinetics induced by the presence of the capping layer in ultrathin films will be discussed.

Effects of Si Doping on the Electronic Structure and Electrical Conductivity of Ge5Sb2Te12 Crystals—First-Principles Study Rajarshi Sinha Roy, Magali Benoit and Lionel Calmels; CEMES, CNRS, Université de Toulouse, Toulouse, France.

The transport properties of Ge-Sb-Te (GST) ternary phase-change materials can be tuned by controlling their atomic structure and the concentration of charge carriers. Doping with atoms of different chemical species is a major method to reach this aim in GST crystals. The effects of doping on the transport properties of GST are challenging to study
experimentally, since the crystalline phase of doped GST samples generally possesses a complicated microstructure, consisting of grains with different compositions. They are also challenging to investigate by first-principles methods based on the calculation of Kohn-Sham wave functions, as huge supercells are needed to describe the unavoidable chemical disorder among Ge, Sb, dopant atoms, and vacancies.

In this work, we perform first-principles calculations of the electronic structure and electrical conductivity of Si-doped GST ec-crystals, using the spin polarized relativistic Korringa-Kohn-Rostoker (KKR) method based on the multiple-scattering theory [1,2]. The doped GST crystals have been described with a rock-salt unit cell, in which the chemical disorder is taken into account through the coherent potential approximation (CPA). The accuracy of the results is verified by comparing, for several Si contents, the density of electronic states (DOS) calculated with this method and with a method that uses Kohn-Sham wave functions in big supercells. The calculated Bloch spectral function (BSF) shows the dispersion of the electron states and its modification with doping. We show the Si-doping dependence of the electrical conductivity, and discuss it in terms of the concentration of charge carriers and of the modification of their scattering by the atomic disorder induced by doping. These results can be used to model samples, the microstructure of which consists of grains with different concentrations of Si atoms, each grain being described by a conductivity that depends on its composition.

The Role of Electric Fields in the Structural Rearrangements of iPCM Building Blocks

Paul Fons1, Alexander Kolobov1, Yuta Saito2, Kotaro Makino1 and Junji Tominaiga3
1 Nanoelectronics Research Institute, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan; 2Spring8, Japan Synchrotron Radiation Institute (JASRI), Hyogo, Japan.

One of the more active research areas in phase-change memory is the concept of van der Waals (vdW)-bonded GeTe/Sb2Te3 superlattices (SL) also known as interfacial phase-change memory (iPCM). Devices based upon GeTe/Sb2Te3 SL structures have demonstrated both lower energy consumption as well as order of magnitude faster switching speeds. Unlike conventional Ge-Sb-Te alloy-based devices in which the SET and RESET states correspond to the crystalline and amorphous phases, the SET and RESET states in SL change memory (iPCM). Devices based upon GeTe/Sb2Te3 SL structures have demonstrated both lower energy consumption as well as order of magnitude faster switching speeds.

As electrical device components are scaled down to atomic sizes, management of waste heat becomes a major issue in device performance. Minimizing energy consumption of electrical components and waste heat generation are critical issues in the operation of electronic devices. This has spurred interest in alternative cooling mechanisms, such as those provided by electrocaloric, magnetocaloric, elastocaloric, and thermoellectric materials, for mitigating issues associated with waste heat generation. In this work, we provide theoretical predictions for an alternative cooling mechanism, accomplished by utilizing electrostatic gating to induce structural phase transitions in monolayer materials. We refer to this mechanism as the electrostaticaloric effect in reference to the mechanism of electrostatic doping that drives the structural phase transformation and entropy change in the material. Recent predictions and experimental observation that electrostatic gating can induce structural phase transitions in monolayer materials opens the possibility for new application areas. Here, we explore the potential for electrostatically-induced structural phase transformations in monolayer MoTe2 to be used in a Carnot refrigeration cycle. We predict that a temperature change of 10–15 K may be possible in devices that utilize monolayer MoTe2 as the active phase change material. This mechanism may prove useful for future electronic devices which require cooling at the component level, and for which small monolayer devices are necessary.

1:30 PM EP08.10.01
Synthesis and Characterization of TaS3-Based Superlattices for Applications in Electrically-Driven Quantum Phase Transitions

Saez Baurx, Demissie M. Roberts, John D. Perkins and Andriy Zakutayev; National Renewable Energy Laboratory, Lakewood, Colorado, United States.

Typical phase-change materials used in microelectronics rely either on amorphous-crystalline transitions or on redox reactions. Each of these mechanisms rely on slow and energy-intensive processes, such as heating and quenching or solid-state ion diffusion. Another approach without these drawbacks is to use materials with quantum phase transitions, but these are generally activated and maintained thermally rather than electrically. However, some reports exist of electrically-activated charge-density wave (CDW) transitions, which are similar to a Peierls distortion and sometimes observed in low-dimensional materials.

Inspired by work in selenide-based superlattices, where charge exchange between layers can modulate an emergent CDW transition, our group is working on synthesis and characterization of superlattices based on a well-known CDW material, TaS3. Using the novel approach of depositing thin modulated layers of Ta and Sn that are combinatorially sputtered from metallic targets in the presence of sulfur plasma, we build libraries of such superlattices from the “bottom-up.” This is new because sulfide based superlattices have not been previously made using this approach. The deposition process is monitored using quartz crystal microbalances, which provide real-time in-situ feedback on the growth conditions.

Our x-ray reflectivity results show that we can form ultrathin smooth films with control of the integer number of 2D monolayers in the repeating structure. We have also demonstrated that by altering deposition conditions we can vary sulfur content and adjust composition to promote formation of either SnS5 or SnS3 layers, according to RBS measurements. Similar to selenium-based superlattices, changing layer thicknesses is expected to affect the electrical transport properties, since this changes the degree of charge transfer between the layers. Overall, the initial results from this work suggest that a similarly superlattice-modulated CDW phase transition may be observed in TaS3-based superlattice materials.
The crystallization process of phase change materials has been largely investigated in literature in a wide range of temperature and for many compositions. On the contrary, there is a lack of information on the mechanisms governing the amorphization, since it can be obtained only by driven conditions, largely far from equilibrium, usually implying melting and quenching. Understanding which are the accessible local atomic configurations towards amorphization and how atoms move through a crystalline environment, even highly defective, hence, seems desirable. With this aim we have investigated the damaging process of crystalline GeSbTe alloys up to amorphization, by using ion irradiation. Irradiation with light ions (Ar$^+$) has been adopted to produce diluted cascades, which allows very low amount of disorder to be introduced and to follow the structural evolution towards complete amorphization.

In situ reflective measurements and ex-situ resistance and Raman spectroscopy analysis have been employed to study the disordering process and its impact on the electrical properties and on the chemical bonds. Different compositions are compared: Ge$_7$Sb$_5$Te$_9$, Ge$_9$Sb$_8$Te$_7$ and Ge$_8$Te$_5$. The effect of disordering is studied at low temperature (77K), at which the atomic mobility and disorder recovery is hindered, and at room temperature. For all the studied compositions large differences are observed upon irradiation at low or room temperature, indicating that there is a large effect of dynamic annealing. Several phase transitions are observed before amorphization. In all the cases, the first is the metal to insulator transition. However, the mechanism driving such a transition is different changing from the ternary compositions to the binary GeTe. Indeed, in the case of crystalline GeSbTe alloys (with Ge < 30%) the disordering process is dominated by the presence of the stoichiometric vacancies. The van der Waals like gaps present in the stable hexagonal crystalline structure act as preferential sink for the diffusion of the displaced atoms, and are therefore effective in stabilizing the disordered material. The filling of the gaps tunes the electronic and structural properties, driving the metal-insulator transition and the successive conversion into the metastable rocksalt structure and then in the amorphous.

In the case of GeTe there are no structural vacancy layers. The metal-insulator transition, observed at very low fluences, occurs in a mainly crystalline material with low resistivity value (~0.5 mOhm cm) and, according to Raman spectroscopy investigation, seems to be induced by Te vacancy, characterized by an energy level into the gap. As the irradiation fluence increases the displaced atoms form distorted octahedral bonds that, being energetically unfavourable, tend to disappear, going back to a more stable configuration. Such a process seems to be facilitated by the high atomic mobility that, according to crystal growth rate data available in literature, at room temperature is expected to be larger in GeTe than in GeSbTe alloys. As a consequence, GeTe exhibits unique marked self-healing properties and the irradiation fluence required for complete amorphization is one order of magnitude higher than that of GeSbTe alloys.

The role of the interfaces on the amorphization process has been also investigated and we found that by properly choosing the substrate and the capping layer it is possible to reduce or enhance the stability of the amorphized state. On the other hand we concluded that the interfacial high-atomic mobility is the key parameter to the amorphization.

Our results indicate the possibility to tune the structural and electrical properties by interface and/or by defects engineering. Such an approach could help to avoid the employment of complex compositions, usually needed to finely tune the material properties, but which, on the other hand, can produce reliability problems, related to unwanted deviations from the optimized stoichiometry.

References

higher value (about 280 °C) in the Ge rich region. A phase boundary between the Sb-Te phase and the Ge-Sb-Te phase has been clearly identified using synchrotron diffraction.

Refractive index and extinction coefficient were measured at each composition spot using a scanning ellipsometer: some composition ratios were found to have a small extinction coefficient in the amorphous state, a high phase-change temperature, and a large difference in the extinction coefficient between the amorphous state and the crystalline state, suggesting that such compositions can be promising for photonic devices for neuromorphic control. We find that compositions with promising properties are near the boundary between the Sb-Te and the Ge-Sb-Te phases, indicating that co-existence of the phases at microstructural level may be playing a role in giving rise to their properties. This work is funded by an ONR MURI (Award No. N00014-17-1-2661).

Rules in van der Waals Epitaxy Fabrizio Arciprete1, 2, Jos E. Boschker1, 3, Stefano Cecchi1, Eugenio Zallo1, Valeria Bragaglia1, 4 and Raffaella Calarco1; 1Paul-Drude-Institute, Berlin, Germany; 2Fisica, Università di Roma “Tor Vergata”, Rome, Italy; 3Leibniz-Institut für Kristallzüchtung, Berlin, Germany; 4IBM Research-Zurich (en dash), Rüschlikon, Switzerland.

Besides graphene, many classes of 2D systems developed over the last few years: group-IV graphene-like Xenes (with X such as Si, Ge, Sn), transition metals dichalcogenides (such as MoS2, WS2, MoSe2, WSe2, MoTe2), III-VI and V monochalcogenides (such as h-BN or InSe, GaS, GaSe, GaTe), and V-VI chalcogenides (V = As, Sb, Bi and VI = S, Se, Te). Sb2Te3 and the pseudobinary alloy GeSbTe exhibit a 2D structure with the size of the building block depending on composition: Sb2Te3 (5 layers), GeSb2Te2 (7 layers), GeSbTe3 (9 layers), GeSb2Te5 (11 layers), etc. The prerequisite for application, as well as for studying the fundamental properties, of such new crystalline materials is the capability of growing high-quality large-area films. Van der Waals (vdW) epitaxy, in which the epitaxy is mediated by weak vdW interactions, represents the way to realize such high-quality films on large scale.

Despite the intense research efforts by many groups toward the vdW epitaxy, a general description of all the phenomena involved is not yet given. In fact, the epitaxial rules for 2D materials are really different from ordinary 3D materials. In 2D epitaxy, the prediction of the phase formed by the vdW heterostructures, the commensurability, the strain relaxation during the interface formation, and the role of the substrate surface reconstructions need to be investigated further.

In this contribution, a general description of the vdW epitaxy will be proposed. We will discuss the epitaxial growth of the 2D GeSbTe alloy deposited by Molecular Beam Epitaxy on the low-mismatched InAs(111) substrates (lattice mismatch ≈1%) for both In- and As- terminated surfaces. The occurrence of the vdW epitaxy is discussed in comparison to other results from literature in order to identify the key mechanisms underlying the process.

3:45 PM EP08.10.06

Growth and Characterization of Epitaxial GeSbTe Films Towards Ge-Rich Compositions Stefano Cecchi, Eugenio Zallo and Raffaella Calarco; Paul-Drude-Institute, Berlin, Germany.

Phase change materials (PCMs) have attracted in the last years the interest of research as concrete candidates for the development of storage class memories. GeSbTe (GST) alloys along the GeSb2Te3 pseudo-binary line are nowadays used as the active material for non-volatile solid-state memories. [1]

For automotive applications, however, higher working temperatures are needed for embedded electronics. This prevents the use of GeSb2Te3 (GST225), which is among (GeTe)x(Sb2Te3)(1-x), compounds the one traditionally employed in PCM memory devices. One strategy to adapt PCM technology to the requirements of automotive applications is to tailor the crystallization temperature and thermal stability of GST by engineering the alloy composition. In this framework, Ge-rich GST alloys have shown increased crystallization temperatures proportional to the excess of Ge. [2]

Here we present a study of epitaxial GST films towards Ge-rich compositions grown by molecular beam epitaxy on Sb-passivated Si(111) substrates. Starting from stoichiometric GST225, the composition of GeSb2Te3 was controlled by increasing the atomic flux of Ge while keeping fixed the other growth parameters. The growth of GeSb2Te3 films was checked in situ by reflection high-energy electron diffraction. We found a gradual loss of crystalline quality with increasing Ge content, possibly related to the deficiency of Te which characterizes the present experiments. The evolution of the composition was studied by X-ray diffraction (XRD) radial scans and Raman spectroscopy. Interestingly, a combination of XRD rocking curves and azimuthal scans provides evidence of stronger in-plane rotational coherence with respect to the substrate, while the material is more prone to form domains misaligned out-of-plane. The characterization of the switching functionality will be carried out.

4:00 PM EP08.10.07

Phase Segregation and Crystallization of Amorphous Ge-Rich GST Alloys Marta Agati1, Daniel Benoit1 and Alain Claverie2; 1CEMES-CNRS, Toulouse, France; 2STMicroelectronics, Crolles, France.

GST alloys have recently been reported to significantly increase the range of working temperatures of PCM memories, an important characteristic to extend their range of potential applications. Moreover, N doping may further increase their endurance and reduce the undesired drift of the low resistance state (crystalline state) upon time. However, the crystallization process i.e., the mechanisms by which amorphous N-doped Ge-rich GST transforms into one or several stable crystalline compounds, is rather unknown. For this reason in this work we report on a systematic study of the structural and compositional changes which affect thin films of amorphous N-doped Ge-rich GST during thermal annealing at various temperatures. The structural evolution was studied using a variety of transmission electron microscopy techniques (HRTEM, SAED, ASTAR), both in-situ and ex-situ, and X-ray diffraction. The chemical composition was analyzed by STEM-HAADF and STEM-EDX.

We show that, during annealing at 380°C, the initially homogeneous Ge-rich GST material locally fluctuates in composition until phase separation occurs while no crystal nuclei are formed. This work is funded by an ONR MURI (Award No. N00014-17-1-2661).

4:15 PM EP08.10.08

Atomic Imaging and Modelling of Bilayers in Hexagonal GST Jianqiing Wang1, Chunlin Ji2, 3 and Wei Zhang1; 1Center for Advancing Materials Performance from the Nanoscale, State Key Laboratory for Mechanical Behavior of Materials, Xi’an Jiaotong University, Xi’an, China; 2Peter Grünberg Institute and Ernst Ruska-Centre for Microscopy and Spectroscopy with Electrons, Forschungszentrum Jülich GmbH, Jülich, Germany; 3The School of Electronic and Information Engineering, State Key Laboratory for Mechanical Behavior of Materials, Xi’an Jiaotong University, Xi’an, China.

Disorder plays an essential role in shaping the transport properties of GeSbTe phase-change materials (PCMs) to enable non-volatile memory applications. Recently, increasing efforts have been undertaken to investigate disorder in the layer-structured GST compounds, especially a special type of swapping bilayer defects. In this work, we focus on hexagonal GST. The samples were prepared by magnetron sputtering and were annealed at 300 oC for half an hour. We thoroughly characterized the structural and chemical features of the major defects in hexagonal GST at atomic scale through chemi-scanning transmission electron microscopy (STEM) experiments. By combining nanoscale density functional theory (DFT) modelling and simulations, we identify that the intermixing of Sb and Te in the bilayers is crucial to stable the defects, and attribute their abundance to the small energy cost. The bilayer defects are demonstrated to be ineffective in altering the electron localization nature but may affecting the quantitative value of electrical resistance in hex-GST.

Steep-Slope Devices with New Operation Mechanisms for Ultra-Low-Power Applications Ru Huang1,2, Qianqian Huang1,2, Huimin Wang2, Yang Zhao2, Cheng Chen2 and Yangyuwan Wang1,2; 1Key Laboratory of Microelectronic Devices and Circuits (MOE), Peking University, Beijing, China; 2Institute of Microelectronics, Peking University, Beijing, China.

Standby power becomes much more serious than dynamic power with the technology scaling and becomes one critical issue of IC development, particularly for the power constrained applications, such as Internet of things (IoT) and implantable chips which have stringent ultra-low-standby-power requirements. Different from conventional MOSFET, novel device concepts with new operation mechanisms which can achieve ultra-slope subthreshold slope can be found from the conventional thermal limit of subthreshold slope (SS), have attracted immense attention for ultra-low-voltage and ultra-low-power applications. Among all kinds of steep-slope devices, Tunnel FET (TFET) utilizing band-to-band tunneling (BTBT) mechanism and Negative Capacitance FET (NCFET) with ferroelectric (FE) gate are the two of the most promising candidates, with reported demonstrations of their capability of sub-60mV/dec SS at room temperature. However besides the steep SS, the devices need further comprehensive investigation as well as further physical clarification for device design optimization and future circuit applications. TFET devices with the gated p-n structure can theoretically achieve steep SS and ultralow off-state leakage current. However, they face the fundamental low on-current issue due to the relatively low tunneling efficiency. Moreover, it is difficult to obtain high on-current, steep SS and ultralow off-current simultaneously, even adopting narrow bandgap materials. From the perspective of mechanism engineering, a new kind of hybrid operation mechanism of Schottky injection and BTBT is presented, fundamentally addressing the issue of low drive current in conventional TFETs and obtaining higher on-current and lower SS while maintaining ultralow off-current. The proposed multi-finger-gate Schottky barrier TFET (MFSB-TFET) exhibits superior performance with the steep SS of 29mV/decade and large on-off current ratio of >10. The ON-current is improved by 2.5 decades compared with conventional TFET. In addition, the MFSB-TFET also experimentally demonstrates comprehensive electrical properties enhancement in terms of output behavior, capacitance, delay, gain, noise, variability and reliability, showing its great potential for ultra-low-power digital and analog circuits applications. The other possible solution for sub-60mV/dec SS is NCFET. Integrating the FE layer into the gate stack of conventional FET, the voltage amplification effect induced by the NC of FE can lead to the steeper SS than conventional FET without on-current penalty. However, the FE film usually exhibits hysteretic loops of polarization-voltage, and most NCFETs experimentally demonstrate the confliction between SS and hysteresis. Besides, the theoretical explanations of NC effect and hysteresis in NCFETs are still controversial. We present the first direct experimental observation of NC effect in a standalone FE capacitor, proving that the NC is generated from the dynamic polarization switching instead of steady-switching of FE. A new dynamic polarization matching condition is derived and provides new understanding of the steep-slope in the NCFETs. In addition, the physical origin of hysteresis behavior in NCFETs is analyzed, theoretically explaining the SS and hysteresis optimization confliction, which indicates a huge challenge for logic applications of NCFETs. Due to the voltage amplification effect of NC, by further integrating NC to TFET, NC-TFET devices are expected to obtain higher on-current and steeper SS without off-current degradation. A novel NC-TFET design with striped gate configuration is proposed and experimentally demonstrated with sub-60mV SS and nearly non-hysteresis behavior. Benefiting from the hybrid modulation of NC effect and junction depleted-modulation effect, the proposed new NC-TFET design shows great potentials for some standby-power constrained applications.

11:00 AM *EP09.01.02

Negative Capacitance in Ferroelectric Hafnium Oxide Thomas Mikolajick1,2; Uwe Schroeder1, Michael Hoffmann1, Benjamin Max2 and Stefan Slesazeck1,2; 1NaMLab, Dresden, Germany; 2HHM, Technische Universität Dresden, Dresden, Germany.

More than ten years ago, ferroelectric negative capacitance has been proposed [1] to overcome the basic limitations of the voltage scalability in complementary metal oxide semiconductor circuits (CMOS) imposed by the fact that the subthreshold swing cannot be reduced below 60 mV/dec. However, to realize this proposal it was necessary to overcome the massive issues associated with integrating a ferroelectric into a CMOS process [2]. The first report on ferroelectricity in doped hafnium oxide in 2011 [3] therefore quickly turned this idea into a possibly mass manufacturable option for future CMOS scaling. However, although the benefits of voltage amplification achieved by the integration of the ferroelectric into the gate stack can be easily shown using fundamental Landau theory, the possibility of a practical implementation of the effect into CMOS devices is still under discussion in the scientific community. When measuring ferroelectric properties, in general the voltage is forced and therefore the negative capacitance region cannot be observed. Using a series resistor, first indications of negative capacitance could be observed in doped HfO2 [4]. Recently, a pulse measurement technique together with dielectric layer in direct contact to the ferroelectric, finally made it possible to extract the S-shaped curve predicted by Landau theory [5,6]. Already in [1] the idea of introducing a suitable dielectric capacitor in series has been described and used as the basis for subsequent investigations by many groups. However, an important feature of ferroelectrics, namely domain formation, is often neglected in basic simulation work, where Landau theory is used in a way that implies a single domain state [7]. When introducing domains into the theory, it still seems possible to stabilize the negative capacitance region [8]. However, the metal electrode introduced between the dielectric and the ferroelectric in many experimental demonstrations will be detrimental and limit the stabilization to extremely small devices. Coming from the practical side, encouraging data on hafnium oxide based ferroelectrics integrated into state of the art devices have been shown [9], but the connection to the basic material work and theory is often missing. In this presentation the authors will give an overview on their own findings of negative capacitance in hafnium oxide and connect these to literature results on fully integrated devices.

A Ferroelectric Semiconductor Field-Effect Transistor
Peide P. Ye; Purdue University, West Lafayette, Indiana, United States.

A ferroelectric semiconductor field-effect transistor (FeFET) was proposed and experimentally demonstrated for the first time. In this novel FeFET, a 2D ferroelectric semiconductor α-InSe$_2$ is used to replace conventional semiconductor as channel. n-In$_2$Se$_3$ is identified due to its proper bandgap, room temperature ferroelectricity, the ability to maintain ferroelectricity down to a few atomic layers and the feasibility for large-area growth. An atomic layer deposited (ALD) Al$_2$O$_3$ passivation method was developed to protect and enhance the performance of the α-InSe$_2$:FeFETs. The fabricated FeFETs exhibit high performance with a large memory window, a high on/off ratio over 10$^4$, a maximum on-current of 671 μA/μm, high electron field-effect mobility with $\mu_{FE} = 312$ cm$^2$/Vs in forward sweep and $\mu_{FE} = 488$ cm$^2$/Vs in reverse sweep, and the potential to exceed the existing Fe-FETs for non-volatile memory applications.

SESSION EP09.02: 2D Materials

Prospects and Challenges of 2D Materials and Devices
Won Jong Yoo; Sungkyunkwan University, Suwon, Korea (the Republic of).

Two dimensional (2D) materials are being investigated very intensively, some of them holding great promise as emerging semiconducting materials for future nano-electronics, beyond current semiconductor technology which faces hard limitation in performance enhancement due to excessive power dissipation during high frequency operation, while they present ultra-thin body and short channel effect-free state with efficient electrostatic control. These properties enable 2D materials to be very promising candidates that can meet major requirements for high performance memory and logic applications using CMOS and also for electronic and photonic devices operated in emerging future mobile and IoT environment. However, research towards the realization of the 2D materials based CMOS semiconductor devices faces serious challenges which require various innovative technical breakthroughs. In this talk, I would like to firstly address prospects of 2D devices for the future semiconductor applications. Then, I would like to address challenges from the semiconductor device point of view, mainly on crystalline growth of large scale 2D materials, doping of charge carriers into 2D substrates, strong Fermi level pinning from surface defects sensitive material properties, high contact resistance at the interfaces with metal electrodes, and inefficient power dissipation along ultra-thin 2D structures leading to early breakdown.

2D/3D Semiconductor Heterojunctions of MoS$_2$ and GaN
Michael D. Valentin, 1,2, Matthew Chin, 3, Dmitry A. Ruzmetov, 2, Robert Burke, 2, Kehao Zhang, 2, A G. Birdwell, 2, Masha R. Neupane, 4, 5, Joshua Robinson, 6, Madan Dubey, 6, and Ludwig Bartels; 1, 6 University of California, Riverside, Riverside, California, United States; 2, Sensors and Electron Devices, U.S. Army Research Laboratory, Adelphi, Maryland, United States; 3, The Pennsylvania State University, University Park, Pennsylvania, United States.

A promising approach for high speed and high-power electronics is to integrate two-dimensional (2D) materials with conventional electronic components such as bulk (3D) semiconductors and metals. In this study we explore 2D/3D integration with MoS$_2$ and GaN utilizing vertical heterojunctions to fabricate a 2-terminal device then a 3-terminal bipolar junction (BJT) with novel electronic and optoelectronic properties. Heterojunctions are especially vulnerable to interfacial defects and contamination from transfer processes. Lattice mismatch between MoS$_2$ and GaN has a calculated difference of 1.1% leading to an epitaxial driven growth mechanism. By doping MoS$_2$ during a MOVCD growth process and GaN via MBE, we demonstrate both n-p-n and p-n-p 3-terminal BJTs. We probe interfaces using Raman spectroscopy and cross sectional TEM and confirm our electrical results with I–V analysis.

2:45 PM EP09.02.04
STM Investigation of Graphene/Few-Layer Molybdenum Disulfide Memristor Devices
Jesse E. Thompson, 1, Tanja Roy, 1 and Masa Ishigami, 2; 1 Physics, University of Central Florida, Orlando, Florida, United States; 2 Materials Science & Engineering, University of Central Florida, Orlando, Florida, United States.

Nanoscale mechanisms of memristors and electronic synapses fabricated from vertical graphene/MoS$_2$, van der Waals heterostructures remain largely unexplored. We used scanning tunneling microscopy (STM) and spectroscopy (STS) to investigate the electronic properties of these devices at the atomic scale. We were able to resolve the contributions from defects, specifically to the formation of atomic-scale conductive regions during switching events in these devices. We were also able to induce switching through these devices using the STM tip and to tune the performance of memristors and electronic synapses. We will discuss these results along with theoretical calculations.

2D Semiconductor Electronics—Advances, Challenges and Opportunities
Ali Javey; Electrical Engineering and Computer Sciences, University of California, Berkeley, California, United States.

Two-dimensional (2-D) semiconductors exhibit excellent device characteristics, as well as novel optical, electrical, and optoelectronic characteristics. In this talk, I will present our recent advancements in defect passivation, contact engineering, surface charge transfer doping, ultrashort transistors, and heterostructure devices of layered chalcogenides. We have developed a defect passivation technique that allows for observation of near-unitary photoluminescence quantum yield in monolayer MoS$_2$. The work presents the first demonstration of an optoelectronically perfect monolayer. Forming Ohmic contacts for both electrons and holes is necessary in order to exploit the performance limits of enabled devices while shedding light on the intrinsic properties of a material system. In this regard, we have developed different strategies, including the use of surface charge transfer...
doping at the contacts to thin down the Schottky barriers, thereby, enabling efficient injection of electrons or holes. We have been able to show high performance n- and p-FETs with various 2D materials, including the demonstration of a FET with 1nm physical gate length exhibiting near ideal switching characteristics. Additionally, I will discuss the use of layered chalcogenides for various heterostructure device applications, exploiting charge transfer at the van der Waals heterointerfaces.

**Contact Engineering for 2D Field-Effect Transistors**

Po-Wen Chiu$^1$, Chun-Hao Chu$^1$ and Chao-Hui Yeh$^1$; National Tsing Hua University, Hsinchu, Taiwan; Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei, Taiwan.

Moving beyond the limits of silicon transistors requires both a high-performance channel and high-quality electrical contacts. The type of barrier at a metal/TMD junction is one of the key issues in TMD field-effect transistors (FETs). It is important to design contacts such that the transmission is dictated by intrinsic properties of the TMD channel rather than by details of the contacts. In this work, we report a systematic study of TMD contacts, with monolayer channel materials WS2 and MoS2 grown by chemical vapor deposition. We show how the contact barrier can be modulated by the work function of contact metals, defects, and contact geometry on a clean surface of TMD. The Fermi level pinning can be effectively mitigated or eliminated through the proper contact engineering. The end-bonded contact, formed through the reaction of transition metals with the TMD channel, exhibited no Schottky barrier and holds great promise for high-performance TMD FETs, enabling future ultimately scaled device technologies.

**Reducing Contact Resistances, Unpinning Fermi Levels and Understanding Schottky Barriers**

Yuzheng Guo$^2$ and John Robertson$^1$; Cambridge University, Cambridge, United Kingdom; Swansea University, Swansea, United Kingdom.

A major factor limiting the performance of devices is the contact resistances which depend on Schottky barrier heights (SBHs). Fermi level pinning (FLP) by a high density of states in the semiconductor band gap generally limits the ability to vary the contact work function to minimize the SBH. Recently, it was found that contacts with Bi or Sb between the main contact metal and Si [1] would be less strongly pinned than those with direct contact to Si. To understand the cause of this effect, the SBH of metals on Sb were calculated by DFT. It was found that the low density of states at E_F allows a SB pinning factor S of 0.2 - 0.4, depending on Sb thickness. This suggests that the SBH follows the Fermi Level Theory [2] model where only the density of states at E_F matters. On the other hand, the SBHs of silicones on Si are easier to interpret in terms of the polarization of interfacial bonds (‘Tung model [3]’). This indicates how the control of Schottky barriers, critical to one of the simplest limits to device performance, are still not well understood.

SESSION EP09.03: Poster Session: Devices and Materials to Extend the CMOS Roadmap for Logic and Memory Applications

Session Chairs: Catherine Dubourdieu, Rinus Lee and John Robertson

Tuesday Afternoon, April 23, 2019

5:00 PM - 7:00 PM

PCC North, 300 Level, Exhibit Hall C-E

**EP09.03.01**

**MEMS Process and Characterization for Strain-Engineered 2D Materials**

Edgar Acosta$^1$, Mariana Martinez$^1$, Aldo I. Vidaña$^1$, Sergio Almeida$^1$, Jose Mireles$^1$ and David Zubia$^2$; University of Texas at El Paso, El Paso, Texas, United States; Electrical Engineer and Computer Science, Universidad de California, Berkeley, Berkeley, California, United States; Universidad Autónoma de Ciudad Juárez, Ciudad Juárez, Mexico.

In recent years, an incredible increase in the number of transistors per chip has been observed, which has led to an increasing demand for more power efficient electronics. Additionally, recent studies of two layered materials such as graphene and some transition-metal dichalcogenides (TMDs) have shown strong potential for future use in electronics. One useful property of TMDs is that their electrical and optical properties are highly sensitive to strain. Furthermore, Micro-Electro-Mechanical System (MEMS) can be designed to provide a high level of stress. A low-power switch was recently proposed using a MEMS actuator to strain a MoS2 bilayer with switching energies as low as E < 1.0733 eV [1].

In this work, we present the design and fabrication process of a MEMS-TMD switch designed to provide strain up to 6%. A comb-drive architecture is used for the MEMS actuator. A fabrication process for the MEMS is developed using SiGe technology. Finally, a process to transfer and clamp the TMD onto the MEMS is presented.

**EP09.03.02**

**Application-Driven Perovskite Thin Films with Oxygen Vacancies Controlled**

Prathvek Gopalakrishnan$^1$, Nikoleta Theodoropoulou$^2$ and Ethan C. Ahn$^1$; Electrical and Computer Engineering, The University of Texas at San Antonio, San Antonio, Texas, United States; Texas State University, San Marcos, Texas, United States.

Crystalline metal-oxide thin films are an attractive group of materials for a wide variety of device applications. Among these, the perovskite family of complex oxides have experienced extensive research and development efforts due to their unique multifunctional properties. Despite numerous advances in the field, it is still a challenging task to create a high-quality epitaxial heterostructure on silicon where the intrinsic properties and functionalities of the perovskite oxides are preserved. Additionally, the practical, application-driven methodology to best tune their properties remain relatively unexplored. In this work, these two challenges are addressed by adopting an advanced oxide-MBE technique and controlling the amount or density of the oxygen vacancies, respectively. The flagship perovskite oxide, STO (SrTiO$_3$), was grown directly on top of silicon in an oxide-MBE chamber by co-deposition of Sr, Ti, and molecular O$_2$, and our preliminary analysis indicates that formation of an amorphous SiO$_2$ layer at the interface was well suppressed (ensuring the epitaxy) and oxygen deficiencies (defects) were created inside the STO layer (ensuring tunability). Thotho-step annealing process was applied to control both the crystallinity and oxygen vacancy of the 8.6 nm-thick perovskite thin film. Based on the structural and electrical testing results on the STO/Si heterostructure thin films prepared by oxide-MBE, we propose that STO has great potential to advance the next-generation memory and storage device applications. Its ultra-high dielectric constant (100 to 300) that can be accomplished by eliminating the oxygen vacancies inside the STO layer can significantly improve the EOT for the purpose of developing a high-capacity DRAM. The hysteretic resistance change in the very low operating current regime (a few to a few hundred amperes) suggests that the STO thin film can also contribute to the development of low-power memristor devices.

**EP09.03.03**

**Single- and Double-Gate Synaptic Transistor with a TaOx Gate Insulator and an IGZO Semiconductor Channel Layer**

Keonwon Beom, Paul Yang, Daehoon Park, Minju Kim, Sukni Kim, Hyung Jun Kim, Chi Jung Kang and Tae-Sik Yoon; Myongji University, Yongin, Korea (the Republic of).

To develop brain-inspired neuromorphic computing systems, artificial synaptic devices were investigated using synaptic transistors with single- and double-gate thin-film transistor (TFT) structures. Distinguishable from a two-terminal memristor-synapse, the synaptic transistor enables the synaptic weight to be tuned and then updated by gate biasing during signal processing by drain biasing at the same time. In this study, we demonstrated various synaptic motions with single- and double-gate TFT consisting of an oxygen-deficient TaO$_x$ gate insulator and an indium-gallium-zinc oxide (IGZO) semiconductor channel layer, i.e., an Al-top-gate/SiOx/TaOx/n-IGZO on a SiO$_2$/n-Si-bottom-gate substrate through concurrent changes in gate oxide capacitance, channel mobility, and threshold voltage. This synaptic TFT exhibited the tunable drain current, corresponding to synaptic weight modulation in biological synapse, upon repeatedly applying gate and drain voltages. The drain current modulation features to be analog, voltage-polarity
dependent reversible, and strong with a dynamic range of multiple orders of magnitude (−10^4), as a consequence of the changes in mobility of IGZO channel and gate oxide capacitance, and threshold voltage. The drain current modulation responsive to timing of voltage application emulates synaptic potentiation, depression, paired-pulse facilitation, and memory transition behaviors depending on the voltage pulse amplitude, width, repetition number, and interval between pulses. The synaptic motions could be realized also by double-gate operation that separately tuned the drain current by top-gate bias and sensing it by bottom-gate biasing. It provided the modulated synaptic weight with wide level of synaptic weight with respect to read condition using bottom-gate stack without read-disturbance. It demonstrated an operation scheme that the signal processing can be performed using the bottom-gate biasing during simultaneous updating of synaptic weight with the top-gate biasing. In addition to the application of this synaptic TFT to artificial synapse for neuromorphic system, its analog, reversible, and nonvolatile changes in drain current as a result of gate biasing can be applied to the operation for nonvolatile memory and field-programmable logic devices.

EP09.03.04 Multiscale Modeling Framework for 2D-Material MOS Transistors Madhusudhana Ibrahma and Santanu Mahapatra; Centre for Nanoscience and Engineering, Department of Electronic Systems Engineering, Indian Institute of Science, Bangalore, Bangalore, India.

Atomically thin 2D materials have ushered in a new era in the field of materials science and has been translated to notable advancements in the design of sensors, optoelectronic devices, flexible electronics [1]. These atomically thin materials are predicted to replace conventional bulk materials, Si and Ge, for transistor channels and extend the complementary metal oxide semiconductor technology roadmap beyond the ultimate scaling limit [2]. Constant efforts are being made to synthesize devices based on some of the recently discovered van der Waal's materials such as graphene, hexagonal boron nitride, MoS_2, phosphorene [3,4,5]. Density functional theory (DFT) calculations have suggested a large number of 2D materials and their derivatives for device applications [6]. In order to narrow down the material and design selection space for time- and cost-heavy experimental device fabrication, atomic level DFT calculations need to be coupled with device-level physics models. Thus, starting from first principles DFT calculations, we propose a multiscale computational framework to extract important electronic parameters, such as effective mass, band gap, real and complex band dispersion, and phonon dispersion for various materials and their potential application in electronic and optoelectronic devices.

EP09.03.05 Suppression of Defects at High-K/SiGe Interface with Monolayer Si ALD Deposition Harshil Kashyap1, Mahmut Kavrik1, Victor Wang2 and Andrew Kummel1; 1Material Science, University of California, San Diego, San Diego, California, United States; 2ECE, University of California, San Diego, San Diego, California, United States; 3Chemistry and Biochemistry, University of California, San Diego, San Diego, California, United States.

High mobility SiGe is promising for p-channels in CMOS. Successful integration of SiGe into CMOS necessitate low defect SiGe/gate oxide interfaces for practical device operation. The existence of Ge on SiGe surface is problematic as it forms GeOx during gate oxide deposition and induces defects at the interface. Selective oxidation of Si is challenging especially during ALD deposition at elevated temperatures. In this study, a novel method to form low defect interface is demonstrated to deposit monolayers of Si on SiGe with plasma assisted ALD. In this method, HF cleaned SiGe wafer is subjected to 2 super cycles of SiCl_4 and Ar:H_2 downstream plasma at high temperature (350°C). Hydrogen atoms from the Ar:H_2 plasma interact with SiCl_4 on the SiGe producing Si(s) and HCl(s). HCl desorbs from the surface at high temperature and is purged out. This leaves behind one monolayer of Si(S). This step is followed by N_2:H_2 downstream plasma to help passivate the interface. The downstream plasma operates at high pressure (~100 torr) which ensures negligible ions flux thereby preventing ion induced defect formation. It is hypothesized that N_2:H_2 downstream plasma results in Si-N, Si-H, and N-H bond formation and SiNx prevents outdiffusion of Ge while Si and N-H forms a good nucleation layer for subsequent gate oxide ALD. Experiments with Al,O_3, HfO_2; and ZrO_2 ALD gate oxide deposition after this Si monolayer deposition and N_2:H_2 downstream plasma passivation show up to 50% decrease in interface defect density; for example with approximate 5 nm ZrO_2 gate oxide deposition, the Dit = 1.0 x 10^{12} eV/cm^2 compared to samples with monolayer of Si (~ Dit = 1.9 x 10^{12} eV/cm^2) and compared to samples with just HF treatment (~ Dit = 3.6 x 10^{12} eV/cm^2).

EP09.03.06 Development of a Hierarchical Process for Optimization of the Design for MEMS Vibrating Ring Gyroscope for Miniaturized Space Attitude Control System Daniel Choo1, Ibrahim Ellalde, Muneera Al Shabab and Wajih Syed; Khalifa University of Science and Technology, Abu Dhabi, United Arab Emirates.

Micro-electromechanical systems (MEMS) inertial sensors are expected to enable so many emerging military and commercial applications that they are becoming too numerous to list. MEMS is probably the most exciting new inertial sensor technology ever and development is a worldwide effort. Apart from size reduction, MEMS technology offers many benefits such as batch production and cost reduction, power (voltage) reduction, ruggedness, and design flexibility, within limits. However, the reduction in size of the sensing elements creates challenges for attaining good performance. In general, as size decreases, then sensitivity (scale factor) decreases, noise increases, and driving force decreases. Currently, the performance of MEMS IMUs continues to be limited by gyro performance, which is now around 5-30°/h, rather than by accelerometer performance, which has demonstrated tens of μg or better.

In this study, we develop an innovative, affordable, miniature, low-power, navigation-grade integrated gyroscope for the attitude control system that applies MEMS technology to a variety of applications including, but not limited to, navigation, stabilized platforms, and field programmable logic devices.

EP09.03.07 Influence of Intermixing on Perpendicular Magnetic Anisotropy of Ion-Beam-Deposited CoFeB MTJs for STT-RAM Tania Henry1, Narasimhan Srinivasan2, Katrina Pietruski1, Vincent Ip3 and Frank Cerio1; 1Veeco Instruments Inc, Plainview, New York, United States.

The interface of CoFeB with MgO that forms a Magnetic Tunnel Junction (MTJ) is a critical element of Perpendicular Magnetic Anisotropy (PMA) in STT-RAM devices. The TMR and RA product, which is a key figure of merit for these devices, is very sensitive to the quality of this interface. Intermixing and wettability of the CoFeB on MgO are two critical parameters that are of interest in evaluating this interface. In this work we report the fabrication of MTJ stacks and characterization of this interface. Ion Beam Sputtering (IBS), a very low rate deposition process in which one can control both energy and angle of deposition, is used to fabricate these MTJ structures. We probe intermixing by estimating the magnetic dead layer (MDL) of a stack using magnetic measurements and report a MDL of 0.2 nm after annealing the MTJ stacks at a temperature greater than 300
Role of Hypochlorous Acid in Solution-Processed P-Type Oxide Thin-Film Transistors for Oxide Semiconductor-Based CMOS Logic

Tae Sook Jung, Heesoo Lee, Hee Jun Kim, Jin Hyeok Lee, Hyun Jae Kim and Jusung Chung; School of Electrical and Electronic Engineering, Yonsei University, Seoul, Korea (the Republic of).

Amorphous oxide semiconductor thin-film transistors (TFTs) have achieved enough technological advances to be applied to mass-produced display products. However, the technological development of the oxide TFTs is limited to n-type, and only a few researches on p-type oxide TFTs have been reported due to the lack of p-type oxide materials and rigorous fabrication conditions. Furthermore, since p-type oxides have many localized states near the valence band maximum, it makes control of the amount of metal vacancy, which is the origin of the hole carrier, difficult. Due to the above issues, researches on p-type oxide TFTs have become increasingly challenging. Nevertheless, researches on p-type oxide TFTs are essential due to a demand on oxide semiconductor-based complementary metal oxide semiconductor (CMOS) logic circuits.

Herein, we propose a simple method to enhance the switching characteristic of the p-type copper oxide (CuO) TFTs via the oxidation effect of hypochlorous acid (HClO). HClO is a relatively inexpensive material to manufacture by reacting chlorine gas with water, and a useful oxidant because of generating oxygen radical (O*), one of the strong reactive oxygen species with heat or light conditions. Because of this radical-generating property, HClO is widely used in the fields of sterilization, disinfection, and bleaching in industry. In this study, the HClO treatment was carried out to optimize the hole carrier concentration through the suppression of the copper vacancy (V_{Cu}) in the CuO thin film. Also, we investigated the effects of O* on the CuO thin film generated from HClO, and the variations of chemical composition were verified by chemical analysis. Through the robust oxidation by HClO, the amount of Cu-O bonds increased and the amount of V_{Cu} acting as the origin of hole carriers decreased within the CuO. In the modified CuO TFT, the superior switching characteristic was achieved with the subthreshold swing of 0.70 V/dec., the on/off current ratio of 4.86 \times 10^{4}, and the field-effect mobility of 2.83 \times 10^{-3} cm^{2}/V\cdot s, while pristine CuO TFT did not show switching characteristic.

GeSe/GeSe-M (M = Sn, Al, Ti, W, Cr, Pb, Cu, C)-Based Optically-Gated Transistor—M Influence on Optical and Electrical Properties

Md Faisal Kabirj, Randall Bassine and Kristy A. Campbell; Electrical and Computer Engineering, Boise State University, Boise, Idaho, United States.

Electronic devices made with alternating layers of undoped and doped chalcogenide materials, Ge_{2-x}Se_{x}/Ge_{2-x}Se_{x}-M (M = Sn, Al, Ti, W, Cr, Pb, Cu, C) exhibit transistor-like current-voltage (I-V) curves when illuminated. These devices, referred to as optically-gated transistors (OGTs), have two electrodes: a source and drain. Current is measured between the source and drain electrodes when the chalcogenide material (which acts as a ‘gate’) is illuminated. In this work, the effect of the metal dopant on the transistor characteristics are measured. The transistor materials are characterized using UV-Vis to explore the band gap and electronic structure. Raman spectroscopy is used to verify incorporation of M into the Ge_{2-x}Se_{x} material. Photoconduction is investigated using electrical characterization as a function of wavelength, light intensity, and temperature. The devices were tested from 385 to 1260 nm and were operational over that entire range.

The metal dopant is shown to clearly influence the transistor optical responsivity, maximum current, threshold voltage, electrical switching speed, and optical band gap. A transistor fabricated with M = Al is demonstrated in three applications: as an access transistor to a memristor memory element, voltage control of an optically addressed optical amplifier; and in an optical wavelength converter circuit.

MoTe_{2} p-n Junction Formed via Edge Contact and Oxidation

Changseik Kim and Won Jong Yoo; Sungkyunkwan University, Suwon-si, Korea (the Republic of).

MoTe_{2} is a promising two dimensional material due to phase transition and ambipolar transport with a band gap of 1.0 eV.[4] But MoTe_{2} is sensitive to environment and easy to oxidize.[5] Here, we demonstrated one-dimensional edge contact to MoTe_{2} covered with h-BN passivation layer and etched by SF_{6} plasma. The Schottky barrier height of edge contact is found to be 0.01-0.03 eV for various metals (titanium, chromium and palladium). Additionally, MoTe_{2} edge contact with h-BN passivation shows good stability under ambient environment and oxygen plasma. But MoTe_{2} without h-BN passivation layer is oxidized and changed to strong p-type. Based on the n-type characteristics from edge contact and p-type characteristics from oxidation, we were able to fabricate MoTe_{2} p-n junction with a rectifying ratio of 10^{4}.

This work was supported by the Global Frontier R\&D Program (2013M3A6B1078873) at the Center for Hybrid Interface Materials (HIM), both funded by the Ministry of Science, ICT & Future Planning via the National Research Foundation of Korea (NRF).

Nonvolatile Capacitance Changes in Metal-Oxide-Semiconductor Device with Resistive Switching Floating-Gate Structure for Nonvolatile Memory and Programmable Logic Device Application

Minju Kim, Daehoon Park, Keonwon Beom, Paul Yang, Sunki Kim, Hyung Jun Kim and Tae-Sik Yoon; Myongji University, Yongin, Korea (the Republic of).

Nonvolatile capacitance changes in metal-oxide-semiconductor (MOS) device with floating-gate structure by resistive switching through filament formation were investigated for the application to nonvolatile memory and programmable logic devices. In general, the electrical charging of the floating-gate located inside the gate oxide has been utilized to shift the threshold voltage for nonvolatile memory and programmable logic devices. However, the approach to use the threshold voltage shift by electrical charging has faced difficulties in further scaling due to undesirable cell-to-cell crosstalk. Instead of using the electrical charging of floating-gate, the device performance such as drain current, threshold voltage, and transconductance can be altered by changing the capacitance of gate oxide. In this study, we demonstrated the change of gate oxide capacitance in MOS device with floating-gate structure, i.e., an Ag-control-gate/CoO_{2}/Pt-floating-gate/HfO_{2}/n-Si substrate, where the formation of conducting filament in Ag-control-gate/CoO_{2}/Pt-floating-gate stack by voltage application increased the gate oxide capacitance as reducing the effective oxide thickness. For example, the accumulation capacitance corresponding to the serial capacitance of CoO_{2} and HfO_{2} was increased considerably from ~40 pF before applying positive programming voltage in Ag-control-gate to ~55 pF after applying the voltage while preserving the typical shape of capacitance-voltage curve. The increase of capacitance was induced by the voltage-driven migration of Ag ions through CoO_{2} layer, leading to the formation of filament between Ag-control-gate and Pt-floating-gate and subsequent reduction of effective thickness of gate oxide. In contrast, the reference device with a structure of an Al-control-gate/CoO_{2}/Pt-floating-gate/HfO_{2}/n-Si did not exhibit the increase of capacitance because Al atoms did not migrate through CoO_{2} layer. Instead, it showed little decreased capacitance as increasing voltage possibly due to the migration of oxygen ions from CoO_{2} to Al-control-gate that reduced the relative permittivity of CoO_{2}. Since the gate oxide capacitance could be changed by programming voltage applied to control-gate, which subsequently changes the threshold voltage and drain current, it could be applied for nonvolatile memory and programmable logic devices without the use of electrical charging in floating-gate. These results demonstrated the novel scheme of memory and logic device operations through the change of gate oxide capacitance through resistive switching by filament formation in floating-gate MOS device structure.

Influence of Bulk/Interface Anomalies Upon Resistive Switching in Dual Ion Beam Sputtered ZnO Based Memristive Devices

Amitesh Kumar; Indian Institute of Technology Indore, Indore, India.

In this work, we report the effect of interface anomalies such as disorder-induced interface states, Schottky barrier formation/dissolution for a resistive switch or memristor. Distribution of bulk defects with applied bias governs switching and also attributes to formation/dissolution of interfacial oxide. The present work considerably contributes to...
further understand the conduction mechanisms of a wide range of resistive switches. 

Al/ZrO/Al (AZA) device depicts forming-free bipolar resistive switching with memristive behavior [1]. Bipolar against Unipolar resistive switching [2] is attributed to formation/dissolution of Schottky barrier. To further understand the effect of various other interface anomalies, we performed CV characterization of device in HRS and LRS states for different frequencies. As we can observe from Fig. 1(a), we may observe higher capacitance at a lower frequency which denote the presence of trap charges in bulk as at lower frequencies trap charges also make significant contribution to total capacitance. Further, we can also observe from CV characteristics of device for device in HRS and LRS at 1 MHz in Fig. 1(b) that for device in LRS and near SET voltage, the thickness of the oxide barrier reduces to minimum which leads to set device into LRS and hence total capacitance increases to maximum. As we vary the voltage and it comes near RESET voltage, the thickness of the oxide barrier will increase to its maximum and device will set into HRS and hence total capacitance will decrease to minimum. Fig. 2 (a) shows the I-V characteristics of AZA device. The device AZA shows excellent repeatability for 250 set/reset cycles (Fig. 2(b)).

We believe our work could play a crucial role in further understanding of conduction mechanism of resistive switching devices in the future.

EP09.03.13 Impact of Metal/Semiconductor Junctions in the Resistive Switching of Yttria Based Memristive System Mangal Das, Amithesh Kumar, Sanjay Kumar, Biswajit Mandal, Pawan Kumar and Shaibal Mukherjee; Indian Institute of Technology, Indore, India.

In this work, self-directed channel (SDC) memristor devices [1] with a Sn-Ch layer (Ch = O, S, or Se) were fabricated and electrically characterized in order to determine the role of the chalcogen atom in the memristor properties. The SDC device structure is a sandwich structure consisting of the following layers (from bottom to top electrode): W/GeO/Sn-Ch/GeO/Ag/GeO/W. The device is fabricated by depositing all layers via in-situ sputtering. The final W electrode layer effectively caps the device.

Current-voltage (I-V) curves of the devices were obtained. The I-V curves were analyzed to study the conduction mechanisms of each device type. This includes the analysis of Schottky emission, Space-charge limited Conduction [2], and Poole-Frenkel emission [3]. In addition, the first and second write threshold voltage of these devices are compared. The response of each device type to a sinusoidal input signal was also measured and used to classify the memristor type [4].

EP09.03.15 Enhancement of Electrical Properties for Black Phosphorus Using the via Contacts Embedded in h-BN Myeongjin Lee and Won Jong Yoo; Sungkyunkwan University Advanced Institute of Nano-Technology, Sungkyunkwan University, Suwon-si, Korea (the Republic of).

Black phosphorus (BP), one of the allotropes of phosphorus, is a promising candidate for future nano-electronics and nano-photoelectronics. Unlike conventional two dimensional semiconductor materials which show n-type property and high electron mobility, BP shows p-type property and high hole mobility [1]. However, BP faces limitations in application to future electrical devices since BP is easily degraded in air atmosphere, and therefore studies to prevent BP from being oxidized in air atmosphere are required. Here, we suggested a via method for suppressing degradation of BP, which uses metal embedded hexagonal boron nitride (hBN) on BP. The fabricated devices showed good electrical properties because of the suppression of degradation of BP. The devices also showed low contact resistance since ultra clean surface between metal and BP was formed. Furthermore, through the applying force between metal and BP by atomic force microscopy (AFM) probes, the performance of the devices were increased because contact between metal BP become better.

This work was supported by the Global Research Laboratory (GRL) Program (2016K1A1A2912707) and Global Frontier R&D Program (2013M3A6B1078873), both funded by the Ministry of Science, ICT&Future Planning via the National Research Foundation of Korea (NRF).
One of the most prominent features of the ferroelectric domain walls (DWs) is their electrical conductivity, which was observed in a number of ferroelectric materials, such as BiFeO$_3$, Pb(Zr,Ti)O$_3$, ErMnO$_3$. Here, we combine scanning transmission electron microscopy (STEM) and local probe techniques to investigate the conducting properties of the charged DW in the ion-sliced single-crystalline LiNbO$_3$ thin films with sub-$\mu$m thickness. STEM shows large inclination of the electrically-generated 180° DWs away from the polar z-axis (with inclination angles reaching 16°) suggesting that these DWs are strongly charged. Atomic column STEM imaging reveals the dipolar-kinked configuration of the Nb atoms along the inclined DWs. By using piezoresponse force microscopy (PFM) in combination with conductive atomic force microscopy (CAFM) performed both on z- and x-cut surfaces, it was shown that head-to-head DWs exhibit much higher conductivity than the tail-to-tail DWs, suggesting an electronic type of conductance. One of the most important findings is a possibility of DW conductivity modulation by an external voltage. It is demonstrated that the resistance of the LiNbO$_3$ thin film capacitors can be changed continuously by 5 to 9 orders of magnitude by controlling the DW perimeter allowing development of multi-level resistive switching devices. Resistance states can be altered by exposure to cumulative voltage pulses (resistance plasticity), suggesting that these domain wall memristors might be useful in the context of artificial synapses.

Transport Analysis of 4H-SiC Power Devices Using Full-Band Ensemble Monte Carlo Method Chi-Yin Cheng and Dragica Vasileska; Arizona State University, Tempe, Arizona, United States.

Energy issue is one of the most important things for us human kind. Therefore, we need an accurate and reliable model to help us develop and design the power devices. For this purpose, being one of the most promising materials for high power applications, 4H-SiC will be investigated in detail for improving performance of existing technology using in-house full-band Monte Carlo device simulator that is a subject of this work. The commercial TCAD tools are always based on effective mass approximation, however, most of the power electronic devices are operated under high electric field, so the non-parabolic band approximation cannot hold anymore. Hence, we need full-band analysis.

First ingredient in the process of building a device simulator is calculation of the band structure. In that respect, the empirical pseudopotential method (EPM) provides an effective way to get the band structure since we can adjust parameters to fit measurements (optical gaps). Here we refer to findings of G. Ng et al. to re-build the band structure. 205 eV cut-off energy was adopted; hence 527 plane waves were considered. The first Brillouin zone in reciprocal space of 4H-SiC is hexagonal. The full band structure of 4H-SiC is calculated, the indirect band gap is found to be 3.246 eV and is between $\Gamma$ point and M point. It is quite close to the commonly known value of 3.26 eV.

Next task in the sequence is the calculation of the scattering rates for which a Density of States (DOS) function is needed. The most widely used method for DOS calculation was proposed by Gilat and Raubenheimer in 1966. They extended the original method in 1967 also to hexagonal close-packed crystals. The first step in the DOS calculation is to discretize the k-space into smaller volumes. We only consider the irreducible wedge, which is 1/24 of the first Brillouin zone, because of symmetry. The wedge can be discretized into rectangular meshes and smaller wedge meshes. If we assume that linear extrapolation works good in every mesh, then the intersections of constant energy surfaces inside meshes are replaced by parallel planes $S(k, n)$ which are perpendicular to the gradient $\nabla f(E(k, n))$. If $w$ is the distance of a particular energy plane from $k$, inside a mesh, the range $w$ determines the possible cross-section area $S(k, n)$. $L_n$ are defined as $L_n = \lambda_{\text{free}}$. We rearrange them in a decreasing sequence $L_1 \geq L_2 \geq L_3 \geq 0$. All possible $S(k, n)$ for both rectangular meshes and smaller wedge meshes are found. After calculating all cross-section area and relating equations, we obtain the DOS function.

Once the DOS function is calculated, to analyze 4H-SiC devices, we have to consider acoustic, non-polar optical and optical phonon scattering. Thus, we create a scattering table using the information from the DOS. For the typical doping level in 4H-SiC device applications, the Brooks-Herring model is not valid. Hence, both electron-electron and electron-ion interactions are calculated. To save the runtime, we use the particle-particle-particle-mesh (P³M) method to get an efficient analysis procedure. The P³M divides the Coulomb force into two parts, the short-range force and long-range force (mesh force). We only need to consider the short-range forces for the carriers and ions close to the carrier we are tracing during each time step; the long-range force will be included via the solution of the 3D Poisson's solver.

We present at the conference simulation results of a N+-n-N+ resistor from where we extract the results for the low-field electron mobility dependence upon Coulomb in 4H-SiC devices, and the high-field electrons behavior where band structure effects are important.

Fabrication of Ferroelectric V-Doped ZnO Films Fabricated via Sol-Gel Method Woo Jun Seol, Hyun Jin Joh, Jun Young Lee, Tae Yoon Kim and Ji Young Jo; Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of).

Zinc oxide, which has high exciton binding energy (60mV) and a wide band gap (3.73eV)[1], is widely used for optoelectronic devices, piezoelectric sensors and actuators, and for non-volatile memories. Furthermore, ZnO-based ferroelectric materials have been intensively studied for a non-toxic, high temperature ferroelectric applications. While dopants such as Ca,Fe are suggested to induce ferroelectricity of ZnO films[2], especially Vanadium(V)[1], which has smaller ion radius than Zn, induces off-centered behavior of ZnO lattice and relatively larger remnant polarization. These metal-doped ZnO films have been fabricated with Pulsed Laser Deposition, sputtering, etc. However, these methods are high-cost and have difficulties in large-scale process at device scale. We used sol-gel method for fabrication to overcome these drawbacks. Higher crystallinity is needed to induce larger remnant polarization of the film, which could be controlled by elements such as deposition, preheating conditions. Here, we suggest dopant concentration and annealing condition to induce higher crystallinity of V-doped ZnO film via sol-gel method.

In this work, zinc acetate dihydrate (Zn(CH$_3$COO)$_2$•2H$_2$O) and vanadyl acetylacetonate (C$_{9}$H$_{9}$O$_{5}$V) were dissolved in 2-methoxyethan with 2-dimethylaminoethanol (C$_{9}$H$_{11}$NO) as a stabilizer at 75°C for 2 hours on a hot plate to make a solution for sol-gel method. The 200 nm-thick V-doped ZnO film was deposited using spin-coating and preheating and annealing to induce higher crystallization of film. The Pt top electrodes with a thickness of 30 nm were deposited using an electron beam evaporator to form capacitor structures.

Manipulating the Electrochemical Metalization Cell Kinetics by the Anion Electrode and Tunable Electrolyte Ziyang Zhang, Yao Yuan Wang, Huanglong Li and Luping Shi; Tsinghua University, Beijing, China.

Electrochemical metallization (ECM) memories have the potential to replace today's technology, enabling novel memory and computing architectures circumventing the von Neumann bottleneck. Typically, the operation of ECM cell is based on the electrochemical redox reactions of the cation supplying active electrode. However, the possibility of utilizing new materials for the active electrode remains largely undiscovered. In addition, the ECM cell kinetics are strongly determined by the electrolyte, which can hardly be altered after the cell has been fabricated. Therefore, it is necessary to investigate the influence of the electrode and electrolyte on the ECM cell kinetics. In this work, we engineer the anion supplying active electrode and tunable electrolyte into the electrochemical metallization cell. First, to investigate the electrode dependent switching characteristics of the ECM cells, we fabricate the ECM cell with Te as active electrode. It is found that the SET operation of the device occurs under negative voltage on the active electrode. This behavior is opposite to that of the device with Ag electrode, indicating that Te supplies anions by the ECM mechanism. Different modes of switching between the two types of
cells, namely, unipolar switching for Pt/GeS/Te cell and bipolar switching for Pt/Ge2Sb2Te5/GST/Te cell are observed. These phenomena can be attributed to the rupture of the film by Joule heating for the former and by ECM for the latter in the RESET process. Next, we fabricate the ECM cell with solid phase tunable GST electrolyte to investigate the electrolyte dependent switching characteristics of the ECM cells. The resistive switching characteristics of the cells with different GST phases are examined. The magnitude of the high resistance, the SET voltage and the on/off ratio are found to be considerably affected by the solid phase of GST, whereas the magnitude of the low resistance is least affected. Moreover, a transition from volatile to nonvolatile SET switching is only observed for crystalline GST based cell under prolonged voltage sweep, but not for amorphous GST based cell. This work provides a springboard for more studies on the manipulation of the ECM cell kinetics by tunable electrode/electrolyte and the resulting unprecedented device functionalities.

EP09.03.20

Bidirectional and Multilevel Threshold Switching of Ag-Dielectrics Diffusive Devices for Neuromorphic Computing Applications Yaoyuan Wang1,2,3, Ziyang Zhang1,2,3, Shuang Wu1,2, Lei Tian1,2,3, Huaqiong Li1,2 and Luping Shi1,2,3. 1Department of Precision Instrument, Tsinghua University, Beijing, China; 2Center for Brain Inspired Computing Research, Tsinghua University, Beijing, China; 3Beijing Innovation Center for Future Chip, Tsinghua University, Beijing, China.

Non-volatile memristor crossbar arrays have great potential in brain inspired computing and next generation high-density memories. Diffusive devices with volatile threshold switching (TS) behavior, which are based on the phenomenon of spontaneous rupture of filaments in dielectrics, are of importance in selector applications to suppress the sneak current issue of memristor arrays. Besides, their rich synaptic dynamical behaviors can also enable novel designs in neuromorphic computing to extend the circuits based on the complementary metal-oxide-semiconductor. In this work, we have realized reproducible bidirectional and multilevel TS behavior on Ag-dielectrics diffusive devices. The ON/OFF ratio and the OFF current of the device TS behavior are ~10^4 and ~10^2 A, respectively, which are suitable for selector applications. And we also realize stochastic and multilevel TS by optimizing the device structures. For neuromorphic applications, we integrate the stochastic TS into the stochastic learning process of deep neural networks, and demonstrate the multilevel TS into short-term and long-term plasticity for electronic synapses. Simulations of nanoparticles diffusion are also carried out to study the mechanism of this bidirectional and multilevel TS process. The simulations show that these phenomena are mainly caused by the diffusion and redistribution of Ag nanoparticles. This work illustrates that Ag-dielectrics diffusive devices are promising candidates for neuromorphic computing applications.

EP09.03.21

Optoelectronic CMOS Transistors—Performance Advantages for Sub-7nm ULSI, RF ASIC, Memories and Power MOSFETs James Pang; Advanced Enterprise and License Company, Linthicum, Maryland, United States.

Substantial increase of output current, and Ion / Ioff ratio, for sub-7nm low power CMOS transistors can be accomplished using a novel optoelectronic technology, which is 100% compatible to existing CMOS process flow. For RF or mixed signal ASICs, adding photonic components may improve the cut-off frequency, and reduce series resistance. Products that utilize power regulating devices, such as power MOSFETs, will benefit from the optoelectronic configuration to achieve much lower Ron and high avalanch breakdown voltage at the same time. For semiconductor memories, including DRAM or FLASH, the photonic technique may reduce the ERASE / WRITE / access time and improve the reliability.

Photon generating and sensing devices can be integrated in the drain region of a MOSFET, FINFET or power MOSFET as one transistor. The laser diode is turned on only when the MOSFET is switched to on. The laser is off when the MOSFET is switched off. When both laser and MOSFET are on, light is absorbed by the APD ( Avalanche Photo Diode), which is fabricated in the drain / well regions of the MOSFET, and generates avalanche breakdown currents as part of the output drain current. In this paper we will discuss how to implement this optoelectronic technique for low power, high speed sub-7nm CMOS, memories (DRAM, SRAM, FLASH), and high power MOSFETs.

Sub-7nm CMOS Transistors. Process integration of a laser in the drain region of a MOSFET or FINFET may be simplified. Cross section of an optoelectronic MOSFET shows device configuration, where part of the drain is etched and redeposited with laser films. An equivalent circuit of the device provide step-by-step detailed operations. Please notice that if the substrate is silicon, the laser films ( direct band gap materials) can be deposited selectively on silicon through low temperature epitaxy. If the substrate is GaAs, or other compound semiconductor, a thin silicon film may be deposited on the compound substrate. MOSFET is build in the top thin silicon film, and laser is formed on the compound substrate after selective etching of silicon.

Similar integration techniques can be applied to FINFETs, with low temperature selective epitaxy of lasing semiconductor films in the drain area of a FINFET. The fin can be silicon or GaAs. If the fin is GaAs, a thin silicon epi layer needs to be deposited on GaAs, then selectively removed right before the lasing films are deposited.

In order to further simply the process integration, it is feasible to integrate the laser in the contact 1 or via between metal 1 and silicide. Improvement of MOSFET output current depends on external quantum efficiency and the APD absorption rate. To achieve optimized CMOS drive current, high laser quantum efficiency and APD absorption rate are needed.

Power MOSFETs. Cross section of a discrete vertical power MOSFET illustrates how a laser diode is integrated. For this type of devices, the drain is located in the back side of the chip. Source is on the top of the chip. Deposition of compound laser semiconductor films in the back side of the chip creates a laser. When a high voltage is applied to the drain, a large depletion region is formed along the drain junction in order to sustain a high breakdown voltage. High-intensity light is produced from the laser in the backside, and absorbed in the depletion region to produce light current, which reduces Ron.

Nonvolatile Memories: SRAM, DRAM, FLASH, SONOS, EEPROM – Light Assisted Very High Speed Operations. An optoelectronic Flash memory is a SONOS memory (NOR Flash) with a laser integrated in the drain area. For the Write operation, typically with hot carrier injection, a gate voltage is applied to turn on the word line transistor, and a drain voltage is applied to turn on the laser – light is produced and absorbed in the depletion regions in the channel and drain. Hot carrier injection is enhanced by the light current, and the Write operation is much faster.

EP09.03.22

Atomic Force High Frequency Phonons Nonvolatile Dynamic Random-Access Memory Compatible with Sub-7nm ULSI CMOS Technology James Pang; Advanced Enterprise and License Company (AELC), Linthicum, Maryland, United States.

This paper reports a novel low power, fast nonvolatile memory utilizing high frequency phonons, atomic force dual quantum wells, ferromagnetism, coupled magnetic dipoles and CMOS-based magnetic devices. Random access is accomplished with the magnetic fields generated from ring-gate MOSFETs. Very high-speed memories, such as SRAM and DRAM, are mostly volatile (data are lost when power is off). Nonvolatile memories, including FLASH and MRAM, are typically not as fast as has DRAM or SRAM, and the voltages for WRITE/ERASE operations are relatively high. This paper describes a silicon nonvolatile memory that is compatible with advanced sub-7nm CMOS process. It consists of only one transistor (MOSFET) – small size, and more cost effective, compared with a 6-Transistor SRAM. There is no need to refresh, as required by DRAM. The access time can be less than 1ns – close to the speed level of relaxation time - much faster than traditional FLASH memories and comparable to volatile DRAM. The operating voltages for all memory functions can be as low as high speed CMOS.

A fast non-volatile dynamic random access memory is different from NAND Flash, for which random access is not possible, and NOR Flash, which is relatively slow and high operation voltages are required. Traditional MRAM (Magnetic Random-Access Memory) uses the material properties of magnetic films, which might not be reliable after many operational cycles. A magnetic nonvolatile DRAM (MNV-DRAM) consists of a main gate on top of a silicon substrate with implanted source and drain regions, a floating phonon gate above the main gate, and a control gate above the phonon gate. In between the gates there are vacuum gaps of a few Å. The floating phonon gate consists of polarized ferromagnetic thin films. The control gate is made of a conducting layer on top of a ferromagnetic thin film. The main gate is made of a ferromagnetic thin film on top of a conducting layer. The ferromagnetic films in the phonon gate are implanted with positive or negative charges. As the result, there is an electro-magnetic field with dual quantum wells in between the control and main gates from atomic forces, where the floating phonon gate switches from one quantum well to the other with very high frequency. The layout
design of the 3 gates may be rectangular, or circular (3 loops on top of each other), in order to achieve random access with magnetic fields from the currents in the loops. Due to the currents flowing in the loops, magnetic fields from each loop couple with each other, forming two magnetic dipoles. Motions of the loops depend on the polarity of the dipoles. When currents flow in the same direction, there is an attracting force between the two loops. If currents flow in opposite directions, there is a repelling force. The channel length of the ring gate MOSET is approximately the length of the ring, as described by a cross section (cut along the ring). If the device is cut across the ring, this shows the width of the MOSET.

Conclusion: A novel atomic force magnetic nonvolatile memory is presented in this paper. Nonvolatile functions are achieved by high frequency phonons and quantum wells. Random access is accomplished with coupling of magnetic dipoles. This type of memory requires very low voltages for Write / Erase / Read operations and no Refresh is necessary. The speed is much higher than traditional FLASH memories. Manufacturing of the memory is low cost, without exotic materials, and compatible to deep nanometers CMOS technology. Access time vs. current and memory device dimensions are presented in this paper.

EP09.03.23
Generic 2D Schrödinger-3D Poisson Solver for AlGaN/GaN Nanowire FinFETs
Viswanathan Naveen Kumar and Dragica Vasilevska; Arizona State University, Tempe, Arizona, United States.

AlGaN/GaN heterojunction FETs (HFETs) possess unique properties such as a wide band-gap, high drift velocity and high critical electric field which make them uniquely suitable for high voltage power devices. Unique properties of Gallium nitride (GaN) such as a wide band gap significantly reduces band to band tunneling making it suitable for sub-10 nm transistors. Ballistic transport is also possible in GaN devices because of the high optical phonon energy. Presence of a 2DEG at the AlGaN/GaN hetero-interface contributes to a high sheet charge density, and subsequently high mobility. However, this very presence of polarization-induced charge density leads to poor turn-off characteristics. In the past decade, 2D FETs, such as FinFETs and Gate-all-around (GAA) FETs, have been developed as viable alternatives to traditional planar transistors. Recent works demonstrate such an approach to AlGaN/GaN HFETs as well. Introduction of non-planarity such as a fin has shown to improve off-state characteristics and push the threshold voltage into the positive. Previous works have shown experimentally the dependence of threshold voltage and the electron density on the width of the nanowire channel.

The focus of this work is to develop a generic 2D Schrödinger-3D Poisson solver for GaN Nanowire FETs. A 3D Poisson solver coupled with a 2D Schrödinger solver allows us to accurately map the charge density in the channel. The solver can also help us model the dependence of electron density in 2DEG and sidewalls on geometry of the nanowire channel. The electron wavefunctions generated by the solver is used to compute overlap integrals in the Ensemble Monte Carlo (EMC) algorithm. Three scattering mechanisms: acoustic phonon scattering, polar optical phonon scattering, and piezoelectric scattering are considered to account for the electron phonon interactions in the system. The EMC solver is then used to determine the low field electron mobility and drift velocity in the channel.

EP09.03.24
Observation of Threshold and Resistive Switching Behaviors in Epitaxially Regrown GaN-p-n Diodes by MOCVD
Hong Chen, Jossue Montes, Chen Yang, Jingan Zhou and Yuji Zhao; Arizona State University, Tempe, Arizona, United States.

Resistive random access memory (RRAM) has been extensively investigated due to its great potential in synaptic and neuromorphic computing applications. In the crossbar array of RRAM architecture, threshold switching selector devices are one of the crucial components to cut off the sneak current path of the unselected cells. This work reported the first observation of threshold and resistive switching behaviors in epitaxially regrown vertical GaN p-n diodes by MOCVD. They showed excellent thermal reliability up to 300 °C, which is a significant improvement over traditional oxide-based devices. The device can be integrated with mature III-nitride high electron mobility transistors (HEMTs) technology and facilitate the development of GaN-based integrated circuits, especially for harsh environments.

The eplayers were grown homoepitaxially on bulk n–GaN substrates by MOCVD. The device structure consists of a 0.5 µm n–GaN buffer layer, a 7 µm unintentionally doped (UID) GaN drift layer, 1 µm n–GaN contact layer, 0.3 µm regrown UID-GaN and 1 µm regrown p-GaN after the etching of 1.5-µm-deep trenches in the UID-GaN drift layer and n–GaN contact layer. The regrown layers on top of the n–GaN contact layer were removed to form the top n-contact. The top p-contact was formed on the regrown p-GaN, and the bottom n-contact was on the backside of the substrate. The forming process was completed by soft break down of either lateral p-n diode between the top n– and p-contact or the vertical p-n diode between the top p-contact and bottom n-contact. After the forming process, we observed the threshold switching process in the vertical diodes with a high resistance state (HRS) and a low resistance state (LRS). Reliability study showed that the devices can operate stably up to 1000 cycles at both room temperature and 300 °C, indicating the excellent thermal stability of the threshold switching behaviors.

The I-V characteristics of the devices was analyzed in log-log scale to explain the operation mechanism. At the LRS, the I-V curve was similar to that of a conventional p-n diode. At the HRS, there are two regions, which follow the trap-assisted space charge limited current (SCLC) theory. At low voltage region, it is dominated by the ohmic law where I V; at high voltage region, it is dominated by the Child’s square law with defects where I V. As shown by the TEM study, the regrowth interface was highly disordered with defects. We hypothesized that after the soft breakdown, the regrowth interface layer may behave like a thin insulating layer with trap states which leads to the HRS. It’s reported that these traps can form/rupture a conductive path by trapping/detrapping carriers. From 0 V to the set voltage, the traps at the interface will be filled with carriers to form a conductive path, resulting in the transition from HRS to LRS. Carriers. From the reset voltage to 0 V, the traps will be depleted of carriers to cut off the conductive path, and the devices change from LRS to HRS. We also observed an increase in set voltage with increasing temperature, which can be explained by the enhanced detrapping effect at high temperatures. Furthermore, the memory behavior can also be observed if the voltage is large than the turn-on voltage of the p-n diode. This is analogous to a diode and a RRAM cell connected in series.

In summary, we demonstrated threshold switching and memory behaviors in epitaxially regrown GaN p-n diodes. This physical mechanism was attributed to the forming/rupturing of the conductive path formed by traps through trapping/detrapping carriers at the regrowth interface. The device showed excellent reliability up to 1000 cycles and thermal stability up to 300 °C. In addition, memory behaviors can be observed when the reset voltage was higher than the turn-on voltage. These results open up opportunities for the development of GaN-based memory devices and integrated circuits.

EP09.03.26
Non-Volatile Discrete Memristive and Memcapacitive States Enabled by Electric Field Controlled Charge Disproportionate Redox
Shreeosh Goswami and Thirumalai V. Venkatesan; NUSNNI, National University of Singapore, Singapore, Singapore.

Handling ‘big data’ is one of the biggest problems for next-generation computing. This calls for major breakthroughs in digital electronics, the backbone of modern computing, where emerging technologies like artificial intelligence is being implemented. For this, memristors are considered an important building block since they facilitate key strategies for big data handling, viz. (i) increasing data density and (ii) reducing the asymptotically increasing demand for computing power. The main challenge in increasing data density is that the existing non-volatile memristors consist of many analog states, suitable for neuromorphic computing but not optimized for a digital platform. We report here a memristor, based on a molecular film of a Ru-complex of an azo-aromatic ligand, having 3 discrete, non-volatile states with conductance values separated by >3 orders of magnitude that are temporally and thermally stable – an ideal candidate for high-density digital electronics. Formation of these discrete states is enabled by field-driven transitions between three different molecular redox states in the film resulting in significant changes in conductance. Of these redox states, the ground state of the film is characterised by charge disproportionation (CD), formation and disruption of which can be reversibly controlled by an external bias at room temperature. Based on electrical and spectroscopic measurements and quantum mechanical calculations, we conclude that the applied field displaces the counterions w.r.t. the molecules, making or breaking the coulombic symmetry and stabilizing the CD and non-CD states. The resulting CD results in a binary memcapacitance concurrent with the ternary memristance and could lead to ultra-low energy computing. In contrast to the highly correlated electronic systems, where only specific physical conditions (like high or low temperature or ultra-high pressure) can cause a broken electronic symmetry (i.e. CD), in our molecular films electronic symmetry/asymmetry (i.e. non-CD and CD states) can be reversibly controlled by external voltage at ambient conditions – one of the Holy Grails in condensed matter physics.

Self-Purification of the Highly Pure Semiconducting Carbon Nanotube Arrays
Zhenxing Zhu1, Nan Wei2, Weijun Cheng2 and Fei Wei1; 1Department of Chemical Engineering, Beijing Key Laboratory of Green Chemical Reaction Engineering and Technology, Beijing, China; 2Department of Applied Physics and Center for New Materials, School of Science, Aalto University, Aalto, Finland; 1Institute of Microelectronics, Tsinghua University, Beijing, China.
Performance Degradation Due to Nonlocal Heating Effects in Resistive ReRAM Memory Arrays

Marius K. Orlovsky and Mohammad Al-Mamun; Virginia Tech, Blacksburg, Virginia, United States.

Conventionally, resistive RAM memory is manufactured in a cross-point architecture. A cross-point at which a memory cell is located, is an intersection of vertical and lateral metal lines for the active and inert electrodes of the resistive memory cell. Here, we investigate the thermally induced degradation of Cu/TaOx/Pt/Ti ReRAM devices. When one cell is repeatedly switched on and off, a certain amount of heat is being deposited in the cell. The local temperature to rupture a Cu filament has been estimated to be 600-800°C. The local heating affects not only the device itself, but the heat dissipated along the electrode metal lines causes performance degradation of the neighboring cells. To monitor the cell degradation we choose specific set condition to form a marginal, i.e. weak, highly resistive Cu filament by imposing low IO of 10μA and ramp rate r=1.2V/s, while the reset is performed at low r=0.1V/s with no IR in order to maximize the Joules heating. Such a fragile Cu filament acts as a canary in the coal mine with respect to ambient heat. The heat deposited in a stressed device leads to a limited number of switching cycles, usually 11-14. When the device is preheated, the maximum number of cycles may decrease to zero and thus as a service for a measure for performance degradation of the neighboring cell. Within 3-4 minutes, after reaching maximal cycles for a given device, we test the switching behavior of the neighboring cells, one at a time. We find that only the cells that share either metal line of the heated device, suffer performance degradation. Direct neighbors (like a cell at the intersection of the adjacent Cu and Pt line) to the heated cell thus not sharing any the electrode of the heated device, are not affected at all by the heat, provided that the intermediate cells are in off-state. However, when the intermediate cells are programmed to the on-state and provide thus a direct heat conduction path to the heated device via copper line, Cu filament of the intermediate cell, and the Pt line, the diagonal neighbors suffers performance degradation. We find that the neighbors along the common Cu electrode line are affected more than the neighboring cells along the Pt electrode line. The heat transport along the Cu line is more effective and reaches further neighbors than for Pt line. Although the heat conductivity of Cu is roughly 3 higher than of Pt and the Cu metal line is 150 nm while the Pt line is 50 nm thick, we found this result surprising because it challenges the conventional assumption that the shape of the Cu filament is that of a sharply tipped cone with a broad base forming an interface with the Pt line and the tip of the cone touching the Cu line. This shape would imply very small contact of the filament with Cu and large contact with Pt, favoring heat transfer to the Pt line rather than to the Cu line. The observed more efficient heat transfer from the filament to Cu than to Pt line implies that the shape of the Cu filament appears to be more likely that of hour glass rather than a cone. When the tested neighboring cells are allowed to cool off for sufficiently long time (20 min or more) they return to the original performance levels of 11-14 cycles. We find also that the minimum cooling off period for cells disposed along the Cu lines rather than along the Pt lines. The width of Cu and Pt lines in our arrays varies between 5 μm and 35 μm and the distance between the lines is ca 150 μm. We find more pronounced degradation of the neighboring cells along the Pt lines, for 35 μm wide Pt lines than for 5 μm wide Pt lines, indicating that metal lines with smaller cross-section are less effective in heat dissipation to the surroundings. In commercial arrays, the thickness, width, and line pitch of the electrode metal lines are of the order of couple 10s of nm. We therefore expect much more pronounced heat effects and over a longer time period in commercial memory arrays.

EP09.03.28

Suppression of Gate-Induced Drain Leakage in Single-Gate Feedback Field Effect Transistors

Dooyeok Lim and Sangsik Kim; Korea University, Seoul, Korea (the Republic of).

In this work, we demonstrate single-gate feedback field-effect transistors (FBFETs) consisting of p'-n-i-n' silicon nanowires (SiNWs). SiNWs were derived from a bulk-Si wafer including ion implantation and crystallographic wet etching processes, and the SiNWs were then transferred onto a plastic substrate. The SiNWs had a diameter of 100 nm, BF2+ and As+ ions were implanted for the formation of p' and n' regions in the p'-n-i-n' SiNWs, respectively. The aluminum electrodes were formed on top of the SiNW in p'-drain and n'-source regions. The i-regions of the channels were covered with Al2O3 high-k dielectric layers. Tungsten top-gate electrodes with widths of 2 μm were also formed via photolithography and thermal evaporation processes. The SiNW FBFET exhibits good switching characteristics in terms of an on/off current ratio, a subthreshold swing, and gate-induced drain leakage (GIDL) current. Specifically, the GIDL can be effectively suppressed because the p' potential barrier in p'-n'-i-n' silicon nanowires can block the injection of tunneling electrons, unlike the conventional metal oxide semiconductor FETs (MOSFETs).

EP09.03.30

Introducing a Single MOF Crystal into a Micro CBRAM Device by a Selective Growth Method of MOF

Atsushi Shimizu1, Kentaro Kinoshita1, Yusuke Nakaume1, Hissashi Shima2, Makoto Takahashi2, Yasuhisa Naioh2 and Hiro Akinaga2; Department of Applied Physics, Faculty of Science, Tokyo University of Science, Katsushika-ku, Japan; 3Emerging Device Group, Nanoelectronics Research Institute, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

Conducting-bridge resistive random access memory (CBRAM) is attracting attention thanks to its advantages such as low power consumption and high applicability to multi-bit data storage. However, CBRAM has issues to be solved, such as, ex., large deviation of switching voltage and resistance, for putting it into practical use. Above all, semiconductor technology is facing a miniaturization limit that prevents the density of memory devices higher. Metal organic frameworks inherently have periodically and densely aligned subnanoscale subunits that self-assembled to the MOFs. We propose replacing a metal oxide film in a CBRAM cell that works as a memory layer with MOF. This is because we expect the subnanoscale pores of MOF enhance ion diffusion and the directionality of the diffusion along the pores, leading to superior performance including the improvement of the deviations of a switching voltage and resistance. In this paper, to introduce MOF into actual CBRAM devices, we established a method to grow a single MOF crystal selectively at a via. We also show resistive switching behavior observed in the MOF-CBRAM. SiO2 was deposited on a Cu (50 nm)/Pt (20 nm)/TiN (20 nm)/SiO2/ Si substrate, followed by the formation of vias with the diameter of 100 nm, through which the surface of the Cu layer was exposed to the solution, using electron beam lithography. 1,3,5-Benzenetricarboxylic acid (BTC) of 1.8 g was dissolved into the mixed solution of ethanol of 15 ml and dimethylformamide (DMF) of 15 ml. The processed substrate was soaked into the solution to synthesize HKUST-1 [1] that is one of the most popular MOF due to its high stability in the atmosphere. Finally, we fabricated top electrodes of Au (20 nm)/Ti (20 nm), filling the vias, by EB evaporation. Electric characteristics were measured using a semiconductor parameter analyzer (B1500A, Keysight).

In our proposed method, HKUST-1 synthesis advances by dissolving Cu from the Cu layer of the processed substrate into the solution through the vias. Since no Cu is contained in the synthesized MOF, HKUST-1 can be synthesized without the presence of Cu ions. To keep the concentration of dissolved Cu around the via high, another substrate was placed facing the processed substrate through thin glass sheets that works as a spacer. In fact, we confirmed by SEM that a single HKUST-1 crystal was selectively synthesized at the via region. For electric characteristics, our MOF-CBRAM showed relatively low resistance in an initial state. This may be attributed to the presence of residual Cu ions that were not incorporated into the crystal and were left in the pores. Accordingly, electrical preparation process similar to reset, which is resistive switching from a low to high resistance state, is necessary for the development of resistive switching phenomena. After the preparation process, bi-polar resistive switching, which means that bias voltages with different bias polarities are necessary to cause set and reset switching, respectively, was confirmed. Therefore, resistive switching phenomena in a single MOF crystal was achieved as a microfabricated device, for the first time.

In conclusion, we newly developed a method that enables a selective synthesis of MOF crystal accurately at desired points. Combining this method with conventional microfabrication technic that is familiar with silicon process, micro CBRAM cells containing a single MOF crystal each as a memory layer could be fabricated successfully. In addition, our result strongly indicates MOF crystal can be introduced widely into CMOS process.

EP09.03.31

Functional Demonstration of In-Memory Arithmetic Logic Unit in Memristive Crossbar for Software-Defined Memprocessor

Yi Li; Long Cheng and Xiaoguang Miao; Huazhong University of Science and Technology, Wuhan, China.

Abstract: Software-defined microprocessor in computing systems provides the convenience for users to execute the wanted functions in intelligent terminals. In the

Carbon nanotubes (CNTs) are the promising candidates for the novel integrated electronics. Whereas, it’s a challenge to obtain perfect semiconducting CNT (s-CNT) arrays with a high purity. Here, we demonstrate the self-organized 99.9999% s-CNT arrays based on an interlocking between the atomic assembly rate and bandgap of CNTs. Rate analysis verified the Schulz-Flory (SF) distribution for both metallic (m-) and s-CNTs, indicating their different decay rates as length increased. Furthermore, s-CNTs exhibited an averaged ten-fold slower decay rate than that of m-CNTs ensuring that the purification of 99.9999% s-CNTs with the diameters centered at 2.40 nm when the length exceeded 154 nm. Transistors fabricated on them delivered a high current of 1.4 mA/μm with an on/off ratio around 1014 and mobility over 4000 cm2/Vs. Our self-purification strategy offers more degrees of freedom to in-situ control the s-CNT purity, exhibiting significant potential in scale-up production and applications of highly pure s-CNTs.
microprocessor, arithmetic logic unit (ALU) with the information processing ability is the kernel. In this work, the in-memory ALU functions are demonstrated in the memristive crossbar with implementing nonvolatile Boolean logic functions and arithmetic computing. For logic implementation, stateful IMP, OR and NOR logic are reconfigured within three devices in one step. Based on them, other logic functions are constructed within five devices in five steps at most. The program voltage amplitude is decreased at a relatively low standard under “≤Vth” mode. For arithmetic computing, the fundamental functions including n-bit full adder with high parallelism, efficient increment, decrement and shift operations are designed and demonstrated for building other arithmetic blocks, such as subtraction, multiplication and division. Furthermore, the energy consumption is estimated and the design of the peripheral circuit is discussed to evaluate the practicability. This work may pave the way for memristor-based logic and arithmetic computing.

EP09.03.32
CBRAM Based on Single Crystalline Si Thin Films Grown by Solid Phase Epitaxy
Inho Kim, Jong-keuk Park, Beomsic Jung and Gun-hee Kim; Korea Institute of Science and Technology, Seoul, Korea (the Republic of).
Low dimensional defects such as dislocation in single crystal Si serve as fast diffusion path of Ag ions. Recently, efforts have been made to employ dislocations in single crystal based oxide and silicon as reliable Ag filaments in CBRAM (Conductive Bridging Random Access Memory). Conductive Ag filaments are reported to be well confined in one dimensional dislocation facets in nanometer scale and exhibit promising device performances in terms of retention time, endurance, linearity and on/off ratio. However, there has been a rare study of controlling the location of the low dimensional defect formation, which is a key factor to device production. In this study, we performed research to create the low dimensional defects on the active region of the epitaxially grown Si thin films for CBRAM by our proposed approach. The single crystal Si thin films were grown by solid phase epitaxy. We fabricated CBRAM devices by sandwiching the epitaxial Si thin films between the active metal of Ag and highly conductive Si substrate. We investigated the device performance of CBRAM including intentionally controlled defects in the epitaxial Si thin films and discuss the effect of the low dimensional defects on the resistive memory device performances. Furthermore, we performed the feasibility study on the use of the epitaxial Si based CBRAM for artificial synapse for neuromorphic computing. The fundamental process parameters of the epitaxial Si CBRAM were extracted, and we propose the future research direction to optimize the device parameters for the artificial synaptic device applications.

Nanoscale Electronics Realization with a Prospectives from Devices Architecture and Interconnect Circuits Theory
Preetisudha Meher; National Institute of Technology, Yupita, India.
Nanoelectronics is a natural consequence of the earlier successes of microelectronics. However, this realization is likely to continue provided, all new elements fetched by nanometer era of technologies [P. Meher, et al. IEEE Microelectronics and Electronics, 2012, 229]. The primary interest of this investigation is to raise the level of awareness of the IC design community [P. Meher, et al. Journal of The Institution of Engineers (India)], 96 (2015) 391] that design for cost minimization is likely to emerge as a high priority action item on IC design plans [P. Meher, et al. International Journal of Circuit Theory and Applications, 2018]. Few basic important parameters have been formulated for cost minimization via cost objective function and performance via design density (very large scale integration) and yield concurrently. This understanding helps us to realize the CMOS logic gate with simple model developments for delay and power dissipation estimation [S. R. Ghimiray, et al. International Journal of Circuit Theory and Applications, Wiley, 46 (2018) 1953]. These analysis permit us to understand the mechanisms that control the performance, particularly the power dissipation, of a logic circuit [IEEE Region 10 Annual International Conference, Proceedings/TENCON, 2017]. Several CMOS design styles are attempted with a circuit variations of the static complementary CMOS, which are suitable for low-power applications [S. R. Ghimiray, et al. IOP Conference Series: Materials Science and Engineering- Institute of Physics, 2017].

Current Density and Electric Field Decomposition During Nonlinear Electronic Instabilities
Sahas Kumar and R. Stanley Williams; HP Labs, Palo Alto, California, United States.
What physical quantities determine behavior of multistable electronic devices and circuits, especially when multiple stable configurations exhibit identical current, voltage, power input and heat output? This question has been discussed in different forms over several decades. For instance, in 1963 Ridley postulated that under certain bias conditions circuit elements exhibiting a current- or voltage-controlled negative differential resistance will separate into coexisting domains with different current densities or electric fields, respectively. Landauer then postulated that all circuit theorems are in essence heat-generation theorems. These debates were never resolved because of the lack of analytical and experimental techniques to resolve the underlying issues. These issues now assume vital importance especially with the tapering down of Moore's law and the concurrent interest in nonlinear electronic devices such as memristors. We address these issues by using thermal and chemical spectro-microscopy to directly imaged signatures of current-density and electric-field domains in several metal oxides. The local activity theorem successfully predicts initiation and occurrence of spontaneous electronic decomposition, accompanied by a reduction in internal energy, despite identical power input and heat output. This is a process similar to spinodal decomposition of a homogeneous liquid or disproportionation of a metastable chemical compound. This result reveals a thermodynamic constraint required to properly model all nonlinear circuit elements. Our results explain the electroforming process that initiates information storage via resistance switching in metal oxides and has significant implications for improving neuromorphic computing based on nonlinear dynamical devices.

Bi-Directional Analog Synaptic Behavior of SiOx:Ag-Based Diffusive Memristor
Nasir Ilyas1, Dongyang Li1, Yuhuan Yuan1, Xiadingong Jiang1 and Wei Li1, 2; 1School of Optoelectronic Science and Engineering, University of Electronic Science and Technology of China, Chengdu, China; 2State Key Laboratory of Electronic Thin Films and Integrated Devices, University of Electronic Science and Technology of China, Chengdu, China.
Besides conventional digital von Neumann computing system, the brain-inspired neuromorphic system has been proposed as a new computing paradigm considering effective information processing and memorizing simultaneously. Artificial electronic synapses mimicking biological synaptic functions are required for the realization of highly efficient neuromorphic architectures. Therefore, a two terminal memristor based on electromigration of cations (e.g., Ag+) has attracted considerable interests due to its similar behavior with a bio-synapse (e.g., the flux of Ca++ and Na+) at an ionic level. The memristor working on Ag diffusion dynamics in an ionic conductor matrix (i.e., SiOx:Ny, AgS and biopolymer -i-carrageenan) has successfully emulated the Ca++ and Na+ dynamics of bio-synapse. HfOx- or TaOx-based memristors exhibiting gradual resets are also proposed for the adaptive learning to mimic the bio-synapse inhibition process based on the electromigration of the oxygen ions/vacancies under voltage pulses. It is challenging to implement bi-directional analog resistance modulation, i.e., many memristors possess gradual conductance changes only under 1V polarity and cannot dutifully mimic bio-synaptic functions of potentiation and depression. Moreover, bi-directional analog resistive random-access memory (RRAM) is suitable for running more complex deep neural networks. There is no doubt that innovation in the design of a memristor both in materials and electrodes is one of the efficient way to realize this goal. In a memristor, bi-directional analog resistive switching behavior is crucial to adjust the conductance continuously and to mimic various bio-synaptic functions faithfully. The silver-nanoclusters dispersed silicon oxide thin film is an attractive material to fabricate the RRAM devices. It is well-known that in SiOx:Ag-based RRAM devices, the switching mechanism is closely correlated to the formation/dissolution of Ag filaments under an electrical field. Therefore, developing a method to control the filament formation/dissolution is necessary for performance enhancement. Recently, we have proposed a Pt/SiOx:Ag/Ti/Pt memristor which possesses an excellent bi-directional analog resistive switching behavior. We have observed that the formation of a non-stoichiometric high-k TiOx interfacial layer during device fabrication process presents a good barrier property for Ag diffusion under a relatively high electric field. The device has shown a gradual increase and decrease of conductance under positive and negative pulse trains without setting compliance current (iCL). The results of the bi-directional gradual set/reset are a benefit to obtain a reliable “analog” switching for the corresponding synaptic characteristics.
Moreover, the short- and long-term plasticity, paired-pulse facilitation (PPF) and transition from short-term memory (STM) to long-term memory (LTM) have also been realized.

In our Pt/SiO$_2$/Ag/Ti/Pt memristor architecture, a stack of pure Ti-layer and SiO$_2$/Ag composite film was deposited on Pt bottom electrode using DC sputtering and RF co-sputtering, respectively. Subsequently, by using the lithography process, 100-nm-thick Pt top electrodes of 200 nm in diameter were patterned. XPS, XRD and SEM were used to demonstrate the formation of TiO$_2$ interfacial layer during device fabrication process. The resistance switching characteristics have been determined by modulating the interfacial resistance under 0~±1.5V pulse trains using a digital power source (Keithley 2636B) hooked with a probe system.

In short, we have successfully demonstrated a bi-directional synaptic behavior based on Pt/SiO$_2$/Ag/Ti/Pt memristor and proposed a new way for the design of multi-functional resistive switching devices which are promising for future memory and neuromorphic computing applications.

### Introduction

The physical limitations of Si material are faced, the performance improvement of charge storage memories enabled by conventional scaling rules is noticeably slowing. In the meantime, emerging memories that are theoretically advantageous for device scaling based on resistance changes in oxides and chalcogenides driven by spin orientation, phase change, and atomic filament formation have begun to be implemented for a storage class memory, which is a newly introduced technology in the traditional memory hierarchy. Particularly, by employing a cross-point architecture, the memory is sandwiched by perpendicularly located word line and bit line. This passive array allows the highest memory density at the smallest cell size, but is inherently affected by unwanted sneak-path currents generated from adjacent cells, causing read errors. Therefore, a two-terminal threshold selector (TS) that can prevent the sneak-path current below a threshold voltage ($V_{th}$) and provide a sufficient current instantly above the $V_{th}$ is required for each memory cell (1T-1R) in the cross-point array.

From a material perspective, the TS can be realized using certain transition-metal oxides such as VO$_2$, TiO$_2$, and TiN during different RS periods. This highlights the significance of oxide/metal interfaces in RRAM, even in filament type devices. Finally, we developed a RRAM device with geometric confinement of the oxygen vacancy distribution and nanofilament location. The nanotip based devices show good RS properties including forming-free, stable endurance and retention. This demonstrates a route to CMOS compatible devices and an effective way to control cycle-to-cycle resistance switching in RRAM technology. Our progress in understanding the materials issues and RS mechanism, as well as the development of filament confinement solutions, will certainly facilitate the possible regulation of RS modes and thus further the optimization of RRAM device performances.
Ferroelectric Spiking Neurons for Unsupervised Clustering

It is observed that the programming current in a memristor is decreased by using 2D materials. This is enabled by the brain’s synapses which form a highly complex and efficient interconnection between neurons in the brain. Therefore, a nano-electronic device which can emulate brain’s synaptic behavior is needed to enable high accuracy in unsupervised learning, increases sparsity in spiking, and efficient implementation of synaptic weights. Two of the most critical aspects of such a device are 1) the switching medium, and 2) the switching behavior.

In this talk, we will present experimental demonstration of ferroelectric spiking neuron based on a compact 1T-1FEFET structure and compare them to other state-of-the-art memristor devices. These devices are fabricated using a high-yield CMOS process and do not scale down with the scaling of the technology node. Deep neural network (DNN) is a class of artificial neural networks (ANNs) that benefits from both the availability of big data (large amount of multi-media data for model training) and the continual performance improvement of semiconductor technologies in the past decade. However, the memory hierarchy of today’s computing architectures is not specifically designed to leverage the predictable dataflow and potential data reuse of DNN processing, resulting in longer latency and insufficient energy-efficiency for memory access. To reduce these expensive memory access, hardware accelerators for DNNs are designed to employ more fine-grained local memory hierarchy and more specialized dataflow design, which improves the energy efficiency and throughput while maintaining DNN’s inference accuracy. However, the “memory bottleneck” in modern DNNs may not be fully addressed by the acceleration architectures alone. Emerging memory technologies have the potential to play an important and unique role. As these technologies can potentially offer up to tera-bytes of on-chip data storage with a wide range of energy-delay optimization opportunities, they may complement SRAM and DRAM for more efficient DNN inference acceleration. A possible application of the emerging non-volatile memory (NVM) devices is to serve as in-memory computing element where multi-level resistance response of an NVM can store the analog synaptic weights of a DNN on-chip. In another in-memory computing scheme, a crossbar array of non-volatile memory devices can perform the multiply-and-accumulate (MAC) operation at a lower energy cost when the input vector is encoded as analog voltage and the weight matrix is encoded as analog resistance (conductance) values stored in the memory devices. The ability of the NVMs like RRAM, PCM, CBAM to change its resistance values gradually as a function of the applied voltage pulse across its electrode is the key to performing analog in-memory MAC operation.

This paper provides an overview of the current state-of-the-art non-volatile memory devices used for neuromorphic hardwares in applications ranging from biology based learning models to conventional machine learning algorithms solved using neural networks. Furthermore, a more focused overview of the device-level trade-offs required for hardware acceleration of neural network architectures using analog in-memory MAC operation is presented. In general, larger conductance range, more intermediate states, and higher resistance are desirable for both inference and training. For inference, an ideal device should also have linear I-V relationship and long retention time. For training, symmetric and linear pulse response, small device-to-device and cycle-to-cycle variation, and good endurance are crucial.

Our review reveals that controlling the oxygen ion movement during pulsed switching in RRAM can be a promising way to achieve the aforementioned performance goals. Placing an oxygen ion barrier to make a bilayer RRAM and confinement of the generated heat during switching have shown significant improvement in analog switching. Better thermal management in RRAM can also provide filament stability that could improve reliability like retention and endurance. If the ideal device can be achieved, the MAC array using NVMs can provide ultra-low energy, high throughput computing without compromising bit precision that is currently missing in the neural network accelerator landscape.

In this work, we use MoS\(_2\) as the switching medium to fabricate a memristive device. MoS\(_2\) is grown on monolayer graphene forming a vertical heterojunction by the sulfurization of Mo film. Graphene (Gr) is used as the bottom electrode while Ni/Au contact on MoS\(_2\) is the top electrode. The MoS\(_2\)/Gr memristors exhibit memory forming-free non-volatile switching behaviour with a low programming current of 1 nA. In addition, these devices exhibit sub-nW reset power and low energy consumption of ~2 pJ/pulse event which makes them highly energy-efficient. Synaptic characteristics such as multiple conductance states between 1 nA and 1 \(\mu\)A with a minimum reset current of 16 pA is also observed. Furthermore, the MoS\(_2\)/Gr memristors exhibit excellent data retention characteristic of 10\(^5\) s at multiple conductance states viz., 1 nA and 1 \(\mu\)A. Also, MoS\(_2\)/Gr memristors exhibit biological synaptic characteristics like plasticity, multi-state conductance tuning, short and long-term potentiation, long term depression and spike timing plasticity. Additionally, sustained switching at 1 nA and 100 nA programming currents is observed in these devices for 100 DC cycles indicating their robustness.

Filamentary switching with low programmingreset power observed in these devices unravel the prospects of developing nano-scale crossbar arrays of energy-efficient synaptic devices for artificial neural networks.

Emulating Biological Synaptic Behavior for Ultra-Low Power Neuromorphic Applications Using MoS\(_2\)/Graphene Heterojunctions Adithi Pandapally Krishnamoornad Sharanad 1, Nitin Choudhary, Sonali Das 1, Durjoy Das 1, Hirokjyothi Kalita 2, Hee-Suk Chung 3, YeonWoong Jung 4 and Tanja Roy 1, 2, 3 aNanoScience Technology Center, University of Central Florida, Orlando, Florida, United States; 2Department of Electrical Engineering, University of Central Florida, Orlando, Florida, United States; 3Analytical Research Division, Korea Basic Science Institute, Jeonju, Korea (the Republic of); 4Department of Material Sciences and Engineering, University of Central Florida, Orlando, Florida, United States.
10. The conventional computing systems based on the von Neumann architecture have reached limits in terms of computational power and data dissipation due to increasing computational complexity. To circumvent these issues, new computational architectures are explored, among which neuromorphic computing based on emulating the human brain stands out. It is known that the human brain supercedes a supercomputer by 6-9 orders of magnitude in power dissipation. The superior features of the brain, such as ultra-high density, low-energy consumption, parallelism, robustness, plasticity, and fault-tolerant operation need to be emulated by computing systems for perception and learning. These qualities are enabled by the brain’s synapses which form a highly complex and efficient interconnection between neurons in the brain. Therefore, a nano-electronic device which emulates the synaptic properties is a crucial building block for brain-inspired computational systems.

Excitons in Two-Dimensional Semiconductors “Talking” to Their Environment
Kvirk L. Bolotin; Freie Universitaet Berlin, Berlin, Germany.

Every atom in two-dimensional semiconductors from the group of Transition Metal Dichalcogenides (TMDs) belongs to the surface. Because of that, TMDs are strongly affected by their microenvironment. In this talk we show that excitons, bound electron/hole pairs, in TMDs can serve as exquisite probes of the physical and chemical properties of that microenvironment.

First, we show that TMD excitons are strongly screened by nearby dielectrics. In suspended TMD, the behavior of pristine material is approached. We also examine frequency-dependent screening of excitons in TMD and show that the frequency-dependent dielectric function of the environment can be effectively “sampled” by examining spectral shifts and intensity redistribution between neutral, charged, and defect-bound excitons. Second, we examine near-field energy transfer between TMDs and nanoscale quantum emitters (semiconductor quantum dots or dye molecules) near it. We show that such energy transfer is very efficient, and that its rate can be controlled through electrical gating. Finally, we examine binding of excitons in TMDs to charged molecules on their surface. We demonstrate new molecule-specific excitonic species produced by such binding.

Near-Ideal 2D/2D and 2D/High-K Dielectric Interfaces Extracted Using the Conductance Method
Durjoy Dev1, 2, Adithi Pandralally Krishnaprasad Sharada1, 2 and Tania Roy4, 2; 1NanoScience Technology Center, University of Central Florida, Orlando, Florida, United States; 2Department of Electrical and Computer Engineering, University of Central Florida, Orlando, Florida, United States; 4Department of Materials Science and Engineering, University of Central Florida, Orlando, Florida, United States.

Two-dimensional transition metal dichalcogenides (TMDs) are expected to have significant contributions to the future electronic and optoelectronic devices due to their unique features, such as sizable bandgaps, uniform thickness, absence of dangling bonds, lower trap density, reduced short channel effects, etc. Molybdenum disulfide (MoS2) one well-known TMD, has drawn interest for high speed, flexible, low power electronic devices since it has a tunable bandgap, reasonable carrier mobility, excellent strength and large surface to volume ratio. One of the key reasons for dominance of silicon over all other semiconductors is the high quality interface between Si and SiO2. Any semiconductor system should possess an interface comparable in quality with the Si/SiO2 interface for its reliable application in electronic and optoelectronic devices.

In this work, we studied the interface quality of 2D/2D and 2D/3D interfaces by developing MoS2 based field effect transistors (FET) having hexagonal boron nitride (h-BN) and high-k top gate dielectrics (AlOx and ZrO2). For the 2D/2D MoS2/h-BN FET, 13 nm h-BN flake was dry transferred over exfoliated MoS2. For the MoS2/high k gate dielectric structure, two different nucleation layers SiO2 and AlOx were e-beam evaporated over exfoliated MoS2 prior to atomic layer deposition of high k gate dielectrics AlOx and ZrO2. One of the most direct, precise and sensitive techniques called the conductance method is adopted for extraction of the interface trap density (Dit) [1]. The subthreshold swing for the devices are in the range of 95 mV/decade to 160 mV/decade. In this comparative study, transistors with the MoS2/h-BN 2D/2D interface exhibited lowest trap density in the range of 7×1014 states/cm2-eV at midgap. This superior quality interface is attributed to the absence of dangling bonds at 2D/2D interface [2]. The interface between MoS2 and AlOx exhibited lower trap densities compared to MoS2/ZrO2 interfaces. In the mid gap, the highest trap density (1.35×1015 states/cm2-eV) is obtained for ZrO2 gate dielectric with AlOx nucleation layer, while the lowest one (7×1014 states/cm2-eV near valence band) is obtained for AlO2 gate dielectric with SiO2 nucleation layer. For both AlOx and ZrO2 gate dielectrics, the SiO2 nucleation layer offered lower Dit compared to the AlOx nucleation layer. The interface trap densities obtained by the conductance method are compared with the numbers obtained using other Dk extraction techniques, such as the Terman method and high-low frequency methods. This study shows that the MoS2/h-BN and MoS2/SiO2/AlOx interfaces are at par with the state-of-the-art Si/high-k interface, extending the promise of 2D materials for future high-performance electronics.
